PREFACE

TO

THE SEVENTEENTH EDITION

IN this Edition the text has been carefully revised and, in several sections, rearranged. The B.N.A. terminology has been added in brackets after the names commonly used by English anatomists.

Increased attention has been given to the clinical applications of anatomical data; the title *Surgical Anatomy* has been replaced by that of *Applied Anatomy*, and under this heading many important medical considerations are discussed. MR. FEDDE FEDDEN has revised the surgical, and DR. A. J. JEX-BLAKE has added the medical, notes in these paragraphs.

Some two hundred additional engravings have been introduced, mostly in the sections of Embryology, Angiology, Neurology and Splanchnology. A few of these have been borrowed from standard works, and some are copied from models by His, Keibel and others, but the majority have been drawn from original preparations.

The Editor acknowledges, with gratitude, the valuable help he has received from MR. FRANK HOWSON, M.A., Lecturer on Physiology, and DR. J. DUNLOP LICKLEY, Demonstrator of Anatomy, in this College. Mr. Howson undertook the revision of the Histological part of the book and furnished microscopic slides for drawings. Dr. Lickley has rendered invaluable and ungrudging service in the revision of the text, in the preparation of the Index, and in the making of dissections for the purposes of illustration.

ORGANS OF SPECIAL SENSE

SPLANCHNOLOGY

HUMAN ANATOMY

INTRODUCTION

THE term *human anatomy* comprises a consideration of the various structures which make up the human organism. In a restricted sense it deals merely with the parts which form the fully developed individual and which can be rendered evident to the naked eye by various methods of dissection. Regarded from such a standpoint it may be studied by two methods: (1) the various structures may be separately considered—*systematic anatomy;* or (2) the organs and tissues may be studied in relation to one another—*topographical* or *regional anatomy.*

It is, however, of much advantage to add to the facts ascertained by naked-eye dissection those obtained by the use of the microscope. This introduces two fields of investigation, viz. the study of the minute structure of the various component parts of the body—*histology* ; and the study of the human organism in its immature condition, i.e. the various stages of its intra-uterine development from the fertilised ovum up to the period when it assumes an independent existence—*embryology*. Owing to the difficulty of obtaining material illustrating all the stages of this early development, gaps must be filled up by observations on the development of lower forms—*comparative embryology*, or by a consideration of adult forms in the line of human ancestry—*comparative anatomy*. Finally, the direct application of the facts of human anatomy to the various pathological conditions which may occur constitutes the subject of *applied anatomy*.

SYSTEMATIC ANATOMY.—The various systems of which the human body is composed are grouped under the following headings :

1. *Osteology*—the bony system or skeleton.

2. *Syndesmology*—the articulations or joints.

3. *Myology*—the muscles. With the description of the muscles it is convenient to include that of the fasciæ which are so intimately connected with them.

4. *Angiology*—the vascular system, comprising the heart, blood-vessels, lymphatic vessels and lymphatic glands.

5. *Neurology*—the nervous system. The organs of sense may be included in this system.

6. *Splanchnology*—the visceral system. Topographically the viscera form two groups, viz. the thoracic viscera and the abdomino-pelvic viscera. The heart, a thoracic viscus, is best considered with the vascular system. The rest of the viscera may be grouped according to their functions : (*a*) the *respiratory system* ; (*b*) the *alimentary system* ; and (*c*) the *genito-urinary system*. Strictly speaking, the third sub-group should include only such components of the genito-urinary system as are included within the abdomino-pelvic

cavity, but it is convenient to study under this heading certain parts which lie in relation to the surface of the body, e.g. the testes and the external organs of generation.

For descriptive purposes, the body is supposed to be in the erect posture, with the arms hanging by the sides and the palms of the hands directed forwards. The *mesial plane* is a vertical antero-posterior plane, passing through the centre of the trunk. This plane will pass approximately through the sagittal suture of the skull, and hence any plane parallel to it is termed a *sagittal plane*. A vertical plane at right angles to the mesial plane passes, roughly speaking, through the central part of the coronal suture or through a line parallel to it; such a plane is therefore known as a *coronal plane* or sometimes as a *frontal plane*. A plane at right angles to both the mesial and coronal planes is termed a *transverse plane*.

The terms *anterior* or *ventral*, and *posterior* or *dorsal*, are employed to indicate the relation of parts to the front or back of the body, and the terms *superior* or *cephalic*, and *inferior* or *caudal*, to indicate the relative levels of different structures.

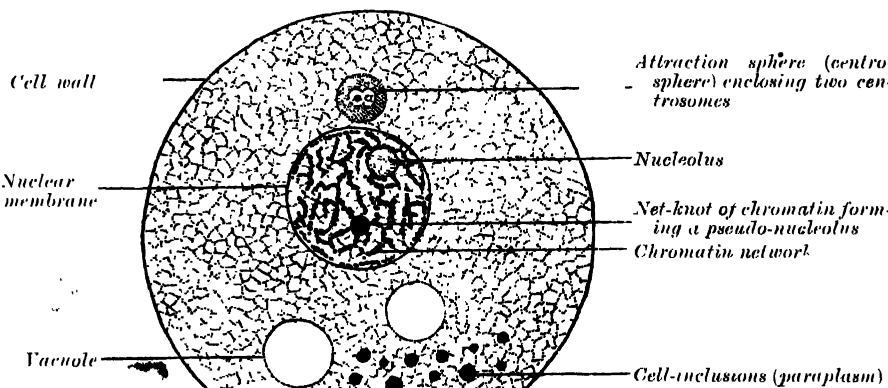
HISTOLOGY

THE ANIMAL CELL (fig. 1)

ALL the tissues and organs of the body originate from a microscopic structure (the *fertilised ovum*), which consists of a soft jelly-like granular material enclosed in a membrane, and containing a vesicle or small spherical body inside which are one or more denser spots. This may be regarded as a complete cell. All the solid tissues consist largely of cells essentially similar to it in nature but differing in external form.

In the higher organisms a cell may be defined as 'a nucleated mass of protoplasm of microscopic size.' Its two essentials, therefore, are: a soft jelly-like granular material, similar to that found in the ovum, and usually styled *protoplasm*; and a small spherical body imbedded in it, and termed a *nucleus*.*

FIG. 1.—Diagram of a cell. (Modified from Wilson.)



The other constituents of the ovum, viz. its limiting membrane and the denser spot contained in the nucleus, called the *nucleolus*, are not essential to the type-cell, and in fact many cells exist without them.

Protoplasm (*cytoplasm*) is a material probably of variable constitution during life, but yielding on its disintegration bodies chiefly of protein nature. Lecithin and cholesterin are constantly found in it, as well as inorganic salts, chief among which are the phosphates and chlorides of the alkali metals and of calcium. It is of a semi-fluid, viscid consistence, and appears either as a hyaline substance, homogeneous and clear, or else it exhibits a granular appearance. Under a high power of the microscope protoplasm is seen to consist of an elastic and refractile network or reticulum, containing in its meshes a clear, semi-fluid, homogeneous substance. The reticulum is composed of a material known as *spongioplasm*, while the enclosed substance is termed *hyaloplasm*. The granular appearance is often caused by the knots of the network; but, in addition to

* In certain lower forms of life, masses of protoplasm without any nuclei have been described by Huxley and others, as cells.

these, protoplasm frequently contains true granules, some of which are protein in nature and probably essential constituents; others are fat, glycogen or pigment granules, and are regarded as adventitious material taken in from without, and hence are styled cell-inclusions or *paraplasm*. The size and shape of the meshes of the spongioplasm vary in different cells and in different parts of the same cell. The relative amounts of spongioplasm and hyaloplasm also vary in different cells; the latter preponderating in the young cell and the former increasing at the expense of the hyaloplasm as the cell grows. In many fixed cells, e.g. epithelial cells, the periphery becomes denser than the rest, and often altered by the deposition in it of a substance, the so-called *cement*, the nature of which is unknown. This cement substance separates the cells from each other, and has been termed by some histologists the cell-wall; when treated with dilute solutions of silver nitrate and then exposed to light it turns a deep brown or black colour.

The most striking characteristics of protoplasm are its vital properties of *motion* and *nutrition*. Its movements, on account of their resemblance to those observed in the Amœba or Proteus animalcule, have been termed 'amœboid movements.' Nutrition is the power which protoplasm has of attracting to itself from surrounding matter the materials necessary for its growth and maintenance. Any foreign particle which comes in contact with the protoplasmic substance becomes incorporated in it, being enwrapped by one or more processes projected from the parent mass. When thus taken up, it may become an integral part of the cell or may remain in the substance of the protoplasm for some time without change, or may be rapidly extruded.

The **Nucleus** is a minute body, imbedded in the protoplasm, and usually of a spherical or oval form, its size having little relation to the size of the cell. It is surrounded by a well-defined wall, the *nuclear membrane*; this encloses the *nuclear substance* (nuclear matrix), which is composed of a homogeneous material containing a substance known as *paralinin*, and a stroma or network. The former is probably of the same nature as the hyaloplasm of the cell; but the latter, which forms also the wall of the nucleus, differs from the spongioplasm of the cell substance. It is sometimes known as the *chromoplasm* or *intranuclear network*, and consists of a network of fibres or filaments arranged in a reticular manner. The substance of the filaments stains very readily with certain dyes, and is therefore named *chromatin*; it is supported by a number of fine threads of a material known as *linin* which stains only faintly or not at all. The interstitial substance does not stain readily, and is hence called *achromatin*. In some nuclei the chromoplasm does not form a network, but presents the appearance of a convoluted skein, similar to that found in a nucleus about to undergo division.

Within the nuclear matrix are one or more highly refracting bodies, termed *nucleoli*, connected with the nuclear membrane by the nuclear filaments. They are regarded as being of two kinds. Some are mere local condensations ('net-knots') of the chromoplasm; these are irregular in shape and are termed *pseudo-nucleoli*; others are distinct bodies differing from the pseudo-nucleoli both in nature and chemical composition; they may be termed *true nucleoli*, and are usually found in resting cells.

The nuclear substance differs chemically from ordinary protoplasm in containing *nuclein*, in its power of resisting the action of acids and alkalis, in its imbibing more intensely the stain of carmine, hæmatoxylin, &c., and in its remaining unstained by some reagents which colour ordinary protoplasm.

Most living cells contain, in addition to their protoplasm and nucleus, a minute particle which, on account of the power it appears to possess of attracting the surrounding protoplasmic granules, is termed the *attraction particle* or *centrosome*; it usually lies near the nucleus. The spherical arrangement of fibrillar rows of granules surrounding the particle is termed the *attraction sphere* or *centrosphere*. As a rule there are in each cell two spheres connected by a spindle-shaped system of delicate fibrils (*achromatic spindle*). They are best seen in young cells which are about to undergo the process of division, a process believed to commence in these bodies.

Reproduction of cells is effected either by *indirect* or by *direct division*. *Indirect division* or *karyokinesis* (*karyomitosis*) has been observed in all the tissues—generative cells, epithelial tissue, connective tissue, muscular tissue, and nerve tissue, and probably it will ultimately be shown that the division of cells

always takes place in this way, and that the process of reproduction of cells by direct division is, as some observers believe, merely a sort of imperfect or abnormal karyokinesis.

The process of indirect cell division is characterised by a series of complex changes in the nucleus, leading to its subdivision; this is followed by cleavage of the cell protoplasm. Starting with the nucleus in the quiescent or *resting* stage, these changes may be briefly grouped under the four following phases:

1. *Prophase.*—The nuclear network of chromatin filaments assumes the form of a twisted *skein* or *spirem*, while the nuclear membrane and nucleolus disappear. The convoluted skein of chromatin divides into a definite number of V-shaped segments or *chromosomes*. The number of chromosomes varies in different animals—in man it is believed to be always sixteen. Coincident with or preceding these changes the centrosome, or attraction particle, which usually lies by the side of the nucleus, undergoes subdivision, and the two resulting centrosomes, each surrounded by a centrosphere, are seen to be connected by a spindle of delicate achromatic fibres, the *achromatic spindle*. The centrosomes move away from each other—one towards either extremity of the nucleus—and the fibrils of the achromatic spindle are correspondingly lengthened. The centrosomes are now situated one at either extremity or pole of the elongated spindle, and each is surrounded by a centrosphere, from which fibrils radiate into the investing protoplasm. A line encircling the spindle midway between its poles is named the *equator*, and around this the V-shaped chromosomes arrange themselves in the form of a star, thus constituting the *mother star* or *monaster*.

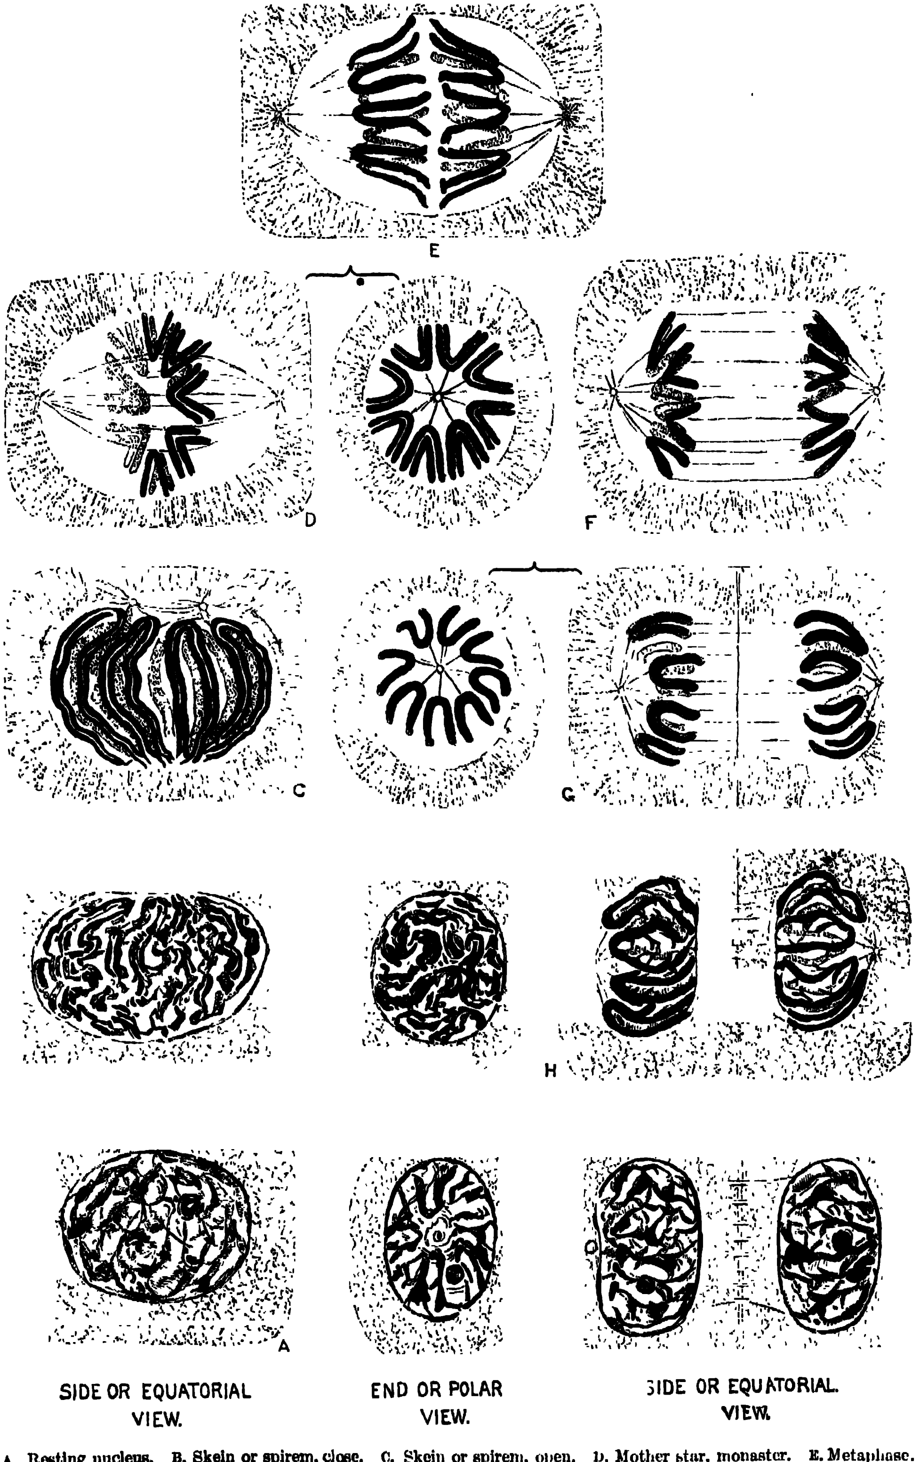
2. *Metaphase.*—Each V-shaped chromosome now undergoes longitudinal cleavage into two equal parts or *daughter chromosomes*, the cleavage commencing at the apex of the V and extending along its divergent limbs. The daughter chromosomes, thus separated, travel in opposite directions along the fibrils of the achromatic spindle towards the centrosomes, around which they group themselves, and thus two star-like figures are formed, one at either pole of the achromatic spindle. This constitutes the *diaster*.

3. *Anaphase.*—The daughter chromosomes now arrange themselves into a *skein* or *spirem*, and eventually form the network of chromatin which is characteristic of the resting nucleus. The nuclear membrane and nucleolus are also differentiated during this phase. The cell protoplasm begins to appear constricted around the equator of the achromatic spindle, where double rows of granules are also sometimes seen. The constriction deepens and the original cell gradually becomes divided.

4. *Telophase.*—In this stage the cell is completely divided into two new cells, each with its own nucleus, centrosome and centrosphere, which assume the ordinary positions occupied by such structures in the resting stage.

The series of diagrams (fig. 2), by Delépine, is intended to explain the formation of some of the most important changes observed in nuclei of cells during karyokinesis; it is based chiefly on the work of Flemming, Strasburger, E. van Beneden, Rabl, O. Hertwig, Henneguy, and others. A. *Resting nucleus.* Nucleolus and nuclear membrane visible. A centrosome is represented near the nucleus. B and C. *Skein* or *spirem*. B. Chromatic filaments much convoluted. Longitudinal splitting is evident in several parts. The centrosome has divided and the nuclear membrane is becoming indistinct. C. The two centrosomes are widely separated, and the space between them is occupied by the achromatic spindle. (Two arrows point to the positions which the centrosomes will ultimately occupy; during their passage to these points the achromatic spindle seems to be within the nucleus.) The nuclear membrane has disappeared. D. *Mother star* or *monaster*. The nuclear segments (chromosomes) resulting from the breaking-up of the chromatic filament into fragments of nearly equal length have moved towards the equator of the spindle, where they now form an equatorial plate. These segments are all split longitudinally. E. *Metaphase.* One half of each chromosome moves in the direction of one pole and the other half in that of the other pole, being guided towards the centrosomes by the achromatic filaments. F. *Daughter stars* or *diaster*. G. *Daughter skeins* or *dispirem*, beginning to form. Segments in the form of thick loops not closely packed. H. *Daughter skeins* or *dispirem*, formed. Segments more closely packed and less distinct, owing to the formation of anastomoses. I. *Resting daughter nuclei.* Cell completely divided into two, but bridges remain between them in the region previously occupied by

FIG. 2.—Karyokinesis: or indirect cell-division.



A Resting nucleus. B. Skein or spirem, close. C. Skein or spirem, open. D. Mother star, monaster. E. Metaphase. F. Daughter stars or diaster. G. Daughter skeins or dispirem, beginning to form. H. Daughter skeins or dispirem formed. I. Resting daughter nuclei.

the achromatic filaments, these being specially distinct in certain cells (e.g. prickle-cells). The nucleus has a distinct nuclear membrane and a nucleolus.

In the reproduction of cells by *direct* division the process is one either of segmentation or of gemmation. In reproduction by *segmentation* or *fission*, the nucleus becomes constricted in its centre, assuming an hour-glass shape, and then divides into two. This is followed by a cleavage or division of the whole protoplasmic mass of the cell; and thus two daughter cells are formed, each containing a nucleus. These daughter cells are at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may take place rapidly. In reproduction by *gemmation*, a budding-off or separation of a portion of the nucleus and parent cell takes place, and, this becoming separated, forms a new organism.

The **cell-wall** is merely the external layer of the protoplasm, firmer than the rest of the cell, and often thickened by the deposit in it of certain chemical substances. It forms a transparent, finely striated membrane, in which are a number of apertures. Through these openings protoplasmic processes can extend from cell to cell. They are often termed intercellular bridges.

THE NUTRITIVE FLUIDS

The **circulating fluids** of the body, which subserve its nutrition, are the blood and the lymph.

Blood

The blood is an opaque, rather viscid fluid, of a bright red or scarlet colour when it flows from the arteries, of a dark red or purple colour when it flows from the veins. It is salt to the taste, and has a peculiar faint odour and an alkaline reaction. Its specific gravity is about 1·06, and its temperature is generally about 99° F., though varying slightly in different parts of the body.

General composition of the blood.—Blood consists of a faintly yellow fluid, the *plasma* or *liquor sanguinis*, in which are suspended numerous minute particles, the *blood corpuscles*, the majority of which are coloured and give to the blood its red tint. If a drop of blood be placed in a thin layer on a glass slide and examined under the microscope, a number of these corpuscles will be seen floating in the clear fluid plasma.

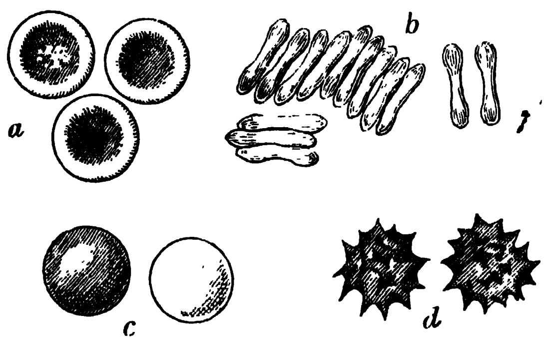
The **blood corpuscles** are chiefly of two kinds: (1) coloured corpuscles or erythrocytes, (2) colourless corpuscles or leucocytes. A third variety, the blood platelets, is of subsidiary importance.

1. **Coloured or red corpuscles** (*erythrocytes*), when examined under the microscope, are seen to be circular discs, biconcave in profile. The disc has no nucleus, but, in consequence of its biconcave shape, presents, according to the alterations of focus under an ordinary high power, a central part, sometimes bright, sometimes dark, which has the appearance of a nucleus (fig. 3, *a*). It is to the aggregation of the red corpuscles that the blood owes its red hue, although when examined by transmitted light their colour appears to be only a faint reddish-yellow. The corpuscles vary slightly in size even in the same drop of blood, but the average diameter of each is about $\frac{1}{3200}$ of an inch, and the thickness about $\frac{1}{12000}$ of an inch, nearly one quarter of the diameter. Besides these there are found certain smaller corpuscles of about one-half or one-third of the size just indicated; these are termed *microcytes*, and are very scarce in normal blood; in diseased conditions (e.g. anæmia), however, they are more numerous. The number of red corpuscles in the blood is enormous; between 4,000,000 and 5,000,000 are contained in a cubic millimetre. Power states that the red corpuscles of an adult would present an aggregate surface of about 3,000 square yards. Each corpuscle consists of a colourless elastic spongework or stroma, condensed at the periphery to form an investing membrane; uniformly diffused throughout the stroma are the coloured fluid contents. The stroma is composed mainly of *nucleo-protein* and of the fatty substances, *lecithin* and *cholesterin*, while the coloured material consists chiefly of the respiratory protein, *hæmoglobin*, which is a compound protein composed of an iron-containing body, hæmatin, and of globin, a protein belonging to the globulin group. Hæmoglobin has a great affinity for oxygen, and, when removed from the body, crystallises readily under certain circumstances;

it is very soluble in water, so that the addition of water to a drop of blood speedily dissolves out the hæmoglobin from the corpuscles.

If the web of a living frog's foot be spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when the blood is drawn and examined on a slide without reagents, the corpuscles often collect into heaps like rouleaux of coins (fig. 3, *b*). It has been suggested that this phenomenon may be explained by alteration in surface tension. During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves, to some extent, to the size of the vessel. They are, however, highly elastic, and speedily recover their shape when the pressure is removed. They are readily influenced by the medium in which they are placed. In water they swell up, lose their shape, and become globular (*endosmosis*) (fig. 3, *c*). Subsequently the hæmoglobin is dissolved out, and the envelope can barely be distinguished as a faint circular outline. Solutions of salt or sugar, denser than the plasma, give them a stellate or crenated appearance (*exosmosis*) (fig. 3, *d*), but the usual shape may be restored by diluting the solution to the same specific gravity as the plasma. The crenated outline may be produced as the first effect of the passage of an electric shock: subsequently, if sufficiently strong, the shock ruptures the envelope. A solution of salt or sugar, of the same specific gravity as the plasma (i.e. an isotonic solution), merely separates the blood corpuscles mechanically, without changing their shape.

Fig. 3.—Human red blood-corpuscles. Highly magnified.



a. Seen from the surface. *b*. Seen in profile and forming rouleaux. *c*. Rendered spherical by water. *d*. Rendered crenate by salt solution.

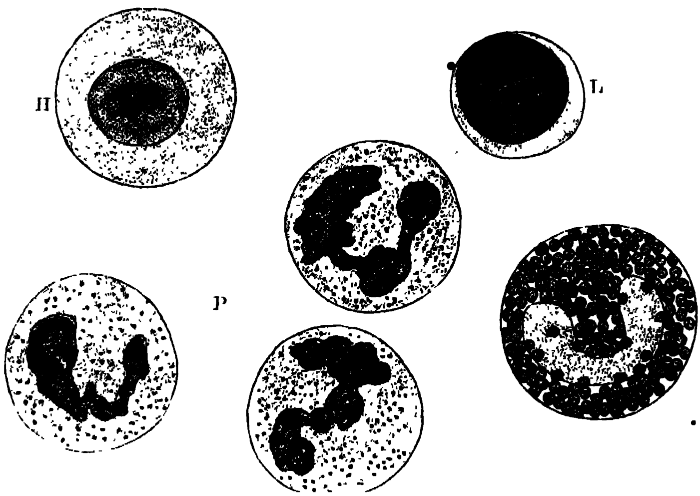
The **colourless corpuscles** or *leucocytes* are of various sizes, some no larger, others smaller, than the red corpuscles. In human blood, however, the majority are rather larger than the red corpuscles, and measure about $\frac{1}{2000}$ to $\frac{1}{2500}$ of an inch in diameter. On the average from 10,000 to 12,000 leucocytes are found in each cubic millimetre of blood.

They consist of minute masses of nucleated protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm, and by the staining reactions of these granules when present (fig. 4). (1) The most numerous (70–80 per cent.) and important are spherical in shape, and are characterised by nuclei, which often consist of two or three parts (multipartite) connected together by fine threads of chromatin. The protoplasm is clear, and contains a number of very fine granules, which stain with acid dyes such as eosin (fig. 4, P). These cells are termed the *polymorphonuclear* leucocytes. (2) A second variety comprises from 2 to 4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of coarsely granular protoplasm, the granules being highly refractile and grouped round single nuclei of horse-shoe shape (fig. 4, E). The granules stain deeply with eosin, and the cells are therefore often termed *eosinophil* corpuscles. (3) The third variety is called the *hyaline* cell (fig. 4, H). This is usually about the same size as the eosinophil cell, and, when at rest, is spherical in shape and contains a single round or oval nucleus. The protoplasm is free from granules, but is not quite transparent, having the appearance of ground glass. (4) The fourth kind of colourless corpuscle is designated the *lymphocyte* (fig. 4, L), because it is identical with the lymphoid cell derived from the lymphatic glands, the spleen, tonsil, and thymus. It is the smallest of the leucocytes, and consists chiefly of a spheroidal nucleus with a very little surrounding protoplasm of a homogeneous nature; it is regarded as the immature form of the hyaline cell.

The third and fourth varieties together constitute from 20 to 30 per cent. of the colourless corpuscles, but of these two varieties the lymphocytes are by far the more numerous. Leucocytes having in their protoplasm granules which stain with basic dyes (basophil) have been described as occurring in human blood, but they are rarely found except in disease.

The colourless corpuscles are very various in shape in living blood (fig. 5), because many of them have the power of constantly changing their form by protruding finger-shaped or filamentous processes of their substance, by which they move, and take up granules from the surrounding medium. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and then

FIG. 4.—Varieties of leucocytes found in human blood. Highly magnified.



shifts the rest of the body into it. In the same way when any granule or particle comes in its way the corpuscle wraps a pseudopodium round it, and then withdraws the pseudopodium with the contained particle into its own substance. By means of these amœboid properties the cells have the power of wandering or emigrating from the blood-vessels by penetrating their walls and thus finding their way into the extra-vascular spaces. A chemical investigation of the protoplasm of the leucocytes shows the presence of nucleo-protein and of a globulin. The occurrence of small amounts of fat and glycogen may also be demonstrated.

The **blood platelets** are discoid or irregularly shaped, colourless, refractile bodies, much smaller than the red cells. Considerable discussion has arisen as to their significance. Recent observers have shown that under the action of certain

FIG. 5.—Human colourless blood-corpuscle, showing its successive changes of outline within ten minutes when kept moist on a warm stage. (Schofield.)

stains the centrally situated portion of the blood platelet takes on an appearance suggestive of a nucleus. In spite of this, and of the fact that they have been observed in the blood-vessels during life, there is still a tendency to regard them as products of disintegration of the white cells, or as precipitates, possibly of nucleo-protein, and not as living elements of the blood.

Origin of the blood corpuscles.—In the embryo the red corpuscles are developed from cells in the vascular area of the blastoderm. These cells unite with one another to form a network, their nuclei multiply in number, and around some of the nuclei aggregations of coloured protoplasm take place. After a time the fibres of the network become hollowed out by an accumulation of fluid, and form capillary blood-vessels, and in the fluid those nuclei which are surrounded by

coloured protoplasm float as the first red blood cells.* The embryonic corpuscles are thus nucleated, and, further, they have the power of amœboid movement. These cells disappear in later embryonic life, to be replaced by smaller non-nucleated corpuscles, having all the characters of the adult erythrocytes, and formed, according to Schäfer, within certain cells of the connective tissue. Small globules of reddish colouring matter appear in their protoplasm, and the cells eventually becoming larger, more uniform in size and disc-shaped, float in a cavity which results from the coalescence of numerous vacuoles. After birth the important source of the red corpuscles is the red marrow in the ends of the long bones and especially in the ribs and sternum. Here are found special, nucleated, coloured cells, termed *erythroblasts,* which are probably direct descendants of the nucleated, embryonic red cells. These erythroblasts by atrophy and disappearance of their nuclei (or, as some observers maintain, by extrusion of their nuclei) and by assumption of the biconcave form are transformed into the adult red corpuscles. Of the colourless corpuscles of the blood, the lymphocytes are derived from lymphatic tissue generally, and from the lymphatic glands especially, and enter the blood by way of the lymph stream; the hyaline cells probably develop from the lymphocytes, while the eosinophil cells are believed to originate mainly in the bone marrow and possibly also in the connective tissues.

The **plasma** or **liquor sanguinis,** the fluid portion of the blood, has a yellowish tint, is alkaline in reaction, and has a specific gravity of 1·028. It contains in solution about 10 per cent. of solids, of which four-fifths are protein in nature; the remainder being salts, chiefly chlorides, phosphates and sulphates of the alkali metals; carbohydrates, chiefly sugar; fats and soaps; cholesterin, urea, and other nitrogenous extractives. The proteins are three in number, *serum albumin, serum globulin,* and *fibrinogen.* Fibrinogen is a body of the globulin class, but differs from serum globulin in several respects. It is the substance from which the *fibrin,* which plays so important a part in the clotting of the blood, is derived. In addition there may be present in plasma several substances of very great importance in connection with immunity, such as antitoxins, opsonins, &c. The chemical nature of these bodies is at present the subject of close investigation, and for a detailed account of them reference should be made to the most recent works on bacteriology.

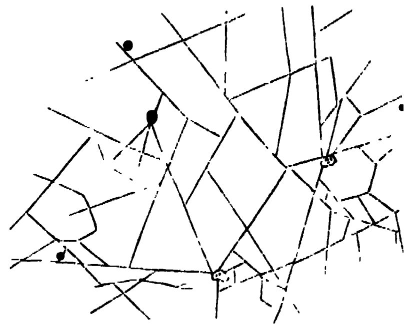
Coagulation of the blood.—When blood is drawn from the body and allowed to stand, it solidifies in the course of a very few minutes into a jelly-like mass or *clot,* which has the same appearance and volume as the fluid blood, and, like it, looks quite uniform. Soon, however, drops of a transparent yellowish fluid, the *serum,* begin to ooze from the surface of the mass and to collect around it. Coincidently the clot begins to contract, so that in the course of about twenty-four hours it has become considerably smaller and firmer than the first formed jelly-like mass, and is surrounded by a quantity of yellowish serum. The clotting of the blood is due to the formation of a fine meshwork of the insoluble material, *fibrin,* which entangles and encloses the blood corpuscles. Many theories have from time to time been brought forward as to the nature of the processes concerned in the clotting of blood. It is undoubtedly due to a ferment, *fibrin-ferment,* acting on *fibrinogen,* one of the proteins present in plasma. Under the agency of the fibrin-ferment the fibrinogen is split up into an insoluble portion, fibrin, and a soluble portion, fibrino-globulin, which remains in solution in the serum. The mode of formation of the ferment is still the subject of much discussion. It is supposed that when blood is shed, small quantities of a substance, *thrombokinase,* are liberated from the leucocytes and blood platelets; thrombokinase is also present in the tissues. It acts on another substance, *thrombogen,* present in the blood platelets, and converts it into the actual fibrin-ferment. Thrombogen, besides existing in the blood platelets, is also present in minute quantities in the circulating plasma. Calcium salts play an important rôle in the process of the formation of the ferment, for unless they are present in a soluble form the thrombokinase is unable to act on the thrombogen.

Fibrin may be obtained, practically free from corpuscles, by whipping the blood, after it has been withdrawn from the body, with a bundle of twigs; the fibrin adheres to these as it is formed. By various means the clotting of the

* Recent observations tend to show that the endothelial lining of the vessels and the blood corpuscles are of entodermal origin.

blood may be retarded so that the plasma may be obtained free from corpuscles; from this plasma there may be derived fibrin and serum, without the cellular elements. Fibrin thus obtained is a white or buff-coloured stringy substance, and when observed, in the course of formation, under the microscope, shows a meshwork of fine fibrils (fig. 6). After exposure to the air for some time it becomes hard, dry, brown, and brittle. It is one of the class of coagulated proteins, insoluble in hot or cold water, saline solution, alcohol, or ether. Under the action of dilute hydrochloric acid it swells up but does not dissolve, but, when thus swollen, is readily dissolved by a solution of pepsin.

FIG. 6.—Fibrin from human blood.



Serum, with the exception of its proteins, has a composition identical with that of plasma. The fibrinogen, characteristic of plasma, has disappeared, and the fibrin ferment and fibrino-globulin are found instead, as well as the serum albumin and serum globulin which are not involved in the process of coagulation.

Blood crystals.—Hæmoglobin, as already stated, readily crystallises when separated from the blood corpuscles. In human blood the crystals are elongated prisms (fig. 7, A), and in the majority of animals belong to the rhombic system, though in the squirrel hexagonal plates are met with. Small brown prismatic crystals of *hæmin* (fig. 7, B) may be obtained by mixing dried blood with common

salt and boiling with a few drops of glacial acetic acid; a drop of the mixture on a slide will show the characteristic crystals on cooling. *Hæmatoidin* crystals (fig. 7, C) occur sometimes in old blood clots.

LYMPH

Lymph is a transparent, colourless or slightly yellow fluid, which is conveyed by a set of vessels, named *lymphatics*, into the blood. These vessels arise in nearly all parts of the body as *lymph capillaries*. They take up the blood plasma which has exuded from the blood capillaries for the nourishment of the tissue elements, and return it into the veins. The greater number of these lymphatics empty themselves into one main duct, the *thoracic duct*, which passes upwards along the front of the vertebral column and opens into the large veins on the left side of the root of the neck. The remainder empty themselves into a smaller duct which ends in the corresponding veins on the right side of the neck.

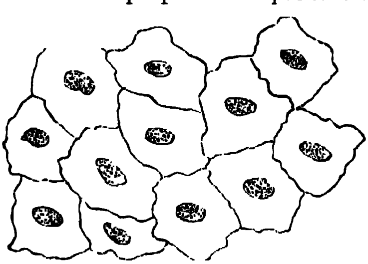
Lymph is a watery fluid of sp. gr. about 1·015; it closely resembles the blood plasma, but is more dilute, containing only about 5 per cent. of proteins and 1 per cent. of salts and extractives. When examined under the microscope, leucocytes of the lymphocyte class are found floating in the transparent fluid; they are always increased in number after the passage of the lymph through lymphoid tissue, as in lymphatic glands.

Lymph varies greatly in composition in different parts of the body. The lymph leaving the liver contains the greatest percentage of proteins and has the highest specific gravity. In the limbs the lymph is scanty and has a low specific gravity. The intestinal lymph (chyle) is intermediate in composition and contains in addition the fat absorbed by the lacteals, which gives it a milky appearance.

EPITHELIUM

All the surfaces of the body—the external surface of the skin, the internal surfaces of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coats of the vessels, the acini and ducts of all secreting and excreting glands, the ventricles of the brain and the central canal of the spinal cord—are covered by one or more layers of simple cells, called *epithelium* or *epithelial cells*. These cells are also present in the terminal parts of the organs of special sense, and in some other structures, such as the pituitary and thyroid bodies. They serve various purposes, forming in some cases a protective layer, in others acting as agents in secretion and excretion, and again in others being concerned in the elaboration of the organs of special sense. Thus, in the skin, the main purpose served by the epithelium (here called the *epidermis*) is that of protection. As the surface is worn away by the agency of friction new cells are supplied, and thus the true skin and the vessels and nerves which it contains are defended from damage. In the gastro-intestinal mucous membrane and its glands, the epithelial cells appear to be the principal agents in preparing the digestive secretions and in selecting and modifying materials for absorption. In other situations (as the nose, fauces, and respiratory passages) an important office of the epithelial cells appears to be to maintain an equable temperature by the moisture with which they keep the surface always slightly lubricated. In the serous cavities they also keep the opposed layers moist, and thus facilitate their movements on each other. Finally, in all internal parts they insure a perfectly smooth surface.

FIG. 8.—Simple pavement epithelium.



Epithelium consists of one or more layers of cells, united together by an interstitial cement substance and supported on a basement membrane. It is naturally grouped into two classes according as to whether there is a single layer of cells (*simple epithelium*), or more than one (*stratified epithelium* and *transitional epithelium*).

FIG. 9.—Columnar epithelium from an intestinal villus.

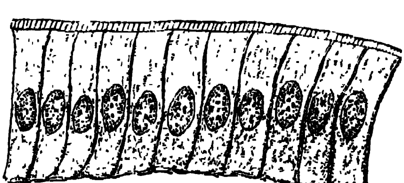


FIG. 10.—Goblet cells. (From Kirke's 'Physiology.')

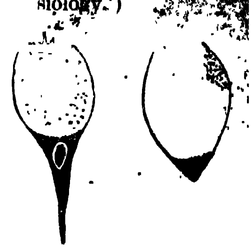
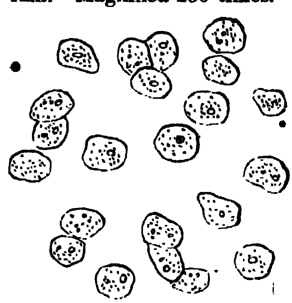


Simple epithelium.—The different varieties of simple epithelium are squamous or pavement, columnar, glandular or spheroidal, and ciliated.

The *pavement* epithelium (fig. 8) is composed of flat, nucleated scales of different shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal; the flattening depends upon the thinness cell. The protoplasm of the cell presents a fine reticulum or honeycomb

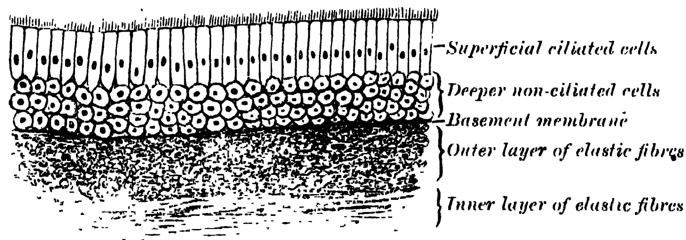
network, which gives to the cell the appearance of granulation. This kind of epithelium forms the lining of the air-sacs of the lungs. The *endothelium*, which covers the serous membranes, and which lines the heart, blood-vessels, lymphatics, and the anterior chamber of the eye, is also of the pavement type, being composed of a single layer of flattened transparent squamous cells, joined edge to edge in such a manner as to form a membrane of cells. The basement membrane, which supports the epithelial cells, is composed of a homogeneous material. In some instances it has a number of apertures, and is then spoken of as a fenestrated membrane, whilst in other cases it is formed of flattened cells.

FIG. 11.—Spheroidal epithelium. Magnified 250 times.



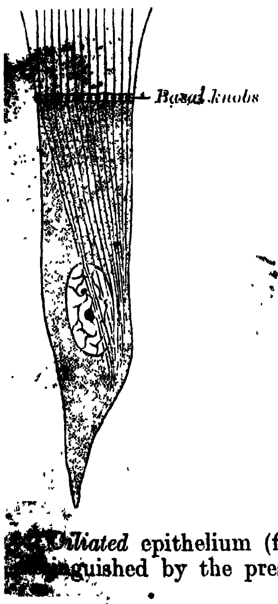
The *columnar* or *cylindrical* epithelium (fig. 9) is formed of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, flattened from mutual pressure, and are set upright on the surface on which they are supported. Their protoplasm is always more or less reticulated, and fine longitudinal striæ may be seen in it; the nucleus of each is oval in shape and contains an intranuclear network.

FIG. 12.—Ciliated epithelium from the human trachea.



The outer free border of each of these cells is distinctly marked off from the rest of the protoplasm, and contains well marked vertical striations. This form of epithelium covers the mucous membrane of nearly the whole gastro-intestinal tract and its glands, the greater part of the urethra, the vas deferens, the prostate, Cowper's glands, Bartholin's glands, and a portion of the uterine mucous membrane. In a modified form it also covers the ovary.

FIG. 13.—Isolated ciliated cell (semidiagrammatic)



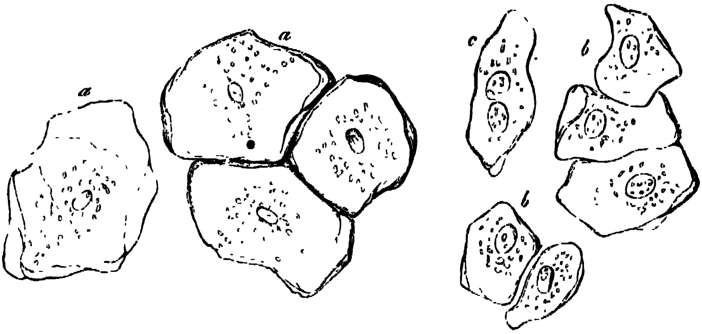
Goblet or *chalice* cells are modified columnar cells. The goblet cell appears to be formed by an alteration in shape of a columnar cell (ciliated or otherwise) consequent on the formation of granules, which consist of a substance called *mucigen*, in the interior of the cell. This distends the upper part of the cell, while the nucleus is pressed down towards its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane (fig. 10), the cell then assuming the shape of an open cup or chalice.

The *glandular* or *spheroidal* epithelium (fig. 11) is composed of spheroidal or polyhedral cells, but the cells may be columnar or cubical in shape in some situations. As in other forms of epithelial cells, the protoplasm is a fine reticulum, which gives to the cells the appearance of granulation. Glandular cells are found in the terminal recesses of secreting glands, and the protoplasm of the cells usually contains the materials which the cells secrete.

Ciliated epithelium (fig. 12) generally inclines to the columnar shape. It is distinguished by the presence of minute processes, like hairs or eyelashes (cilia)

standing up from the free surface. The cilia (fig. 13) at their points of attachment to the free border of the cell, possess small nodular enlargements (*basal knobs* of Engelmann). Within the cell they converge, and according to some authorities meet at or near the attraction sphere. If the cells be examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells be separated, they will often be seen to be moved about in the field by this ciliary action.

FIG. 14.—Epithelial cells from the oral cavity of man. Magnified 350 times.



a. Large. *b.* Middle sized. *c.* The same with two nuclei.

The situations in which ciliated epithelium is found in the human body are: the respiratory tract from the nose downwards to the smallest ramifications of the bronchial tubes, except a part of the pharynx and the surfaces of the vocal cords; the tympanum and Eustachian tube; the Fallopian tube and upper portion of the uterus; the vasa efferentia, coni vasculosi and the first part of the excretory duct of the testicle; the ventricles of the brain and the central canal of the spinal cord.

FIG. 15. – Stratified epithelium from the œsophagus.

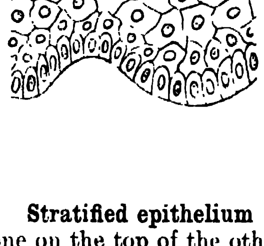


FIG. 16.—Portion of epidermis from a section of the skin of the finger. (Ranvier.) (From Schäfer's 'Essentials of Histology.')

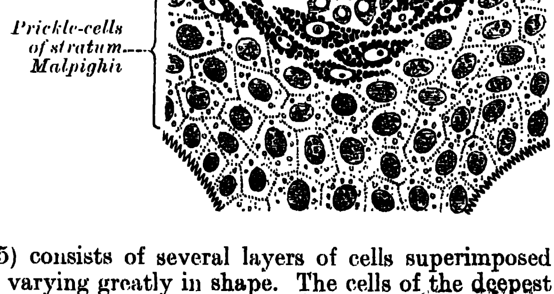


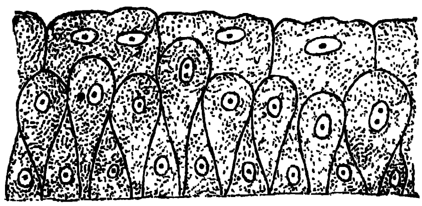
Stratified epithelium (fig. 15) consists of several layers of cells superimposed one on the top of the other and varying greatly in shape. The cells of the deepest layer are for the most part columnar in shape, and are placed vertically on the basement membrane; above these are several layers of spheroidal cells, which as they approach the surface become more and more compressed, until the superficial ones are found to consist of flattened scales (fig. 14), the margins of which overlap one another so as to present an imbricated appearance. The protoplasm of the superficial cells is completely converted into a horny substance termed *keratin*. An intermediate body, *eleidin*, is often present in the deeper layers

of this superficial portion. It exists in the form of coarse granules, and is especially well seen in the stratum granulosum of the epidermis. The most superficial layers lose their nuclei, die, and are thrown or worn off.

Stratified epithelium is found in the skin, in the mucous membrane of the nose, excepting the olfactory portion, in the mucous membrane of the mouth, part of the pharynx, the œsophagus and in the conjunctiva.

Certain cells found in the deeper layers of stratified epithelium, and termed *prickle-cells* (fig. 16), constitute a variety of squamous epithelium. They possess short, fine fibrils, which pass from their margins to those of neighbouring cells, serving to connect them together. They are not closely joined together by cement-substance, but are separated from each other by intercellular channels, across which the fibrils may be seen bridging. When a cell is isolated, it appears to be covered over with a number of short spines, in consequence of the fibrils being broken through. These cells were first described by Max Schultze and Virchow, and it was believed by them that the cells were dovetailed together. Martyn subsequently showed that this was not the case and that the prickles were attached to each other by their apices: and Delépine believes the prickles to be parts of fibrils forming internuclear bundles between the nuclei of the cells of an epithelium in a state of active growth (see page 7, and fig. 2).

FIG. 17.—Transitional epithelium.



Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are cubical, with depressions on their under surfaces, to fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement membrane. Between the tapering points of the cells of the second layer is a third variety of cells of smaller size than those of the other two layers (fig. 17).

CONNECTIVE TISSUES

The term **connective tissue** includes a number of tissues which possess this feature in common, viz. they support and connect the other tissues of the body. The connective tissues may differ considerably from each other in appearance, but they present many points of relationship, and are, moreover, developed from the same layer of the embryo, the mesoderm. They are divided into three great groups: (1) the connective tissues proper, (2) cartilage, and (3) bone. Blood, which has already been described, is, strictly speaking, a form of connective tissue, and is so dealt with by many histologists.

THE CONNECTIVE TISSUES PROPER

Several forms or varieties of connective tissue are recognised: (1) Areolar tissue. (2) White fibrous tissue. (3) Yellow elastic tissue. (4) Mucous tissue. (5) Retiform tissue. They are all composed of a homogeneous matrix, in which are imbedded cells and fibres—the latter of two kinds, white, and yellow or elastic. The distinction between the different forms of tissue depends upon the relative preponderance of one or other kind of fibre, of cells, or of matrix.

Connective tissue corpuscles.—The cells of the connective tissues are of three principal kinds: (1) Flattened lamellar cells, which may be either branched or unbranched. The branched lamellar cells are composed of clear cell-substance, and contain oval nuclei. The processes of these cells unite so as to form an open network, as in the cornea. The unbranched cells are joined edge to edge like the cells of an epithelium. The 'tendon cells,' presently to be described, are examples of this variety. (2) Granule cells, which are ovoid or spheroidal in shape. They are formed of a soft protoplasm, containing granules which are albuminous in character and stain deeply with eosin. (3) Plasma cells of Waldeyer, varying greatly in size and form, but distinguished from the other two varieties by containing a vacuolated protoplasm. The vacuoles are filled with fluid, and the

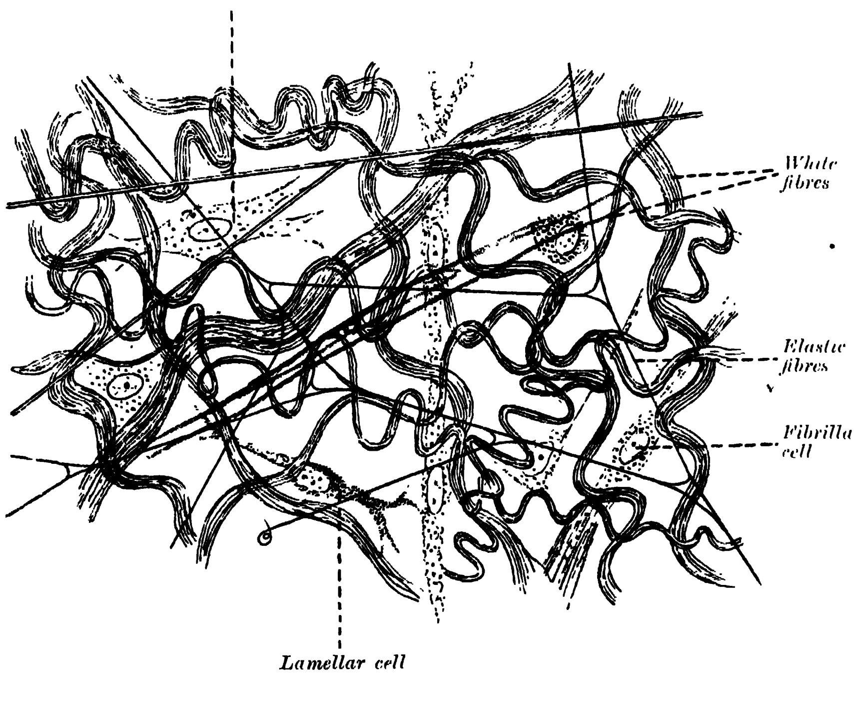
protoplasm between the spaces is clear, with occasionally a few scattered granules.

In addition to these three typical forms of connective tissue corpuscles, areolar tissue may be seen to possess *wandering cells*, i.e. leucocytes which have emigrated from the neighbouring vessels; in some instances, as in the choroid coat of the eye, cells filled with granules of pigment (*pigment cells*) are found.

The connective tissue corpuscles lie in spaces in the ground substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light. This will colour the ground substance and leave the cell-spaces unstained.

Areolar tissue (fig. 18) is so called because its meshes can be easily distended with air or fluid and thus separated into areolæ or spaces, which open freely into each other. Such spaces, however, do not exist in the natural condition of the body, the whole tissue forming one unbroken membrane composed of a number of interlacing fibres, variously superimposed. The chief use of areolar tissue is to bind parts together; while by the laxity of its fibres, and the permeability of its areolæ,

FIG. 18.—Subcutaneous tissue from a young rabbit. Highly magnified. (Schäfer.)



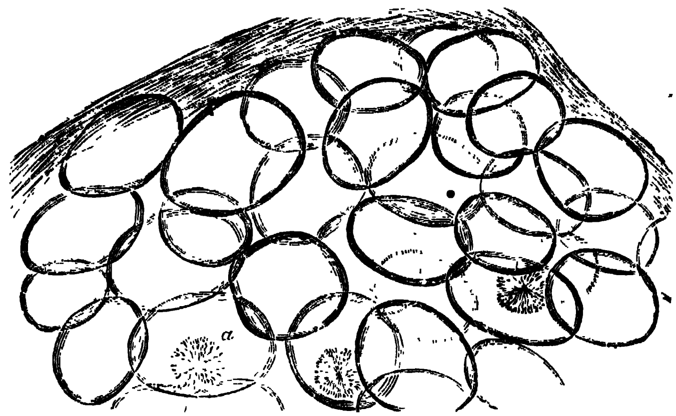
it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids. It is one of the most extensively distributed of all the tissues. It is found beneath the skin in a continuous layer all over the body, connecting it to the subjacent parts. In the same way it is situated beneath the mucous and serous membranes. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. In addition to this, it is present in the interior of organs, binding together the various lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles, &c., and thus forms one of the most important connecting media of the various structures or organs of which the body is made up. In many parts the areolæ or interspaces of areolar tissue are occupied by fat-cells, constituting *adipose tissue*, which will presently be described.

Areolar tissue presents to the naked eye an appearance somewhat like spun-silk. When stretched out, it is seen to consist of delicate soft elastic threads interlacing with each other in every direction, and forming a network of extreme delicacy. When examined under the microscope (fig. 18) it is found to be com-

posed of white fibres and yellow elastic fibres intercrossing in all directions, and united together by a homogeneous cement or ground substance, the *matrix*, showing cell-spaces wherein lie the *connective tissue corpuscles*; these contain the protoplasm out of which the whole is developed and regenerated.

The *white fibres* are arranged in waving bands or bundles of minute transparent homogeneous filaments or fibrillæ. The bundles have a tendency to split up

FIG. 19.—Adipose tissue. High power.

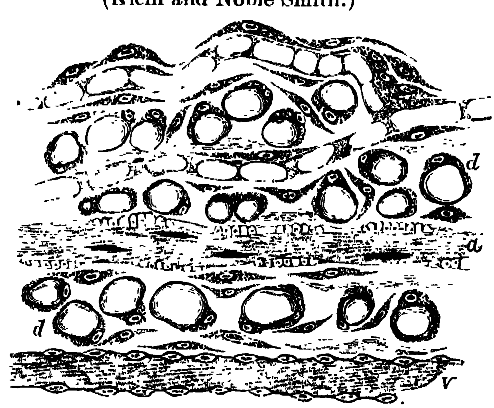


a. Starlike appearance, from crystallisation of fatty acids.

longitudinally or send off slips to join neighbouring bundles, and receive others in return, but the individual fibres are unbranched, and never join other fibres. The *yellow elastic fibres* have well-defined outlines and are considerably larger in size than the white fibrillæ, but vary much, being from the $\frac{1}{24000}$ to the $\frac{1}{4000}$ of an inch in diameter. They form bold and wide curves, branch, and freely anastomose with each other; they are homogeneous in appearance, and tend to curl up, especially at their broken ends.

Adipose tissue.—In almost all parts of the body the ordinary areolar tissue contains a variable quantity of fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, of the penis and scrotum, of the nymphæ; within the cavity of the cranium; and in the lungs, except near their roots. Its distribution is not uniform; in some parts it is collected in great abundance, as in the subcutaneous tissue, especially of the abdomen; around the kidneys, and in some other situations. Lastly, fat enters largely into the formation of the marrow of bones. A distinction must be made between fat and adipose tissue; the latter being a distinct tissue, the former an oily matter, which in addition to forming adipose tissue is also widely present in the body, as in the brain and liver, and in the blood, chyle, &c.

FIG. 20.—Development of fat. (Klein and Noble Smith.)



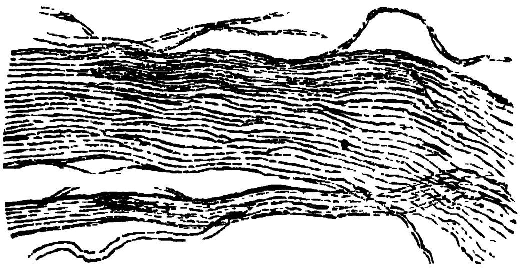
a. Minute artery. *v.* Minute vein. *c.* Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. *d.* The ground substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

Adipose tissue consists of small vesicles, *fat-cells*, lodged in the meshes of areolar tissue. Fat-cells (fig. 19) vary in size, but are of about the average diameter of $\frac{1}{500}$ of an inch; each consists of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified

after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less polygonal outline. A nucleus is always present and can be easily demonstrated by staining with hæmatoxylin; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognisable. The fat-cells are contained in clusters in the areolæ of fine connective tissue, and are held together mainly by the network of capillary blood-vessels which is distributed to them.

Chemically the oily material in the cells is composed of the fats, olein, palmitin and stearin, which are glycerin compounds with fatty acids. Sometimes fat crystals form in the cells after death (fig. 19, *a*). By boiling the tissue in ether or strong alcohol, the fat may be extracted from the vesicles, leaving them empty and shrunken.

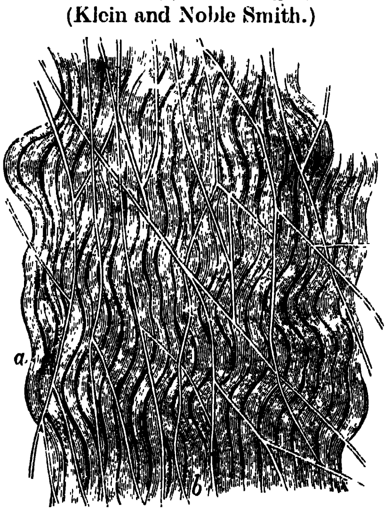
FIG. 21.—White fibrous tissue. High power.



Fat may be first detected in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of connective tissue corpuscles. Small droplets of oil are formed in the protoplasm, and these coalesce to produce a larger drop, which increases until it distends the corpuscle, the remaining protoplasm and the nucleus being displaced towards the periphery of the cell (fig. 20).

White fibrous tissue (fig. 21) is a true connecting structure, and serves three purposes in the animal economy. In the form of ligaments it binds bones together; in the form of tendons it connects muscles to bones or other structures; and it constitutes investing or protecting structures to various organs in the form of membranes. Examples of such membranes are to be found in the muscular fasciæ or sheaths, the periosteum, and perichondrium; the investments of the various glands (such as the tunica albuginea testis, the capsule of the kidney, &c.); the investing sheaths of the nerves (epineurium), and of various organs, as the penis and the eye. In white fibrous tissue, as its name implies, the white fibres predominate; the matrix is apparent only as a cement-substance, the yellow elastic fibres are comparatively few, while the tissue-cells are arranged in a special manner. It presents to the naked eye the appearance of silvery white glistening fibres, covered over with a quantity of loose flocculent tissue which binds the fibres together and carries the blood-vessels (fig. 22). It is not possessed of any elasticity, and only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence, a bone with which it is connected may fracture before the fibrous tissue gives way. In ligaments and tendons the bundles of fibres run parallel with each other; in membranes they intersect one another. The cells found in white fibrous tissue are often called 'tendon-cells.' They are situated on the surfaces of groups of bundles and are quadrangular in shape, arranged in rows, in single file, each cell being separated from its neighbours by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of one of the adjoining cells being in close proximity to it (fig. 23). Upon the addition of acetic acid white fibrous tissue swells up into a glassy-looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin,

FIG. 22.—Connective tissue. (Klein and Noble Smith.)



The white fibrous element—a layer of more or less sharply outlined, parallel, wavy bundles of connective tissue fibrils. On the surface of this layer is *b*, a network of fine elastic fibres.

the white fibres being composed of the albuminoid *collagen*, which is often regarded as the anhydride of gelatin.

Yellow elastic tissue.—In certain parts of the body a tissue is found which when viewed in mass is of a yellowish colour, and is possessed of great elasticity, so that it is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*, which may be regarded as a connective tissue in which the yellow elastic fibres have developed to the practical exclusion of the other elements. It is found in the ligamenta subflava, in the vocal cords, in the longitudinal coats of the trachea and bronchi, in the inner coats of the blood vessels, especially the larger arteries, and to a very considerable extent in the thyro-hyoid, crico-thyroid, and stylo-hyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals (fig. 24). In some parts where the fibres are broad and large and the network close the tissue presents the appearance of a membrane with gaps or perforations

Fig. 23.—Tendon of mouse's tail stained with logwood, showing chains of cells between the tendon bundles. (From Quain's Anatomy, E. A. Schafer.)

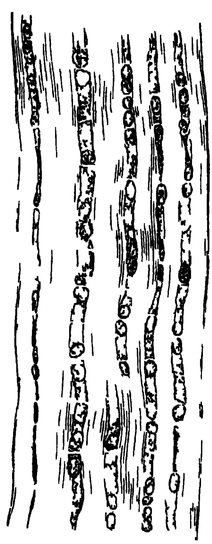


Fig. 24.—Yellow elastic tissue. High power.

corresponding to the intervening spaces. This is to be found in the inner coats of the arteries and to it the name of *fenestrated membrane* has been given by Henle. The yellow elastic fibres remain unaltered by acetic acid. Chemically they are composed of the albuminoid body *elastin*.

Mucous tissue exists chiefly in the 'jelly of Wharton' which forms the bulk of the umbilical cord, but is also found in other situations in the fœtus, chiefly as a stage in the development of connective tissue. It consists of a matrix, largely made up of mucin, in which are nucleated cells with branching and anastomosing processes (fig. 25). Few fibres are seen in typical mucous tissue, though at birth the umbilical cord shows a considerable development of fibres. In the adult the vitreous humour of the eye is a persistent form of mucous tissue in which there are no fibres, and from which the cells have disappeared, leaving only the mucinous ground substance.

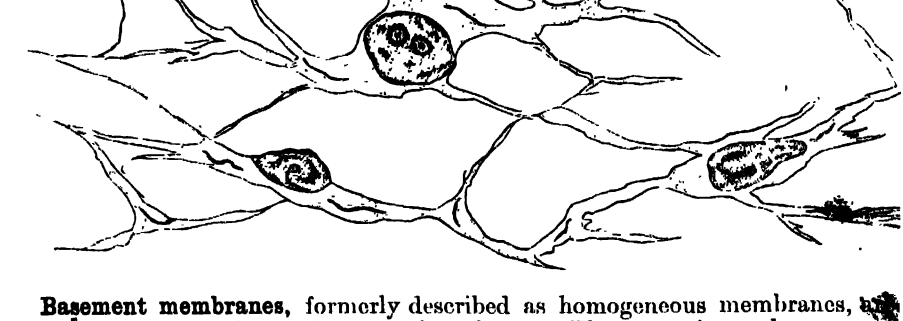
Retiform or **reticular tissue** (fig. 26) is found extensively in many parts of the body, constituting the framework of some organs and entering into the

construction of many mucous membranes. It is a variety of connective tissue, i which the intercellular or ground substance has, in a great measure, disappeare and is replaced by fluid. It is apparently composed almost entirely extremely fine bundles of white fibrous tissue, forming an intricate network, an

FIG. 25.—Mucous tissue from the umbilical cord of the human fœtus (four months).

chemically it yields gelatin. The fibres are covered and concealed in places l flattened branched connective tissue cells. In many situations the interstices the network are filled with rounded lymph-corpuscles, and the tissue is th termed **lymphoid** or **adenoid tissue** (see fig. 83, p. 63).

FIG. 26.—Retiform connective tissue, from a lymphatic gland.



Basement membranes, formerly described as homogeneous membranes, a most cases really a form of connective tissue. They constitute the suppo membrane, or *membrana propria*, on which is placed the epithelium of muc membranes or secreting glands, and they are also found in other situations. means of staining with nitrate of silver they may be shown to consist usua

of flattened cells in close apposition, and joined together by their edges, thus forming an example of an epithelioid arrangement of connective tissue cells. In some situations the cells, instead of adhering by their edges, give off branching processes which join with similar processes of other cells, and so form a network rather than a continuous membrane. Some basement membranes are composed of elastic tissue, as in the cornea, others are merely condensed matrix.

Vessels and nerves of connective tissue.—The *blood-vessels* of connective tissue are very few—that is to say, there are few actually destined for the tissue itself, although many vessels carrying blood to other structures may permeate one of its forms, the areolar tissue. In white fibrous tissue the blood-vessels usually run parallel to the longitudinal bundles and between them, sending transverse communicating branches across; in some forms, as in the periosteum and dura mater, they are fairly numerous. In yellow elastic tissue, the blood-vessels also run between the fibres, and do not penetrate them. *Lymphatic vessels* are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves. *Nerves* are to be found in the white fibrous tissue, where they terminate in a special manner; but it is doubtful whether any nerves terminate in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

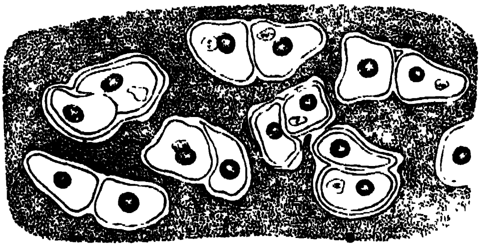
Development of connective tissue.—Connective tissue is developed from cells of the mesoderm. These cells, at first rounded, become fusiform and branched, and ultimately form connective tissue corpuscles. A mucinous intercellular substance or matrix, partly derived from the cells themselves and partly from the lymph exuded by the neighbouring blood-vessels, gradually separates the cells. In the matrix the fibres are deposited, probably under the influence of the cells, but not by any transformation of the cell protoplasm. In the case of yellow elastic fibres, rows of granules of elastin are first laid down; these eventually fuse into the fully developed fibre.

CARTILAGE

Cartilage is a non-vascular structure which is found in various parts of the body—in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, such as the air-passages, nostrils, and ears, which require to be kept permanently open. In the fœtus, at an early period, the greater part of the skeleton is cartilaginous. As this cartilage is afterwards replaced by bone, it is called *temporary*, in contradistinction to that which remains unossified during the whole of life and is called *permanent*.

Cartilage is divided, according to its minute structure, into hyaline cartilage, white fibro-cartilage, and yellow or elastic fibro-cartilage. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, which consists entirely, or almost entirely, of cells, united in some cases by a network of very fine fibres, in other cases apparently destitute of any intercellular substance, the cells being separated from each other by their capsules only, which in this variety of cartilage are extremely well marked. Cellular cartilage is found in the external ears of rats, mice, and some other animals, and is present in the notochord of the human embryo, but is not found in any other human structure. The various cartilages in the body are also classified, according to their functions and positions, into articular, interarticular, costal, and membraniform.

FIG. 27.—Human cartilage-cells from the cricoid cartilage. × 350.

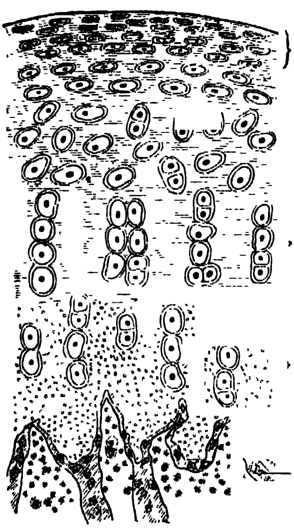


Hyaline cartilage, which may be taken as the type of this tissue, consists of a gristly mass of a firm consistence, but of considerable elasticity and pearly-bluish colour. Except where it coats the articular ends of bones, it is covered externally by a fibrous membrane, the *perichondrium*, from the vessels of which

it imbibes its nutritive fluids, being itself destitute of blood-vessels. It contains no nerves. Its intimate structure is very simple. If a thin slice be examined under the microscope, it will be found to consist of cells of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (fig. 27). The cells, when arranged in groups of two or more, have generally straight outlines where they are in contact with each other, and in the rest of their circumference are rounded. They consist of clear translucent protoplasm, in which fine interlacing filaments and minute granules are sometimes present; imbedded in this are one or two round nuclei, having the usual intranuclear networks. The cells are contained in cavities in the matrix, called *cartilage lacunæ*; around these the matrix is arranged in concentric lines, as if it had been formed in successive portions around the cartilage-cells. This constitutes the so-called *capsule* of the space. Each lacuna is generally occupied by a single cell, but during the division of the cells it may contain two, four, or eight cells.

The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. Some observers have shown that the matrix of hyaline cartilage, and especially of the articular variety, after prolonged maceration, can be broken up into fine fibrils. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the lacunæ with each other, and that these canals communicate with the lymphatics of the perichondrium, and thus the structure is permeated by a current of nutrient fluid.

FIG. 28.—Vertical section of articular cartilage.



Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety. They present minute differences in the size and shape of their cells and in the arrangement of their matrices.

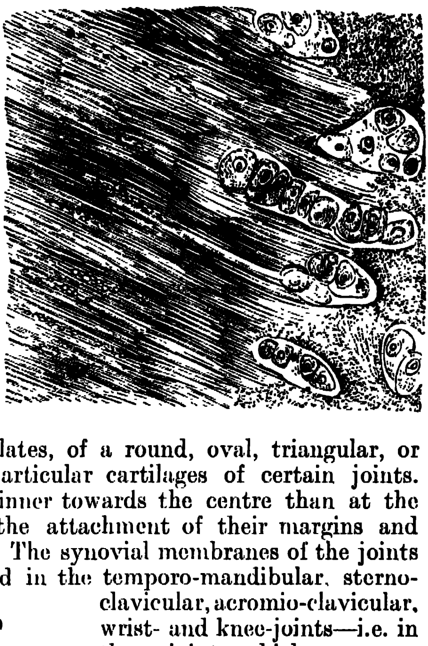
In **articular cartilage** (fig. 28), which shows no tendency to ossification, the matrix is finely granular; the cells and nuclei are small, and are disposed parallel to the surface in the superficial part, while nearer to the bone they become vertical. Articular cartilages have a tendency to split in a vertical direction: in disease this tendency becomes very manifest. The free surface of articular cartilage, where it is exposed to friction, is not covered by perichondrium, though a layer of connective tissue continuous with that of the synovial membrane can be traced in the adult over a small part of its circumference, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective tissue corpuscles of the synovial membrane. Articular cartilage forms a thin incrustation upon the joint-surfaces of the bones, and its elasticity enables it to break the force of concussions, while its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, the reverse being the case on concave articular surfaces. It appears to derive its nutriment partly from the vessels of the neighbouring synovial membrane and partly from those of the bone upon which it is implanted. Toynbee has shown that the minute vessels of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

In **costal cartilage** the cells and nuclei are large, and the matrix has a tendency to fibrous striation, especially in old age (fig. 29). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears, at first sight, to be an exception to the statement that cartilage is a non-vascular

tissue, but is not so really, for the vessels give no branches to the cartilage substance itself, and the channels may rather be looked upon as involutions of the perichondrium. The ensiform cartilage and the cartilages of the nose, larynx and trachea (except the epiglottis and cornicula laryngis, which are composed of elastic fibro-cartilage) resemble the costal cartilages in microscopical characters.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by calcium salts without any appearance of true bone. The process of calcification occurs frequently, according to Rollett, in such cartilages as those of the trachea and in the costal cartilages, where it may be succeeded by conversion into true bone.

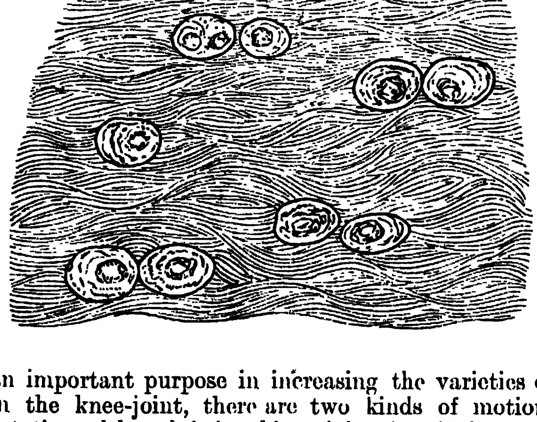
Fig. 29.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. High power.



White fibro-cartilage consists of a mixture of white fibrous tissue and cartilaginous tissue in various proportions; to the former of these constituents it owes its flexibility and toughness, and to the latter its elasticity. When examined under the microscope it is found to be made up of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; the cells to a certain extent resemble tendon-cells, but may be distinguished from them by being surrounded by a concentrically striated area of cartilage matrix and by being less flattened (fig. 30). The fibro-cartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

1. The *interarticular fibro-cartilages* (*menisci*) are flattened fibro-cartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, usually thinner towards the centre than at the circumference, and held in position by the attachment of their margins and extremities to the surrounding ligaments. The synovial membranes of the joints are prolonged over them. They are found in the temporo-mandibular, sterno-clavicular, acromio-clavicular, wrist- and knee-joints—i.e. in those joints which are most exposed to violent concussion and subject to frequent movement. Their uses are to obliterate the intervals between opposed surfaces in their various motions; to increase the depths of the articular surfaces and give ease to the gliding movements; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these interarticular fibro-cartilages serve an important purpose in increasing the varieties of movement in a joint. Thus, in the knee-joint, there are two kinds of motion, viz. angular movement and rotation, although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the interarticular cartilages, the latter between the cartilages and the head of the tibia. So, also, in the temporo-mandibular joint, the movements

Fig. 30.—White fibro-cartilage from an intervertebral disc.

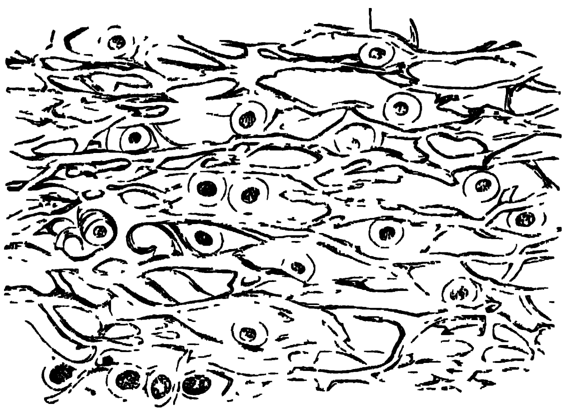


of opening and shutting the mouth take place between the fibro-cartilage and the mandible, the grinding movement between the glenoid cavity and the fibro-cartilage, the latter moving with the mandible.

2. The *connecting fibro-cartilages* are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebræ. They form discs which are closely adherent to the opposed surfaces. Each disc is composed of concentric rings of fibrous tissue, with cartilaginous laminæ interposed, the former tissue predominating towards the circumference, the latter towards the centre.

3. The *circumferential fibro-cartilages* consist of rims of fibro-cartilage, which surround the margins of some of the articular cavities, e.g. the cotyloid ligament of the hip, and the glenoid ligament of the shoulder; they serve to deepen the articular cavities and to protect their edges.

FIG. 31.—Yellow cartilage, car of horse. High power.



4. The *stratiform fibro-cartilages* are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibro-cartilage are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the Peroneus longus and Tibialis posticus.

Yellow or elastic fibro-cartilage is found in the human body in the auricles of the external ears, the Eustachian tubes, the cornicula laryngis, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded by a network of yellow elastic fibres, branching and anastomosing in all directions, except immediately around each cell, where there is a variable amount of non-fibrillated hyaline, intercellular substance (fig. 31). The fibres resemble those of yellow elastic tissue, both in appearance and in being unaffected by acetic acid: and according to Rollett their continuity with the elastic fibres of the neighbouring tissue is demonstrable. Not infrequently the base of the epiglottis is composed of a mixture of hyaline and elastic fibro-cartilage.

The distinguishing feature of cartilage chemically is that it yields on boiling a substance called *chondrin*, very similar to gelatin, but differing from it in several of its reactions. It is now believed that chondrin is not a simple body, but a mixture of gelatin with mucinoid substances, chief among which, perhaps, is a compound termed *chondro-mucoid*.

BONE

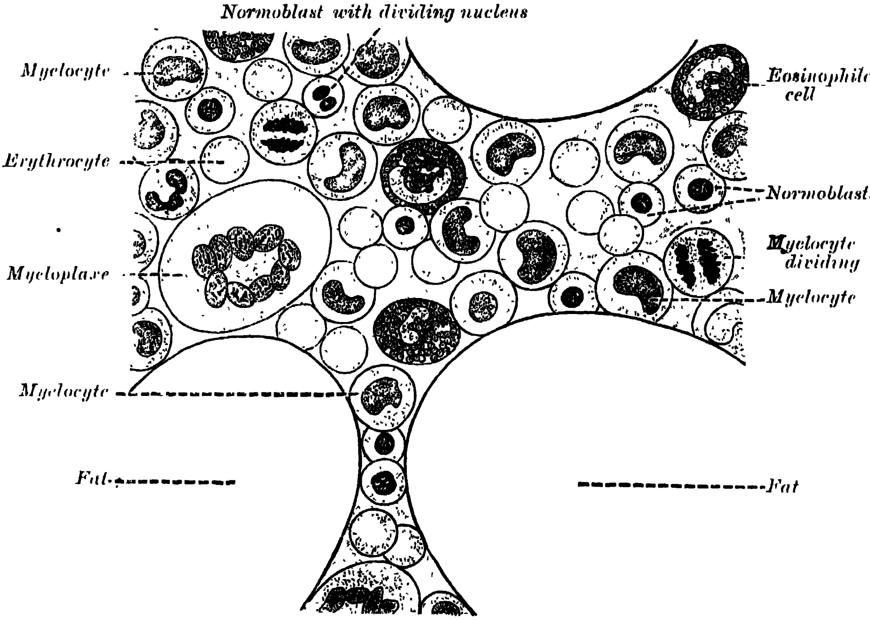
Structure and physical properties.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its colour, in a fresh state, is pinkish white externally, and deep red within. On examining a section of any bone, it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *compact tissue*; the other consists of slender fibres and lamellæ, which join to form a reticular structure; this, from its resemblance to lattice-work, is called *cancellous tissue*. The compact tissue is always placed on the exterior of the bone, the cancellous in the interior. The relative quantity of these two kinds of tissue varies in different bones, and in different parts of the same bone, according as strength or lightness is requisite. Close examination of the compact tissue shows it to be extremely porous, so that the difference in structure between it and the cancellous tissue depends merely upon the different amount of solid matter, and the size and number of spaces in each; the cavities are small in the compact

tissue and the solid matter between them abundant, while in the cancellous tissue the spaces are large and the solid matter is in smaller quantity.

Bone during life is permeated by vessels, and is enclosed, except where it is coated with articular cartilage, in a fibrous membrane, the *periosteum*, by means of which many of these vessels reach the hard tissue. If the periosteum be stripped from the surface of the living bone, small bleeding points are seen which mark the entrance of the periosteal vessels; and on section during life every part of the bone exudes blood from the minute vessels which ramify in it. The interior of each of the long bones of the limbs presents a cylindrical cavity filled with marrow and lined by a highly vascular areolar structure, called the *medullary membrane* or *internal periosteum*, which, however, is rather the areolar envelope of the cells of the marrow than a definite membrane.

The **periosteum** adheres to the surface of each of the bones in nearly every part, but not to cartilaginous extremities. When strong tendons or ligaments are attached to a bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer one formed chiefly of connective tissue, containing occasionally a few fat-cells; the inner one, of elastic fibres of the

FIG. 32.—Human bone-marrow. (Highly magnified.)



finer kind, forming dense membranous networks, which can be again separated into several layers. In young bones the periosteum is thick and very vascular, and is intimately connected at either end of the bone with the epiphysial cartilage, but less closely with the shaft, from which it is separated by a layer of soft tissue, containing a number of granular corpuscles or 'osteoblasts,' in which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner, less vascular, and the osteoblasts are converted into an epithelioid layer on the deep surface of the periosteum. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis, when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periostium.

The **marrow** not only fills up the cylindrical cavities in the shafts of the long bones, but also occupies the spaces of the cancellous tissue and extends into the larger bony canals (Haversian canals) which contain the blood-vessels. It differs in composition in different bones. In the shafts of the long bones the marrow is of a *yellow* colour, and contains, in 100 parts, 96 of fat, 1 of areolar tissue and vessels, and 3 of fluid with extractive matter; it consists of a basis of connective

tissue supporting numerous blood-vessels and cells, most of which are fat-cells, but some are 'marrow-cells,' such as occur in the red marrow to be immediately described. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs, the marrow is of a *red* colour, and contains, in 100 parts, 75 of water, and 25 of solid matter consisting of cell-globulin, nucleo-protein, extractives, salts, and only a small proportion of fat. The red marrow consists of a small quantity of connective tissue, blood-vessels, and numerous cells (fig. 32), some few of which are fat-cells, but the great majority are roundish nucleated cells, the true 'marrow-cells' of Kölliker. These marrow-cells proper, or *myelocytes*, resemble in appearance lymphoid corpuscles, and like them are amœboid; they generally have a hyaline protoplasm, though some show granules either oxyphil or basophil in reaction. A number of eosinophil cells are also present. Among the marrow-cells may be seen smaller cells, which possess a slightly pinkish hue; these are the *erythroblasts* or *normoblasts*, from which, as we have seen, the red corpuscles of the adult are derived, and which may be regarded as descendants of the nucleated coloured corpuscles of the embryo. *Giant-cells* (*myeloplaxes*, *osteoclasts*), large, multinucleated, protoplasmic masses, are also to be found in both sorts of adult marrow, but more particularly in red marrow. They were believed by Kölliker to be concerned in the absorption of bone-matrix, and hence the name which he gave to them—*osteoclasts*. They excavate in the bone small shallow pits or cavities, which are named *Howship's lacunæ*, and in these they are found lying.

a. Haversian canals. *b.* Lacunæ, with their canalicul the lamellæ of these canals. *c.* Lacunæ of the interstitial lamellæ. *d.* Others at the surface of the Haversian systems with canaliculi given off from one side.

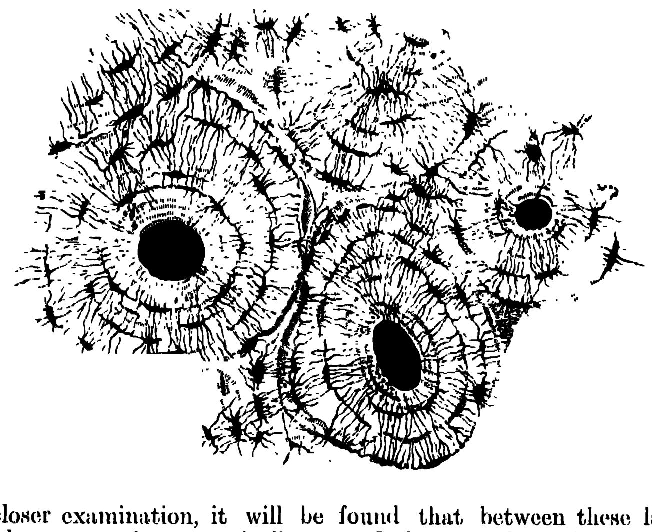
Vessels and nerves of bone.—The *blood-vessels* of bone are very numerous. Those of the compact tissue are derived from a close and dense network of vessels ramifying in the periosteum. From this membrane vessels pass into the minute orifices in the compact tissue, and run through the canals which traverse its substance. The cancellous tissue is supplied in a similar way, but by less numerous and larger vessels, which, perforating the outer compact tissue, are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces; some of these give passage to the arteries of the larger set of vessels referred to; but the most numerous and largest apertures are for the veins of the cancellous tissue, which emerge apart from the arteries. The medullary canal in the shaft of a long bone is supplied by one large artery (or sometimes more), which enters the bone at the nutrient foramen (situated in most cases near the centre of the shaft), and perforates obliquely the compact structure. The *medullary* or *nutrient* artery, usually accompanied by one or two veins, sends branches upwards and downwards, which ramify in the medullary membrane, and give twigs to the adjoining canals. The ramifications of this vessel anastomose with the arteries of the cancellous and compact tissues. In most of the flat, and in many of the short spongy bones, one or more large apertures are observed, which transmit, to the central parts of the bone, vessels corresponding to the medullary arteries and veins. The veins emerge from the long bones in three places (Kölliker)—(1) one or two large veins accompany the artery; (2) numerous large and small veins emerge at the articular extremities; (3) many small veins pass out of the compact substance. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in the diploic tissue, the sides of the canals being formed by thin lamellæ of bone, perforated here and there for the passage of branches from the adjacent cancelli. The same condition is also found in all cancellous

tissue, the veins being enclosed and supported by osseous structure, and having exceedingly thin coats. When the bony structure is divided, the vessels remain patulous, and do not contract in the canals in which they are contained. Hence the occurrence of purulent absorption after amputation, in those cases where the stump becomes inflamed and the cancellous tissue is infiltrated and bathed by pus. *Lymphatic vessels*, in addition to those found in the periosteum, have been traced by Cruikshank into the substance of bone, and Klein describes them as running in the Haversian canals. *Nerves* are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said by Kölliker to be most numerous in the articular extremities of the long bones, in the vertebræ, and in the larger flat bones.

Minute anatomy.—The intimate structure of bone, in all essential particulars identical in the compact and in the cancellous tissue, is most easily studied in a transverse section from the compact wall of one of the long bones after maceration (fig. 33).

If this be examined with a rather low power the bone will be seen to be mapped out into a number of circular districts each consisting of a central hole surrounded by a number of concentric rings. These districts are termed *Haversian systems*; the central hole is an *Haversian canal*, and the rings are layers of bone-tissue arranged concentrically around the central canal, and termed *lamellæ*. More-

FIG. 34.—Transverse section of compact tissue of bone. Magnified. (Sharpey.)

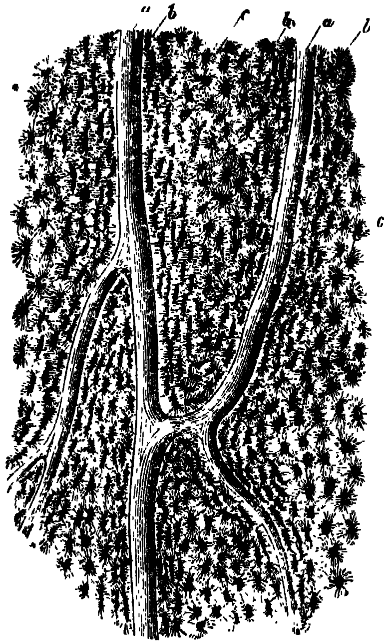


over, on closer examination, it will be found that between these lamellæ, and therefore also arranged concentrically around the central canal, are a number of little dark spots, the *lacunæ*, and that these lacunæ are connected with each other and with the central Haversian canal by a number of fine dark lines, which radiate like the spokes of a wheel and are called *canaliculi*. All these structures—the concentric lamellæ, the lacunæ, and the canaliculi—may be seen in any single Haversian system forming a circular district round a central Haversian canal. Filling in the irregular intervals which are left between these circular systems are other lamellæ, with their lacunæ and canaliculi running in various directions, but more or less curved (fig. 34). These are termed *interstitial* lamellæ. Again, other lamellæ, for the most part found on the surface of the bone, are arranged parallel to the circumference of the bone, constituting, as it were, a single Haversian system of the whole bone, of which the medullary cavity would represent the Haversian canal. These latter lamellæ are termed *circumferential*, or by some authors *primary* or *fundamental* lamellæ, to distinguish them from those laid down around the axes of the Haversian canals, which are then termed *secondary* or *special* lamellæ.

The *Haversian canals*, seen in a transverse section of bone as round holes at or about the centre of each Haversian system, may be demonstrated to be true canals, if a longitudinal section be made (fig. 35). It will then be seen that the

canals run parallel with the longitudinal axis of the bone for a short distance and then branch and communicate. They vary considerably in size, some being as much as $\frac{1}{200}$ of an inch in diameter; the average size is, however, about $\frac{1}{500}$ of an inch. Near the medullary cavity the canals are larger than those near the surface of the bone. Each canal contains one or two blood-vessels, with a small quantity of delicate connective tissue and some nerve filaments. In the larger ones there are also lymphatic vessels, and cells with branching processes which communicate, through the canaliculi, with the branched processes of certain bone cells in the substance of the bone. Those canals near the surface of the bone open upon it by minute orifices, and those near the medullary cavity open in the same way into this space, so that the whole of the bone is permeated by a system of blood-vessels running through the bony canals in the centres of the Haversian systems.

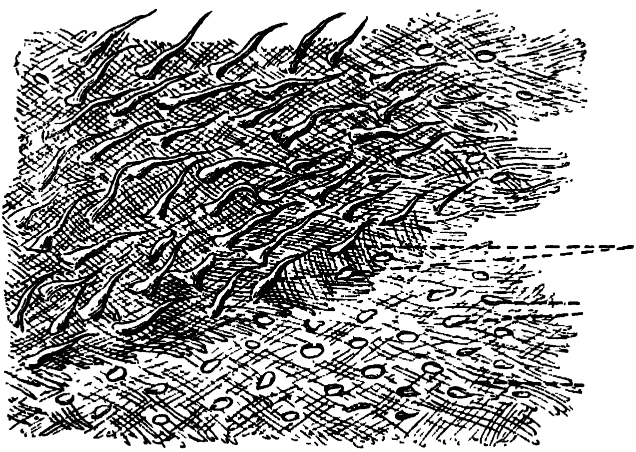
Fig. 35.—Section parallel to the surface from the shaft of the femur. Magnified 100 times.



Haversian canals. *b.* Lacunæ seen from the side. *c.* Others seen from the surface in lamellæ which are cut horizontally.

The *lamellæ* are thin plates of bone-tissue encircling the central canal, and may be compared, for the sake of illustration, to a number of sheets of paper pasted one over another around a central hollow cylinder. After macerating a piece of bone in dilute mineral acid, these lamellæ may be stripped off in a longitudinal direction as thin films. If one of these be examined with a high power of the microscope, it will be found to be composed of a finely reticular structure, made up of very slender transparent fibres, decussating obliquely, and coalescing at the points of intersection. These fibres are composed of fine fibrils identical with those of white connective tissue. The intercellular matrix between the

Fig. 36.—Lamellæ torn from a decalcified human parietal bone to show the perforating fibres of Sharpey. (Copied from a drawing by Allen Thomson.)

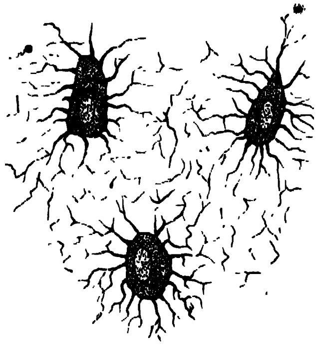


fibres is impregnated by calcareous deposit which the acid dissolves. In many places the various lamellæ may be seen to be held together by tapering fibres, which run obliquely through them, pinning or bolting them together.

These fibres were first described by Sharpey, and were named by him *perforating fibres* (fig. 36).

The *lacunæ* are situated between the lamellæ, and consist of a number of oblong spaces. In an ordinary microscopic section, viewed by transmitted light, they appear as dark, oblong, opaque spots, and were formerly believed to be solid cells. Subsequently, when it was seen that the Haversian canals were channels which lodged the vessels of the part, and the canaliculi minute tubes by which the plasma of the blood circulated through the tissue, the theory was formulated that the lacunæ were hollow spaces filled during life with the same fluid, and only lined (if lined at all) by a delicate membrane. But this view was eventually proved to be erroneous, for examination of the structure of recent bone led Virchow to believe that each lacuna is occupied during life by a branched cell, termed a bone-cell or bone-corpuscle, the processes from which pass down the canaliculi — a view which is now universally accepted (fig. 37). It is by means of these cells that the fluids necessary for nutrition are brought into contact with the ultimate tissue of bone.

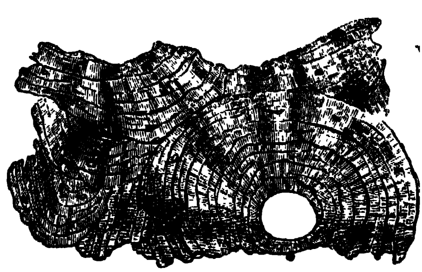
Fig. 37.—Nucleated bone-cells and their processes, contained in the bone-lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)



The *canaliculi* are exceedingly minute channels, which pass across the lamellæ and connect the lacunæ with neighbouring lacunæ and also with the Haversian canal. From the Haversian canal a number of canaliculi are given off, which radiate from it, and open into the first set of lacunæ between the first and second lamellæ. From these lacunæ a second set of canaliculi is given off, which passes outwards to the next series of lacunæ, and so on until the periphery of the Haversian system is reached; here the canaliculi given off from the last series of lacunæ do not communicate with the lacunæ of neighbouring Haversian systems, but after passing outwards for a short distance form loops and return to their own lacunæ. Thus every part of an Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and distributed through the canaliculi and lacunæ.

The *bone-cells* are contained in the lacunæ, which, however, they do not completely fill. They are flattened nucleated branched cells, which are homologous with those of connective tissue; the branches, especially in young bones, pass into the canaliculi from the lacunæ.

Fig. 38.—Section of bone after the removal of the earthy matter by the action of acids.



In a longitudinal section (fig. 35) the appearance of concentric rings is replaced by that of lamellæ or rows of lacunæ, parallel to the course of the Haversian canals, and these canals appear as half-tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance.

In thin plates of bone (as in the walls of the spaces which form the cancellous tissue) the Haversian canals are absent, and the canaliculi open into the spaces of the cancellous tissue (medullary spaces), which thus have the same function as the Haversian canals in the more compact bone.

Chemical composition.—Bone consists of an animal and an earthy part intimately combined together.

The animal part may be obtained by immersing a bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the

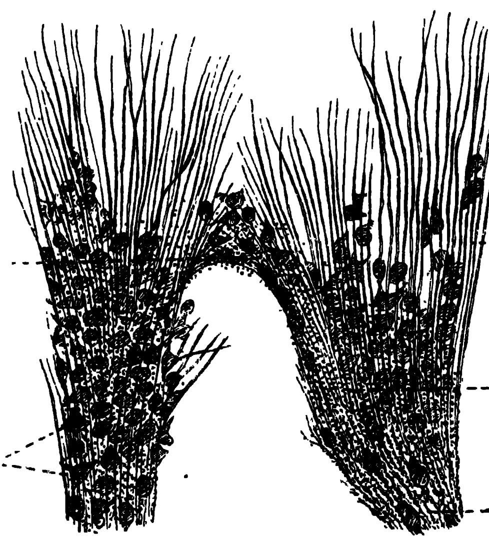
same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. If now a transverse section is made (fig. 38), the same general arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi, is seen, though not so plainly as in the ordinary section.

The earthy part may be separately obtained by calcination, by which the animal matter is completely burnt out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble down with the slightest force. The earthy matter is composed chiefly of calcium phosphate, forming about 66·7 per cent. of the weight of the bone; it confers on bone its hardness and rigidity, while the animal matter (*ossein*) determines its tenacity.

Development.—Some bones are preceded by membrane, such as those forming the roof and sides of the skull; others, such as the bones of the limbs, are preceded by rods of cartilage. Hence two kinds of ossification are described: the *intramembranous* and the *intracartilaginous*.

Intramembranous ossification.—In the case of bones which are developed in membrane, no cartilaginous mould precedes the appearance of the bone tissue. The membrane which occupies the place of the future bone, is of the nature of connective tissue, and ultimately forms the periosteum; it is composed of fibres

FIG. 39.—Part of the growing edge of the developing parietal bone of a fœtal cat. (After J. Lawrence.)

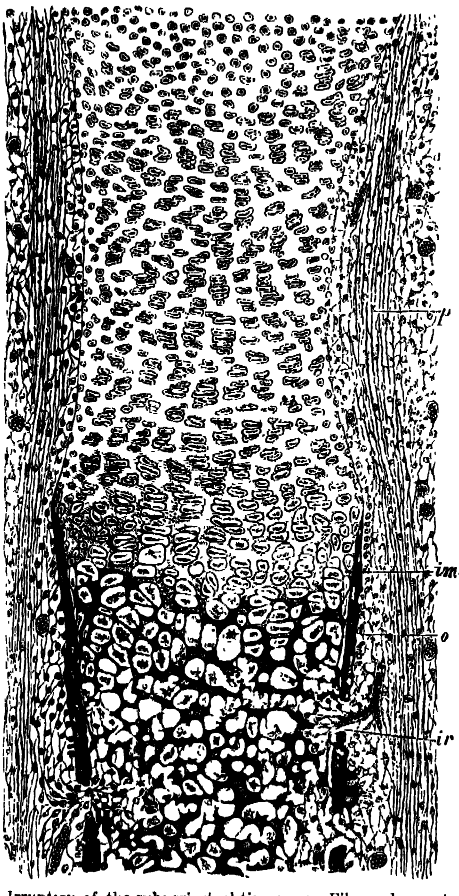


and granular cells in a matrix. The peripheral portion is more fibrous, while, in the interior the cells or *osteoblasts* predominate; the whole tissue is richly supplied with blood-vessels. At the outset of the process of bone formation a little network of bony spicules is noticed radiating from the point or centre of ossification. These rays consist at their growing points of a network of fine clear fibres and granular corpuscles with an intervening ground substance (fig. 39). The fibres are termed *osteogenetic* fibres, and are made up of fine fibrils differing little from those of white fibrous tissue. Like them they are probably deposited in the matrix through the influence of the cells—in this case the osteoblasts. The membrane soon assumes a dark and granular appearance from the deposition of calcareous granules in the fibres and in the intervening matrix, and in the calcified material some of the granular corpuscles or osteoblasts are enclosed. By the fusion of the calcareous granules the tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunæ. As the osteogenetic fibres grow out to the periphery they continue to calcify, and give rise to fresh bone spicules. Thus a network of bone is formed, the meshes of which contain the blood-vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh

layers of bone formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently successive layers of bony tissue are deposited under the periosteum and round the larger vascular channels which become the Haversian canals, so that the bone increases much in thickness.

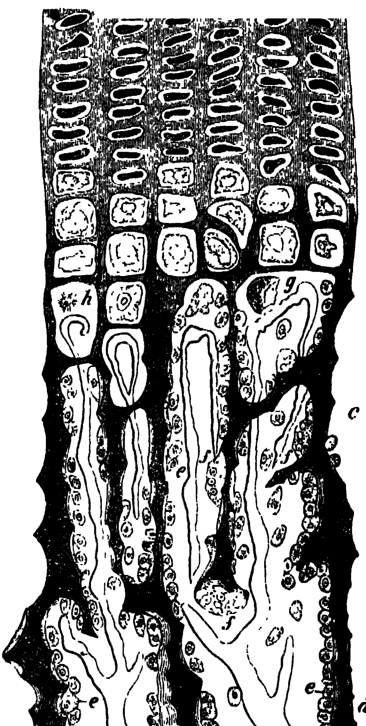
Intracartilaginous ossification.—Just before ossification begins the mass is entirely cartilaginous, and in a long bone, which may be taken as an example, the process commences in the centre and proceeds towards the extremities, which for some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually extends through them. The extremities do not, however, become joined to the shaft by bony tissue until growth has ceased; between the shaft and either extremity a layer of cartilaginous tissue termed the *epiphysial cartilage* persists for a definite period.

Fig. 40.—Section of fœtal bone of cat.



ir Irruption of the subperiosteal tissue. p. Fibrous layer of the periosteum. o. Layer of osteoblasts. im. Subperiosteal bony deposit. (From Quain's 'Anatomy,' E. A. Schafer.)

Fig. 41.—Part of a longitudinal section of the developing femur of a rabbit.



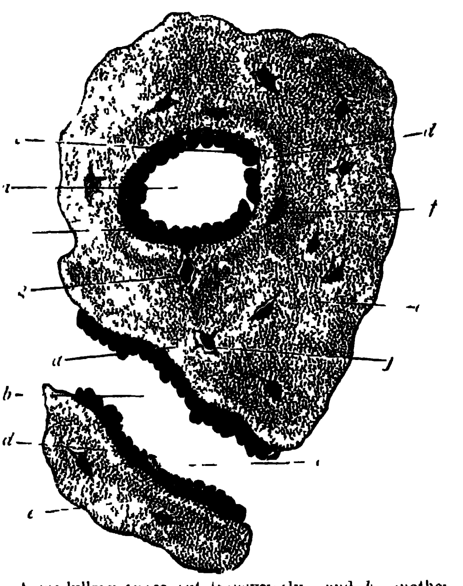
a. Flattened cartilage-cells. *b.* Enlarged cartilage-cells. *c, d.* Newly formed bone. *e.* Osteoblasts. *f.* Giant-cells or osteoclasts. *g, h.* Shrunken cartilage-cells. (From 'Atlas of Histology,' Klein and Noble Smith.)

The first step in the ossification of the cartilage is that the cartilage-cells, at the point where ossification is commencing and which is termed a *centre of ossification*, enlarge and arrange themselves in rows (fig. 40). The matrix in which they are imbedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in this matrix, between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and transverse bars of calcified substance stretch across from one calcareous column to another. Thus there are longitudinal groups of the cartilage-cells enclosed in oblong cavities, the walls of which are formed

of calcified matrix which cuts off all nutrition from the cells; the cells, in consequence, waste, leaving spaces called the *primary areolæ* (Sharpey).

At the same time that this process is going on in the centre of the solid bar of cartilage, certain changes are taking place on its surface. This is covered by a very vascular membrane, the *perichondrium*, entirely similar to the embryonic connective tissue already described as constituting the basis of membrane bone; on the inner surface of this—that is to say, on the surface in contact with the cartilage—are gathered the formative cells, the *osteoblasts*. By the agency of these cells a thin layer of bony tissue is formed between the perichondrium and the cartilage, by the *intramembranous* mode of ossification just described. There are then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, formed of calcified matrix and containing the withered cartilage-cells, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium, which has now become periosteum (fig. 10, ir). The processes consist of blood-vessels and cells—*osteoblasts*, or bone-formers, and *osteoclasts*, or bone-destroyers. The latter are similar to the giant-cells (myeloplaxes) found in marrow, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (fig. 10). Wherever these processes come in contact with the calcified walls of the primary areolæ they absorb them, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* (Sharpey) or *medullary spaces* (Müller). These secondary spaces become filled with embryonic marrow, consisting of osteoblasts and vessels, derived, in the manner described above, from the osteogenetic layer of the periosteum (fig. 41).

Fig. 42.—Transverse section from the femur of a human embryo about eleven weeks old.



a. A medullary space cut transversely, and *b.* another longitudinally. *c.* Osteoblasts. *d.* Newly formed osseous substance of a lighter colour. *e.* That of greater age. *f.* Lacunæ with their cells. *g.* A cell still united to an osteoblast.

Thus far there has been traced the formation of enlarged spaces (secondary areolæ), the perforated walls of which are still formed by calcified cartilage-matrix, containing an embryonic marrow derived from the processes sent in from the osteogenetic layer of the periosteum, and consisting of blood-vessels and round cells, osteoblasts (fig. 11). The walls of these secondary areolæ are at this time of only inconsiderable thickness, but they become thickened by the deposition of layers of new bone on their interior. This process takes place in the following manner. Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as an epithelioid layer on the surface of the wall of the space (fig. 42). This layer of osteoblasts forms a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance. On this a second layer of osteoblasts is arranged, and in its turn forms an osseous layer. By the repetition of this process the original cavity becomes very much reduced in size, and at last only remains as a small tube in the centre, containing the remains of the embryonic marrow—that is, a blood-vessel and a few osteoblasts. This small cavity constitutes the Haversian canal of the completely ossified bone. The successive layers of osseous matter encircling this central canal constitute the lamellæ of which each Haversian system is made up. As the successive layers of osteoblasts form osseous tissue, certain of the osteoblastic cells remain included between the various bony layers. These persist as

he cells of the future bone, the spaces enclosing them forming the lacunæ (fig. 41). The canaliculi, at first extremely short, are supposed to be extended by absorption, so as to meet those of neighbouring lacunæ.

Such are the changes which may be observed at one particular point, the centre of ossification. While they have been going on a similar process has been set up in the surrounding parts and has been gradually proceeding towards the ends of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

The shaft of the bone is at first solid, but a tube is hollowed out in it by absorption around the vessels passing into it, and this becomes the medullary canal. This absorption is supposed to be brought about by large giant-cells, the so-called osteoclasts of Kölliker (fig. 41, *f*). They vary in shape and size, and ain a large number of clear nuclei, sometimes as many as twenty. The occur- of similar cells in some tumours of bones has led to such tumours being nominated 'myeloid.' The absorption of bone from the interior to form the lullary canal is progressive, and is accompanied by a progressive deposition of bone on the exterior from the periosteum, until the bone has attained the shape and size which it is destined to retain during adult life.

While the ossification of the cartilaginous shaft is extending towards the articular ends, the cartilage immediately in advance of the osseous tissue continues ow until the length of the adult bone is reached.

ring the period of growth the articular end, or epiphysis, remains for some entirely cartilaginous, then a bony centre appears, and initiates in it the same process of intracartilaginous ossification; but this process never extends to any great distance. The epiphysis remains separated from the shaft by a narrow cartilaginous layer for a definite time. This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to such processes of bone as are separately ossified, e.g. the trochanters of the femur. The bones therefore continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend behind the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place from within, by which the medullary cavities are increased.

The medullary spaces which characterise the cancellous tissue are produced by the absorption of the original fœtal bone in a manner similar to that by which the original medullary canal is formed. The distinction between the cancellous and the compact tissue appears to depend essentially upon the extent to which this process of absorption has been carried. In some morbid states of the bone inflammatory absorption produces exactly the same change, and converts portions of bone, naturally compact, into cancellous tissue; in other pathological conditions denser bone may be formed.

The number of ossific centres varies in different bones. In most of the short bones ossification commences by a single point near the centre, and proceeds towards the surface. In the long bones there is a central point of ossification for the shaft or diaphysis: and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The times of union of the epiphyses with the shaft vary inversely with the times at which their ossifications began (with the exception of the fibula) and regulate the direction of the nutrient arteries of the bones. Thus, the nutrient arteries of the bones of the arm and forearm are directed towards the elbow, since the epiphyses at this joint become united to the shafts before those at the opposite extremities. In the lower limb, on the other hand, the nutrient arteries are directed away from the knee: that is, upwards in the femur, downwards in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur, and the lower epiphyses of the tibia and fibula, become first united to the shafts.

Where there is only one epiphysis, the medullary artery is directed towards the other end of the bone; as towards the acromial end of the clavicle, towards the distal ends of the metacarpal bone of the thumb and the metatarsal bone

of the great toe, and towards the proximal ends of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For an account of these the reader is referred to the description of the individual bones.

Parsons (*Journal of Anatomy and Physiology*, vol. xxxviii.) groups epiphyses under three headings, viz. (1) *pressure epiphyses*, appearing at the articular ends of the bones and transmitting 'the weight of the body from bone to bone'; (2) *traction epiphyses*, associated with the insertion of muscles; and (3) *atavistic epiphyses*, representing parts of the skeleton which at one time formed separate bones, but which have lost their function 'and only appear as separate ossifications in early life.'

Applied Anatomy.—It has been stated above that the bones increase firstly *in length* by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process; and secondly *in circumference* by deposition of new bone from the deeper layer of the periosteum, on the external surface. A thorough realisation of these facts is essential to the student, when he comes to consider the various pathological changes which affect bone. Anything which interferes with the growth at the epiphysial line will lead to a diminution in the length which the bone should attain in adult life, and similarly anything which interferes with the growth from the deeper layer of the periosteum will result in a disproportion in the thickness of the bone. Thus separation of the epiphysis, septic or tuberculous disease about the epiphysial line, and excisions involving the epiphysial line, will result in varying amounts of shortening of the bone, as compared with that of the opposite side; whereas separation or imperfect nutrition of the periosteum results in defective growth in circumference.

It is thus obvious that a careful study of osseous development is of the very greatest utility in the proper understanding of bone disease; and, moreover, an accurate knowledge of the blood supply of a long bone has also many important bearings. The outer portion of the compact tissue being supplied by periosteal vessels, which reach the bone through muscular attachments, it follows that where the muscular structures are well developed, and therefore amply supplied with blood, the periosteum will also be well nourished and the bones proportionately well developed in girth; this is well seen in strong muscular men with well-marked ridges on the bones. Conversely, if the muscular development be poor, the bones are correspondingly thin and light, and if from any cause a limb has been paralysed from early childhood, the whole of the bones of that extremity are remarkable for their extreme thinness—that is to say, the periosteal blood supply has been insufficient to nourish that membrane, and consequently very little fresh osseous tissue has been added to the bones from the outside.

The best example of this condition is seen in connection with the disease known as *infantile paralysis*, where a limb becomes paralysed at a very early period of childhood, where the muscles become flaccid and atonic, and where the blood supply is in consequence very greatly diminished. In such cases, although the limb does continue to grow in length from the epiphysial lines, its length is considerably less than on the normal side, owing to the imperfect nutrition; but the most striking feature about all the long bones of the limb is their remarkable tenuity, little or no addition having been made to their circumferences.

In cases where the periosteum has been separated from the compact tissue by extensive injury or inflammatory exudation, necrosis or death of the underlying portion of bone takes place owing to its blood supply having been cut off, and the dead portion or *sequestrum* has to be subsequently separated and cast off.

Cases, however, occur where the inflammatory process affects the whole or a great portion of the diaphysis of a long bone, and here extensive death of the affected portion takes place, and the condition goes by the name of *acute infective periostitis*. Where this occurs the shaft of the bone dies very rapidly, especially if the single nutrient artery be thrombosed at the same time. The pus which has formed beneath the periosteum is set free by timely incision, or bursts on the surface; the periosteum then falls back on the necrosed diaphysis and rapidly forms a layer of new periosteal bone, surrounding the sequestrum. This layer is called the *involucrum*, and the openings in it through which the pus escapes the *cloacæ*. When the inflammatory process affects mainly the medullary canal, the condition is spoken of as *osteo-myelitis*, and the two conditions very frequently co-exist, and then go by the name of *acute infective necrosis of bone* or *acute diaphysitis*. When the medullary cavity is filled with pus, septic thrombosis of the veins in the Haversian canals takes place, and there is a very great danger of septic emboli being displaced and carried into the general circulation, thus setting up a fatal *pyæmia*. In fact, pyæmia is more frequently due to septic bone conditions than to any other cause.

In the pre-antiseptic days, pyæmia frequently resulted from amputations, where the medullary canal of a long bone was opened by the saw cut. Osteo-myelitis ensued,

and if the patient survived, a tubular sequestrum of the divided shaft subsequently separated.

A proper understanding of the epiphyses is of the utmost possible importance to the student, and greatly simplifies many of the problems in the pathology of bone disease.

Speaking generally, the long bones have at either end an epiphysis from the cartilage of which growth occurs, and hence the shaft of the bone increases in length from both ends. In every case, however, one epiphysis is the more active, and also continues in its activity for a longer time. This *actively growing epiphysis* is always the one from which the nutrient foramen in the diaphysis points, and it unites to the shaft at a later date. It follows, therefore, that the increase in length of a long bone is largely dependent on this epiphysis, and hence anything which interferes with the growth from this epiphysial line at any time prior to the union of the epiphysis with the shaft must result in a cessation of growth in length of that bone. Thus when dealing with disease in the neighbourhood of this actively growing epiphysis very great care should be taken not to excise or destroy its line of union with the shaft. These epiphyses are particularly prone to become the seat of tuberculous disease, which especially tends to attack the soft, highly vascular cancellous tissue.

Again, the actively growing epiphysial line is the portion of a long bone which is in the vast majority of cases affected by tumour growth in bone, whether it be innocent or malignant, the former (viz. ostooma) usually appearing about puberty, and the latter (viz. sarcoma) usually towards the end of the active period of epiphysial growth.

Epiphysial growth, moreover, has to be considered by the surgeon when he is about to amputate in a child. If the amputation is being performed through a bone, the actively growing epiphysis of which is at the upper end, and which will continue to grow for many years (i.e. humerus and tibia), it will be necessary to make allowance for this and to cut the flaps long ; as otherwise, owing to continued growth, the sawn end of the bone will ultimately project through the stump, and a condition known as '*conical stump*' will result. This requires removal of a further portion of the bone.

An inflammatory condition termed *acute epiphysitis* also occurs, although it is not so frequent as the acute infective conditions of the diaphysis, owing to the freer blood supply of the epiphysis ; in late years it has been shown that acute epiphysitis in children is very frequently the result of a pneumococcal infection, and it may pass on to complete separation of the epiphysis. In this connection it is worthy of note that some of the epiphysial lines lie entirely within the capsules of their corresponding joints, in other cases entirely without the capsules ; and it must follow that in the former case epiphysial disease, acute or chronic, becomes, *ipso facto*, practically synonymous with disease of that joint. The best examples of intra-articular epiphyses are those for the head of the femur and head of the humerus, and the vast majority of all cases of tuberculous disease of the hip start as a tuberculous epiphysitis about the intra-articular epiphysial line of the femur ; again cases of acute septic arthritis of the shoulder or hip joints generally have their origins in these intra-articular epiphysial lines, and often result in separation of the affected epiphysis. The other class, or extra-articular epiphyses, when diseased, do not tend to involve the neighbouring joint so readily ; and it should be the surgeon's duty to keep the disease from involving the joint. For example, the trochanteric epiphysis of the femur is extra-articular as regards the hip joint, and the epiphysial line of the head of the tibia is well below the level of the knee joint, and should a chronic tuberculous abscess form in the latter situation, it should be attacked from the outside before it has time to spread up and involve the cartilage of the head of the tibia. It is therefore of great surgical interest to note in every case the relations which the various epiphysial lines bear to their respective joint capsules.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable ; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the shaft, and such injuries may be mistaken for fracture or dislocation.

PIGMENT

In various parts of the body **pigment** is found ; most frequently in epithelial cells and in the cells of connective tissue. Pigmented *epithelial cells* are found in the external layer of the retina, on the posterior surface of the iris, in the olfactory region of the nose, and in the membranous labyrinth of the ear. Pigment is likewise found in the cells of the deeper layers of the cuticle and in the hairs ; in the skin of the coloured races it is abundantly present, but in the white races it is well marked only in the areolæ round the nipples and in irregular coloured patches.

In the *connective-tissue cells* pigment is frequently met with in the lower vertebrates. In man it is found in the choroid coat of the eye (fig. 43), and

in the iris of all but the light blue eyes and the albino. It is also occasionally met with in the cells of retiform tissue and in the pia mater of the upper part of the spinal cord. The cells are characterised by their large size and by branched processes, which are also filled with granules. The processes of the cells can be withdrawn or protruded under the influence of light. In the retina the cells themselves are also capable of movement in order to protect the delicate rods and cones. The pigment (*melanin*) consists of dark brown or black granules of very small size closely packed together within the cells, but not invading the nucleus. Occasionally the pigment is yellow, and when occurring in the cells of the cuticle constitutes 'freckles.' In the retina another variety of pigment occurs, known as *rhodopsin* or *visual purple*, which on exposure to light is bleached.

FIG. 43.—Pigment-cells from the choroid coat of the eyeball.

Applied Anatomy.—Abnormal pigmentation of the skin may be congenital, when it often takes the form of dark brown or black nævi (moles), scattered over a greater or smaller area of the body. It may also result from the prolonged consumption of various drugs, particularly of salts of silver or arsenic, being most marked wherever the skin is exposed to the action of light. Progressive darkening or bronzing of the skin is also highly suggestive of Addison's disease, which commonly follows destruction or tuberculosis of the suprarenal glands: it is then most obvious in regions where the skin is normally pigmented, or is subjected to pressure or irritation from the clothes. Pigmentation is also associated with certain disorders of the skin, the female genitalia, and the thyroid gland, and with the later stages of wasting diseases such as cancer and phthisis. It does not yield to any medical treatment as a rule.

MUSCULAR TISSUE

The **muscles** are formed of bundles of reddish fibres, endowed with the property of contractility. There are two principal kinds of muscular tissue. One of these, from the characteristic appearances which its fibres exhibit under the microscope, is known as 'striped' muscle, and, from the fact that it is capable of being put into action and controlled by the will, as 'voluntary' muscle. The fibres of the other kind do not present any cross-striped appearance, and for the most part are not under the control of the will; hence they are known as the 'unstriped' or 'involuntary' muscles. The muscular fibres of the heart differ in certain particulars from both these groups, and they are therefore separately described as 'cardiac' muscular fibres.

It is customary therefore to define three varieties of muscular fibres: (1) transversely striated muscular fibres, which are for the most part under the control of the will, although some are not so, such as the muscles of the pharynx and upper part of the œsophagus. This variety of muscle is sometimes called *skeletal*; (2) transversely striated cardiac muscular fibres, which are not under the control of the will; (3) plain or unstriped muscular fibres, which are involuntary and controlled by a different part of the nervous system from that which controls the activity of the voluntary muscles. Such are the muscular walls of the stomach and intestine, of the uterus and bladder, of the blood-vessels, &c.

Striped or **voluntary muscle** is composed of bundles of fibres each enclosed in a delicate web called the *perimysium* in contradistinction to the sheath of areolar tissue which invests the entire muscle, the *epimysium* (fig. 44). The bundles are termed *fasciculi*; they are prismatic in shape, of different sizes in different muscles, and are for the most part placed parallel to one another, though they have a tendency to converge towards their tendinous attachments. Each fasciculus is made up of a strand of *fibres*, which also run parallel with each other, and which are separated from one another by a delicate connective tissue derived

from the perimysium and termed *endomysium*. This does not form the sheath of the fibres, but serves to support the blood-vessels and nerves ramifying between them. The fibres are enclosed in separate and distinct sheaths of their own, but these are not areolar tissue, and therefore not derived from the perimysium.

A *muscular fibre* may be said to consist of a soft contractile substance, enclosed in a tubular sheath named by Bowman the *sarcolemma*. The fibres are cylindrical or prismatic in shape, and are of no great length, not exceeding, it is said, an inch and a half. They end either by blending with the tendon or aponeurosis, or else by rounded or tapering extremities which are connected to the neighbouring fibres by means of the sarcolemma. Their breadth varies in man from $\frac{1}{500}$ to $\frac{1}{600}$ of an inch. As a rule, the fibres do not divide or anastomose, but occasionally, especially in the tongue and facial muscles, they may be seen to divide into several branches. The precise mode in which the muscular fibre joins the tendon has been variously described by different observers. It may, perhaps, be sufficient to say that the sarcolemma appears to blend with a small bundle of fibres, into which the tendon becomes subdivided, while the muscular substance terminates abruptly and can be readily made to retract from the point of junction. The areolar tissue between the fibres appears to be prolonged more or less into the tendon, so as to form a kind of sheath around the tendon bundles for a longer or shorter distance. When muscular fibres are attached to skin or

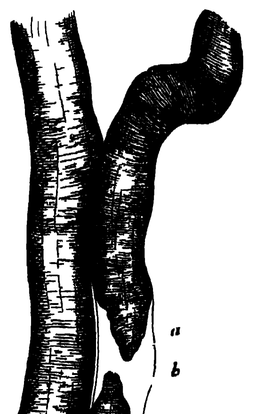
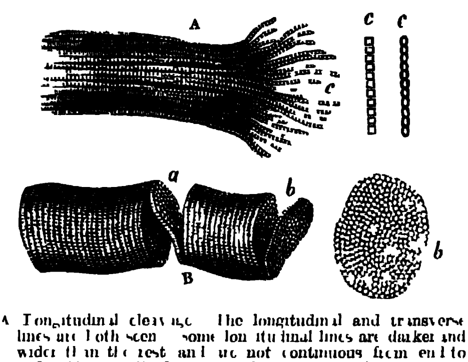
a Epimysium. *b* Fasciculus. *c* Perimysium. *d* Fibre.

FIG. 45. — Two human muscular fibres. Magnified 350 times.



In the one the bundle of fibrillæ (*a*) is torn and the sarcolemma (*b*) is seen as an empty tube.

FIG. 46. — Fragments of striped muscular fibres, showing a double cleavage. Magnified 300 diameters.



A. Longitudinal cleavage. The longitudinal and transverse lines are both seen; some longitudinal lines are darker and wider than the rest, and are not continuous from end to end. This results from partial separation of the fibrillæ. *c*. Fibrillæ separated from one another by violence at the broken end of the fibre, and marked by transverse lines equal in width to those on the fibre. *c′ c″* represent two appearances commonly presented by the separated single fibrillæ (more highly magnified). At *c′* the borders and transverse lines are all perfectly rectilinear, and the included spaces perfectly rectangular. At *c″* the borders are scalloped and the spaces bead-like. When most distinct and definite the fibrilla presents the former of these appearances.

B. Transverse cleavage. The longitudinal lines are scarcely visible. *a*. Incomplete fracture following the opposite surfaces of a disc which stretches across the interval and retains the two fragments in connection. The edge and surfaces of this disc are seen to be minutely granular, the granules corresponding in size to the thickness of the disc and to the distance between the faint longitudinal lines. *b*. Another disc nearly detached. *b′*. Detached disc more highly magnified, showing the sarcous elements.

mucous membranes, their fibres are described by Hyde Salter as becoming continuous with those of the areolar tissue.

The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it sometimes

remains entire when the included substance is ruptured (fig. 45). On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in the lower animals, elongated nuclei are seen, and in connection with these a row of granules, apparently fatty, is sometimes observed.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be marked by alternate light and dark bands or striæ, which pass transversely, or somewhat obliquely, round the fibre (fig. 47). The dark and light bands are of nearly equal breadth, and alternate with great regularity. They vary in breadth from about $\frac{1}{1200}$ to $\frac{1}{1700}$ of an inch. If the surface be carefully focussed, rows of granules will be detected at the points of junction of the dark and light bands, and very fine longitudinal lines may be seen running through the dark bands and joining these granules together. By treating the specimen with certain reagents (e.g. chloride of gold) fine lines may be seen running transversely between the granules uniting them together. This appearance is believed to be due to a reticulum or network of interstitial substance lying between the contractile portions of the muscle. The longitudinal striation gives the fibre the appearance of being

made up of a bundle of fibrils, which have been termed *sarcostyles* or *muscle columns*, and if the fibre be hardened in alcohol, it can be broken up longitudinally and the sarcostyles separated from each other (fig. 46, A). The reticulum, with its longitudinal and transverse meshes, is called *sarcoplasm.*

If now a transverse section be made, the muscular fibre is seen to be divided into a number of areas, called the *areas of Cohnheim*, more or less polyhedral in shape and consisting of the transversely divided sarcostyles, surrounded by transparent series of sarcoplasm (fig. 46, B, b').

Upon closer examination, and by somewhat altering the focus, the appearances become more complicated, and are susceptible of various interpretations. The transverse striation, which in figs. 45 and 46 appears as a mere alternation of dark and light bands, is resolved into the appearance seen in fig. 47, which shows a series of broad dark bands, separated by light bands, each of which is divided into two by a dark dotted line. This line is termed *Dobie's line* or *Krause's membrane* (fig. 49, *k*), because it was believed by Krause to be an actual membrane, continuous with the sarcolemma, and dividing the light band into two compartments. It is now more usually regarded as being due to the light being

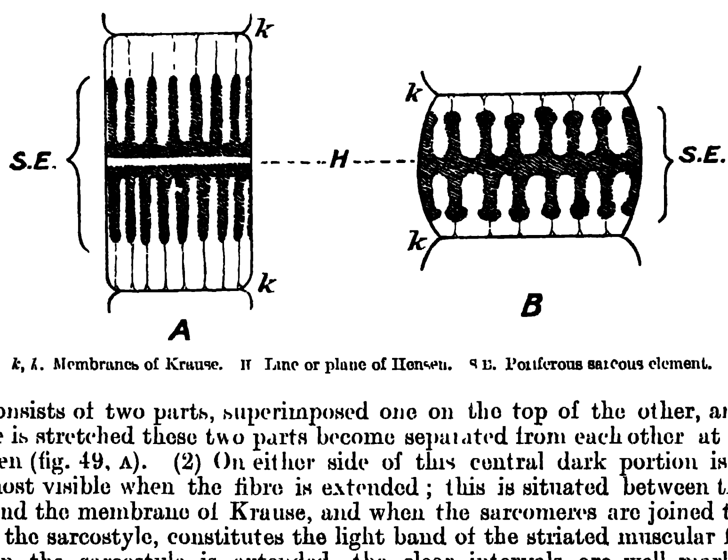
refracted between discs of different refrangibility. In addition to the membrane of Krause, fine clear lines may be made out, with a sufficiently high power, crossing the centre of the dark band; these are known as the *lines of Hensen* (fig. 49, H).

Formerly it was supposed by Bowman that a muscular fibre was made up of a number of quadrangular particles, which he named sarcous elements, joined together like so many bricks forming a column, and he came to this conclusion because he found that under the influence of certain reagents the fibre could be broken up transversely into discs, as well as longitudinally into fibrillæ (fig. 46, B). But it is now believed that this cross-cleavage is purely artificial, and that a muscular fibre is built up of fibrillæ and not of small quadrangular particles.

Assuming that this is so, the minute structure of these longitudinal fibrillæ, or sarcostyles, may now be considered. Perhaps there are few subjects in histology which have received more attention, and in which the appearances seen under the microscope have been more differently interpreted, than the minute anatomy of muscular fibre. Schäfer has worked out this subject, particularly in the wing muscles of insects, which are peculiarly adapted for this purpose on account of the large amount of interstitial sarcoplasm which separates the sarcostyles. In the following description that given by Schäfer will be closely followed (fig. 49).

A sarcostyle may be said to be made up of successive portions, each of which is termed a *sarcomere*. The sarcomere is situated between two membranes of Krause, and consists of (1) a central dark part, which forms a portion of the dark band of the whole fibre, and is named a *sarcous element*.* This sarcous element

FIG. 49.—Diagram of a sarcomere. (After Schäfer.)
A. In moderately extended condition. B. In a contracted condition.



k, *k*. Membranes of Krause. H Line or plane of Hensen. S E. Poriferous sarcous element.

really consists of two parts, superimposed one on the top of the other, and when the fibre is stretched these two parts become separated from each other at the line of Hensen (fig. 49, A). (2) On either side of this central dark portion is a clear layer, most visible when the fibre is extended; this is situated between the dark centre and the membrane of Krause, and when the sarcomeres are joined together to form the sarcostyle, constitutes the light band of the striated muscular fibre.

When the sarcostyle is extended, the clear intervals are well marked and plainly to be seen; when, on the other hand, the sarcostyle is contracted, that is to say, the muscle is in a state of contraction, these clear portions are very small or they may have disappeared altogether (fig. 49, B). When the sarcostyle is stretched to its full extent, not only is the clear portion well marked, but the dark portion—the sarcous element—is separated into its two constituents along the line of Hensen.

The sarcous element does not lie free in the sarcomere, for when the sarcostyle is stretched, so as to render the clear portion visible, very fine lines, which are probably septa, may be seen running through it from the sarcous element to the membrane of Krause.

Schäfer explains these phenomena in the following way. He considers that each sarcous element is made up of a number of longitudinal channels, which open into the clear part towards the membrane of Krause but are closed at the line of Hensen. When the muscular fibre is contracted the *clear* part of the muscular

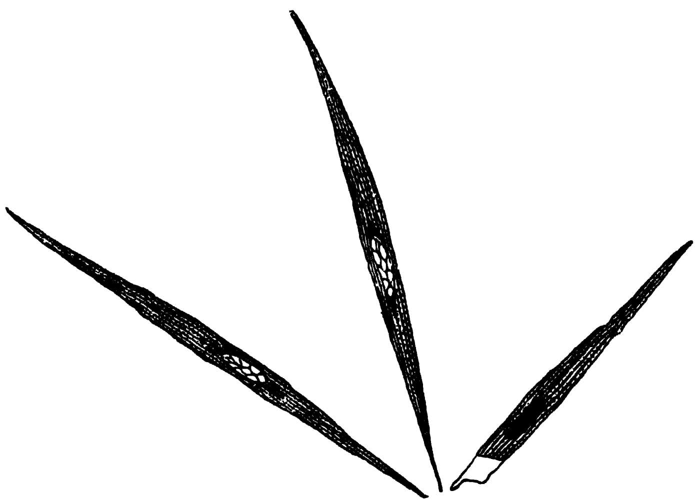
* This must not be confused with the 'sarcous element of Bowman' (see above).

substance is driven into these channels or tubes, and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere. When, on the other hand, the fibre is extended, this clear substance is driven out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

If this view be true, it is a matter of great interest, and, as Schäfer has shown, harmonises the contraction of muscle with the amœboid action of protoplasm. In an amœboid cell there is a framework of spongioplasm, which stains with hæmatoxylin and similar reagents, enclosing in its meshes a clear substance, hyaloplasm, which will not stain with these reagents. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out as in the formation of pseudopodia. In muscle there is the same thing, viz. a framework of spongioplasm staining with hæmatoxylin—the substance of the sarcous element—and this encloses a clear hyaloplasm, the clear substance of the sarcomere, which resists staining with this reagent. During contraction of the muscle—i.e. stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—i.e. when there is no stimulation—it tends to pass out of the spongioplasm.

In this way the contraction is brought about: under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous

FIG. 50.—Non-striated muscular fibre. (From Kirke's 'Physiology.')



element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. The larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi.

Nerves are profusely distributed to striped muscle. Their mode of termination is described on page 53.

The existence of *lymphatic vessels* in striped muscle has not been ascertained, though they have been found in tendons and in the sheaths of the muscles.

Unstriped, plain, or involuntary muscle is found in the following situations—viz. the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi, and the alveoli and infundibula of the lungs; in the gall-bladder and common bile duct; in the large ducts of the salivary and pancreatic glands; in the pelvis and calyces of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz. the ovary, the Fallopian tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the erectile tissue of the clitoris;

in the male sexual organs—viz. the dartos of the scrotum, the vas deferens and epididymis, the vesiculæ seminales, the prostate gland, and the corpora cavernosa and corpus spongiosum; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the arrectores pilorum, and also in the sweat-glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

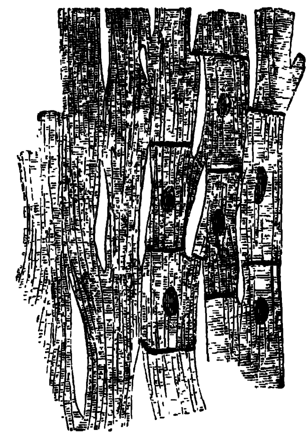


FIG. 51.—*Anastomosing muscular fibres of the heart seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically.*

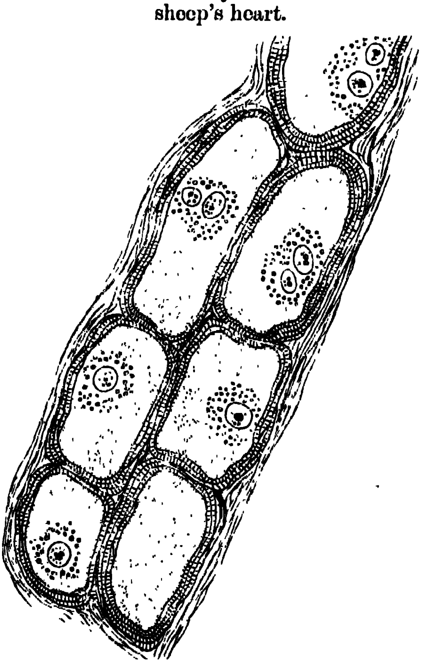
Plain or unstriped muscle is made up of spindle-shaped cells, called *contractile fibre-cells*, collected into bundles and held together by a cement substance (fig. 50). These bundles are further aggregated into larger fasciculi, or flattened bands, and bound together by ordinary connective tissue.

The *contractile fibre-cells* are elongated, spindle-shaped, nucleated cells of various sizes, averaging from $\frac{1}{600}$ to $\frac{1}{300}$ of an inch in length, and $\frac{1}{4500}$ to $\frac{1}{3500}$ of an inch in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure. Each presents a faint longitudinal striation and consists of an elastic cell-wall containing a central bundle of fibrillæ, representing the contractile substance, and an oval or rod-like nucleus, which includes, within a membrane, a fine network communicating at the poles of the nucleus with the contractile fibres (Klein). The adhesive interstitial cement substance, which connects the fibre-cells together, represents the endomysium of striped muscular tissue, while the tissue connecting the individual bundles together represents the perimysium. Unstriped muscle, except the ciliary muscle, is not under the control of the will, neither is the contraction rapid nor does it, as a rule, involve the whole muscle, as is the case with the voluntary muscles. The membranes which are composed of unstriped muscle slowly contract in a part of their extent, generally under the influence of a mechanical stimulus, as that of distension or of cold; and then the contracted part slowly relaxes while another portion of the membrane takes up the contraction. This peculiarity of action is most strongly marked in the intestines, constituting their *vermicular motion.*

FIG. 52.—Purkinje fibres from the sheep's heart.



Cardiac muscular tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are smaller by one-third, and their transverse striæ are by no means so well marked. The fibres are made up of distinct quadrangular cells joined end to end* (fig. 51). Each cell contains a clear oval nucleus, situated near the centre of the cell. The extremities of the cells have a tendency to branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres. The connective tissue between

* The junctions between the cells are only occasionally seen, and some histologists maintain that they are only artefacts.

the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

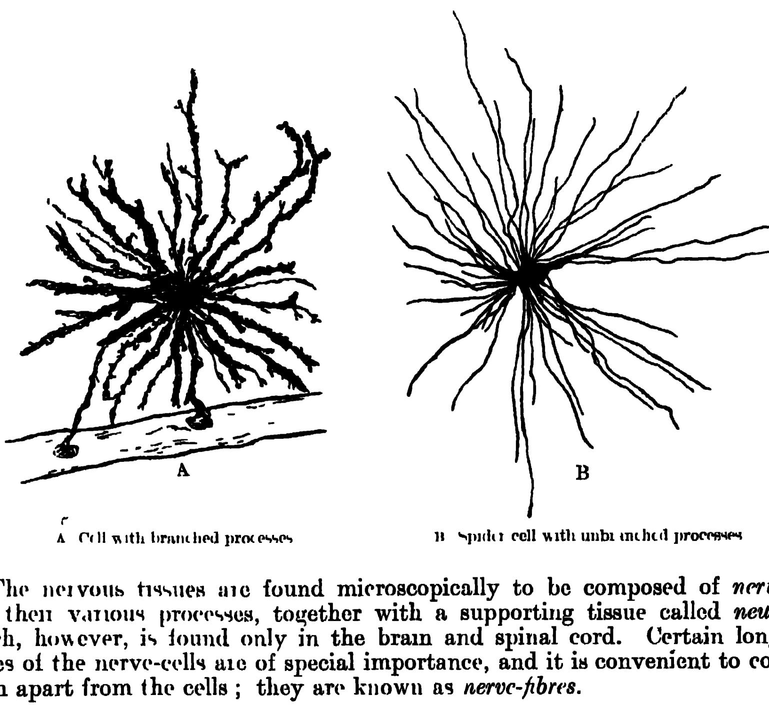
Purkinje fibres (fig. 52).—Between the endocardium and the ordinary cardiac muscle are found, embedded in a small amount of connective tissue, peculiar fibres known as *Purkinje fibres*. They are found in certain mammals and in birds, and can be best seen in the sheep's heart, where they form a considerable portion of the moderator band and also appear as gelatinous-looking strands on the inner walls of the auricles and ventricles. Recently it has been shown that they also occur in the human heart (bundle of His). The fibres are very much larger in size than the cardiac cells and differ from them in several ways. In longitudinal section they are quadrilateral in shape, being about twice as long as they are broad. The central portion of each fibre contains one or more nuclei and is made up of granular protoplasm, with no indication of striations, while the peripheral portion is clear and has distinct transverse striations. The fibres are intimately connected with each other, possess no definite sarcolemma, and do not branch.*

Development of muscle fibres.—Voluntary muscular fibres are developed from the mesoderm, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibres, spreads around the circumference, and ultimately extends to the centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of involuntary muscle the mesodermal cell assumes a pointed shape at the extremities and becomes flattened, the nucleus also lengthening out to its permanent rod like form.

NERVOUS TISSUE

The **nervous tissues** of the body comprise the brain (including the medulla oblongata), the spinal cord, the cranial, spinal, and sympathetic nerves, and the ganglia connected with them.

FIG. 53.—Neuroglia cells of brain shown by Golgi's method. (After Andriezen.) (Copied from Schafer's 'Essentials of Histology.')



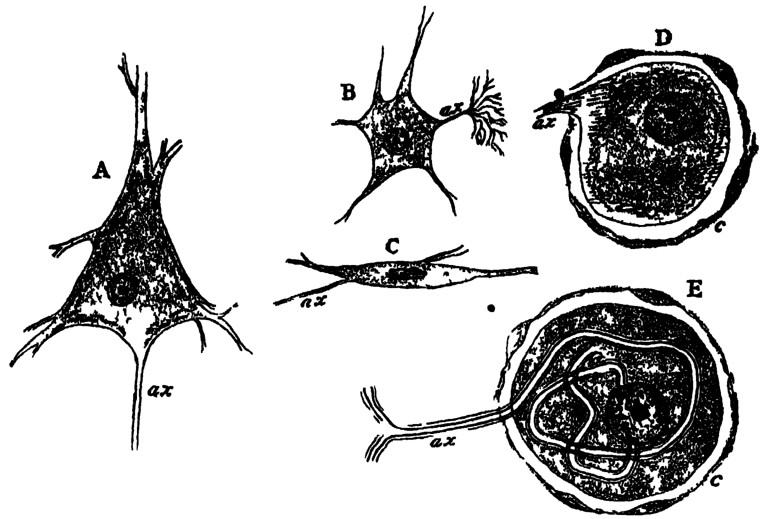
A Cell with branched processes B Spider cell with unbranched processes

The nervous tissues are found microscopically to be composed of *nerve-cells* and their various processes, together with a supporting tissue called *neuroglia*, which, however, is found only in the brain and spinal cord. Certain long processes of the nerve-cells are of special importance, and it is convenient to consider them apart from the cells; they are known as *nerve-fibres*.

* In the human heart the primitive muscle tissue is composed of many types of fibres (Gibson. *British Medical Journal*, January 1909)

To the naked eye a difference is obvious between certain portions of the brain and spinal cord, viz. the *grey matter* and the *white matter*. The grey matter is

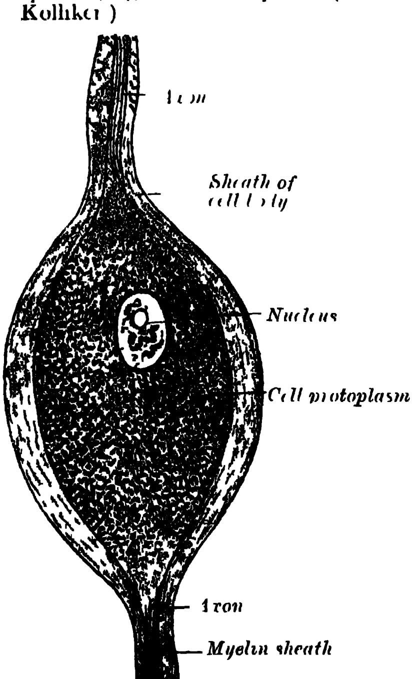
FIG. 54.—Various forms of nerve-cells.



A, Pyramidal cell. B, Small multipolar cell in which the axon quickly divides into numerous branches. C, Small fusiform cell. D and E, Ganglion cells (E shows T-shaped division of axon). *ax*, Axon. *c*, Capsule.

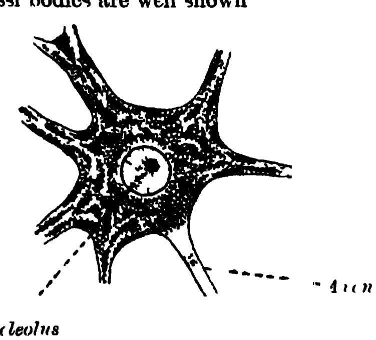
largely composed of nerve-cells while the white matter contains only their long processes, the nerve fibres. It is in the former that nervous impressions and impulses originate, and by the latter that they are conducted. Hence the grey matter forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the brain and spinal cord; while the white matter is found in the commissural portions of the nerve-centres and in the peripheral nerves.

FIG. 55.—Bipolar nerve-cell from the spinal ganglion of the pike. (After Kolliker.)



Neuroglia, the peculiar ground substance in which are embedded the true nervous constituents of the brain

FIG. 56.—Motor nerve-cell from ventral horn of spinal cord of rabbit. (After Nissl.) The angular and spindle-shaped Nissl bodies are well shown.



and spinal cord, consists of fibres and cells. Some of the cells are stellate in shape, and their fine processes become neuroglia-fibres, which extend radially and

unbranched (fig. 53, B) among the nerve cells and fibres which they aid in supporting. Other cells give off fibres which branch repeatedly (fig. 53, A). Some of the fibres start from the epithelial cells lining the ventricles of the brain and central canal of the spinal cord, and pass through the nervous tissue, branching repeatedly to terminate in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function but is not so in development; it is ectodermal in origin, whereas all connective tissues are mesodermal.

Nerve-cells are largely aggregated in the grey substance of the brain and spinal cord, but smaller collections of these cells also form the swellings, called ganglia, seen on many nerves. These latter are found chiefly upon the spinal and cranial nerve-roots and in connection with the sympathetic nerves.

The nerve-cells vary in shape and size, and have one or more processes. They may be divided for purposes of description into three groups, according to the number of processes which they possess: (1) Unipolar cells, which are found in the spinal ganglia; the single process, after a short course, divides in a T-shaped manner. (2) Bipolar cells, also found in the spinal ganglia (fig. 55), when the cells are in an embryonic condition. They are best demonstrated in the sympathetic ganglion-cells of a frog. Sometimes the processes come off from opposite poles of the cell, and the cell then assumes a spindle shape; in other cells they both emerge at the same point. In some cases where two fibres are apparently connected with a cell, one of the fibres is really derived from an adjoining nerve-cell and is passing to end in a ramification around the ganglion-cell, or, again, it may be coiled spirally round the nerve process which is issuing from the cell. (3) Multipolar cells, which are caudate or stellate in shape, and characterised by their large size and by the tail-like processes which issue from them. The processes are of two kinds: one of them is termed the *axis-cylinder process* or *axon* because it becomes

FIG. 57.—Pyramidal cell from the cerebral cortex of a mouse. (After Ramon y Cajal.)

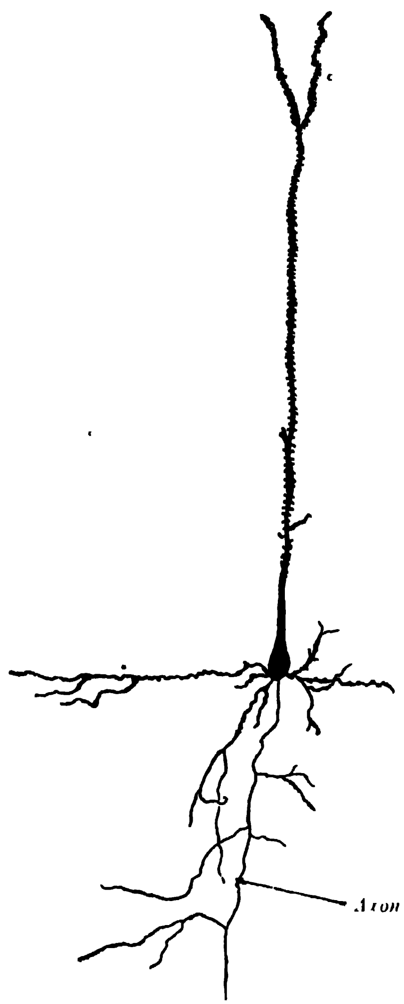


FIG. 58.—Cell of Purkinje from the cerebellum of a cat. (After Ramon y Cajal.)

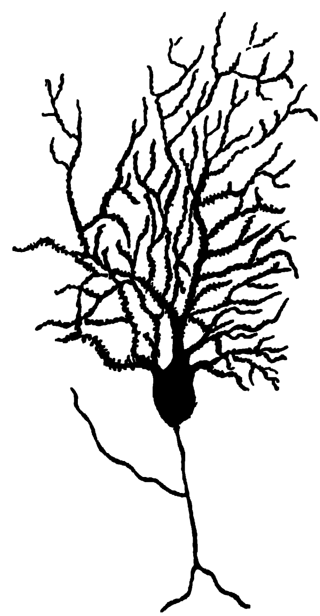


the axis-cylinder of a nerve-fibre (figs. 56, 57, 58). The others are termed the *protoplasmic processes* or *dendrons*; they begin to divide and subdivide as soon as they emerge from the cell, and finally end in minute twigs and become lost among the other elements of the nervous tissue.

Each nerve-cell consists of a finely fibrillated protoplasmic material, of a reddish or yellowish-brown colour, which occasionally presents patches of a deeper tint, caused by the aggregation of pigment-granules at one side of the nucleus, as in the substantia nigra and locus cœruleus of the brain. The protoplasm also contains peculiar angular granules, which stain deeply with basic dyes, such as methylene blue; these are known as *Nissl's granules* (fig. 56). They extend into the dendritic processes but not into the axis cylinder; the small clear area at the point of exit of the axon is termed the *cone of origin*. These granules disappear (*chromatolysis*) during fatigue or after prolonged stimulation of the nerve-fibres connected with the cells. They are supposed to represent a store of nervous energy, and in various mental diseases are deficient or absent. The nucleus is, as a rule, a large, well-defined, round, vesicular body, often presenting an intra-nuclear network, and containing a nucleolus which is peculiarly clear and brilliant.

Nerve-fibres are found universally in the peripheral nerves, and in the white substance of the brain and spinal cord. They are of two kinds—viz *medullated* or *white* fibres, and *non-medullated* or *grey* fibres.

FIG. 59.—Medullated nerve-fibres stained with silver nitrate.

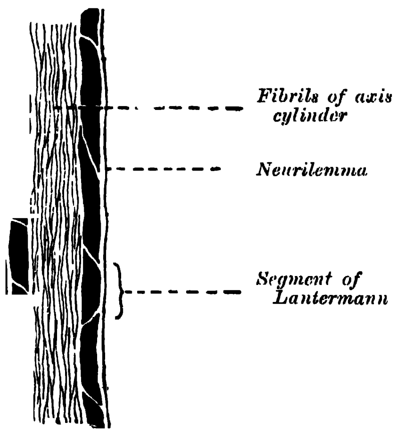
The *medullated fibres* form the white part of the brain and spinal cord, and also the greater part of every cerebro-spinal nerve, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body each fibre presents, when examined by transmitted light, a double outline or contour, as if consisting of two parts (fig. 59). The central portion is named the *axis cylinder of Purkinje*; around this is a sheath of fatty material, staining black with osmic acid, named the *white substance of Schwann* or *medullary sheath*, which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the *neurilemma*, *primitive sheath*, or *nucleated sheath of Schwann* (fig. 52).

The *axis cylinder* is the essential part of the nerve-fibre, and is always present; the medullary sheath and the neurilemma are occasionally absent, especially at the origin and termination of the nerve-fibre. It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-fibre, being greater in proportion in the fibres of the central organs than in those of the nerves. It is quite transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils, which stain darkly with gold chloride (fig. 60), and at its termination may be seen to break up into these fibrillæ. The fibrillæ have

been termed the *primitive fibrillæ* of Schultze. The axis cylinder is said by some to be enveloped in a special, reticular sheath, which separates it from the medullary sheath, and is composed of a substance called *neurokeratin.* The more common opinion is that this network or reticulum is contained in the white matter of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it.

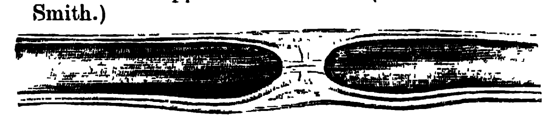
The *medullary sheath* or *white matter of Schwann* (fig. 60) is regarded as being a fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis cylinder. It varies in thickness, in some forming a layer of extreme thinness, so as to be scarcely distinguishable, in others forming about one-half the nerve-fibre. The variation in diameter of the nerve-fibres (from $\frac{1}{12000}$ to $\frac{1}{2000}$ of an inch) depends mainly upon the amount of the white substance, though the axis cylinder also varies within certain limits. The medullary sheath does not always form a continuous sheath to the axis cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These were first described by Ranvier, and are known as the *nodes of Ranvier* (fig. 61). The portion of nerve-fibre between two nodes is called an *internodal segment.* The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. In addition to these interruptions oblique clefts may be seen in the medullary sheath, subdividing it into irregular portions, which are termed *medullary segments*, or *segments of Lantermann* (fig. 60). There is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined, frequently present a beaded or varicose appearance: this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is also promoted by the action of certain reagents.

FIG. 60.—Longitudinal section through a nerve-fibre from the sciatic nerve of a frog. × 830. (After Böhm and Davidoff.)



The *neurilemma* or *primitive sheath* presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each internode. The primitive sheath is not present in all medullated nerve-fibres, being absent in those fibres which are found in the brain and spinal cord.

FIG. 61.—A node of Ranvier of a medullated nerve-fibre, viewed from above, magnified about 750 diameters. The medullary sheath is discontinuous at the node, whereas the axis cylinder passes from one segment into the other. At the node the neurilemma appears thickened. (Klein and Noble Smith.)



Wallerian Degeneration.—When nerve-fibres are cut across, the central ends of the fibres degenerate as far as the first node of Ranvier; but the peripheral ends degenerate simultaneously throughout their whole lengths. The axons break up into fragments and become surrounded by drops of myelin which are formed from the breaking down of the medullary sheath. The nuclei of the primitive sheath proliferate, and finally absorption of the axons and myelin takes place. If the cut ends of the nerve be sutured together regeneration of the nerve-fibres takes place by the downgrowths of axons from the central end of the nerve. At one time it was believed that the regeneration was peripheral in

origin, but this has been experimentally proved by Halliburton and Mott not to be the case, the proliferated nuclei in the peripheral portions taking part merely in the formation of the so-called scaffolding along which the new axons pass.

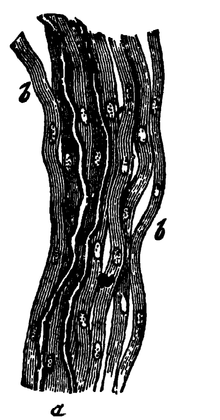
Non-medullated fibres.—Most of the fibres of the sympathetic system, and some of the cerebro-spinal, consist of the *grey* or *gelatinous* nerve-fibres—*fibres of Remak* (fig. 62). Each of these consists of a central core or axis cylinder enclosed in a nucleated sheath which tends to split into fibrillæ, and is probably of the nature of neurokeratin. In external appearance the non-medullated nerve-fibres are semi-transparent and grey or yellowish-grey. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

Development of nerve cells and fibres.—The nerve-cells are developed from certain of the cells which line the neural canal or form the neural crest of the embryo (see section on Embryology). Some of these cells assume a rounded form and are termed *neuroblasts*, and from each neuroblast there grows out a process, the axis-cylinder process or axon, and subsequently the branching processes or dendrons. The axis cylinders, at first naked, acquire their medullary sheaths, possibly by some metamorphosis of their outer layers. The neurilemma is thought to be derived from mesodermal cells which become flattened and wrapped round the fibre, the cement substance at their apposed ends forming the material which stains with silver nitrate at the nodes of Ranvier. Nerve-cells in the sympathetic and peripheral ganglia take their origin from small collections of neuroblasts, which are split off from the rudimentary spinal ganglia. Cells which are, originally, similar to neuroblasts seem to give rise to neuroglia cells, numerous processes sprouting from the cell to form the neuroglial fibres.

The nervous structures are divided into two great systems — viz. the *central*, comprising the brain and spinal cord; and the *peripheral*, consisting of the nerves connected with them. All these structures require separate consideration; they are composed of the two kinds of nervous tissue above described, intermingled in various proportions, and having, in some parts, a very intricate arrangement.

The **brain** and **spinal cord** form the central system. In the **brain** the grey nervous matter is found on the surface, forming the convolutions of the cerebrum, and the laminæ of the cerebellum; in the interior it is collected into large and distinct masses or ganglionic bodies, such as the corpus striatum, thalamus, and corpora quadrigemina; or is intermingled intimately with the white as in the pons Varolii and the floor of the fourth ventricle.

FIG. 62.—A small nervous branch from the sympathetic of a mammal.



a. Two medullated nerve-fibres among a number of grey nerve-fibres, *b*.

In the **spinal cord** the grey matter is accumulated in the centre and the white matter on the periphery. The special arrangement and distribution of the grey and white matter in the central nervous system are described with the anatomy of the nervous system.

The **nerves** are round or flattened cords, formed of the nerve-fibres already described. They are connected at one end with the central nervous system or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the *cerebro-spinal* nerves, which proceed directly from the brain and spinal cord, and the *sympathetic* nerves, which proceed from the ganglia of the sympathetic.

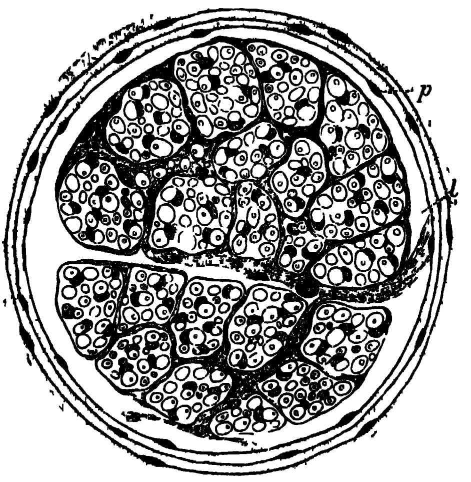
The **cerebro-spinal nerves** consist of numerous nerve-fibres collected together and enclosed in membranous sheaths (fig. 63). A small bundle of fibres, enclosed in a tubular sheath, is called a *funiculus*; if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or *fasciculi*, which are bound together in a common membranous investment.

In structure, the common membranous investment, or sheath of the whole nerve (*epineurium*), as well as the septa given off from it, to separate the fasciculi,

consist of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi (*perineurium*) is a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it is made up of connective tissue, which has a distinctly lamellar arrangement. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue, called the *endoneurium*. It is continuous with septa which pass inwards from the innermost layer of the perineurium, and shows a ground substance in which are imbedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebro-spinal nerves consist almost exclusively of the medullated nerve-fibres, only a very small proportion of the non-medullated being present.

The blood-vessels supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium, and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres, *vaso-motor fibres*, accompany these capillary vessels, and break up into elementary fibrils, which form a network around the vessels. Horsley has demonstrated certain medullated fibres running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Marshall believes to be sensory, and which he has termed *nervi nervorum*, are considered by him to have an important bearing upon certain neuralgic pains.

Fig. 63.—Transverse section through a microscopic nerve, representing a compound nerve-bundle, surrounded by perineurium. Magnified 120 diameters.
The medullated fibres are seen as circles with a central dot, viz. medullary sheath and axis-cylinder, in transverse section. They are imbedded in endoneurium, containing numerous nuclei, which belong to the connective-tissue cells of the latter. (Klein and Noble Smith.)



p. Perineurium, consisting of laminæ of fibrous connective tissue, alternating with flattened nucleated connective tissue cells. *l*. Lymph space between perineurium and surface of nerve bundle.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that these do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the individual nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to intermingle with the nerve-fibres in some adjoining funiculus.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighbouring nerve. The communications which thus take place form what is called a *plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from all the primary nervous trunks which form the plexus. In the formation also of smaller plexuses at the periphery of the

body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual fibres remain separate and distinct.

It is probable that through this interchange of fibres, every branch passing off from a plexus has a more extensive connection with the spinal cord than if it had proceeded to its distribution without forming connections with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic nerves** are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected in funiculi and enclosed in sheaths of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres, and the amount varies in different nerves, and may be known by their colour. Those branches of the sympathetic which present a well-marked grey colour are composed chiefly of non-medullated nerve-fibres, intermixed with a few medullated fibres; while those of a white colour contain many of the latter fibres, and few of the former.

The cerebro-spinal and sympathetic nerve-fibres convey various impressions. The *sensory* nerves, called also *centripetal* or *afferent* nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The *centrifugal* or *efferent* nerves transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origins and terminations of nerves.—By the expression 'the terminations of nerve-fibres' is signified their connections with the nerve-centres, and with the parts they supply. The former are sometimes called their *origins*, or *central terminations*; the latter their *peripheral* terminations.

Origins of nerves.—The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different: as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor, and the posterior sensory. The point where the nerve root or roots emerge from the surface of the nervous centre is named the *superficial* or *apparent* origin, but the fibres of the nerve can be traced for a certain distance into the substance of the nervous centre to some portion of the grey matter, which constitutes the *deep* or *real* origin of the nerve. The centrifugal or efferent nerve-fibres originate in the nerve-cells of the grey substance, the axis cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres grow inwards either from nerve-cells in the organs of special sense (e.g. the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre they branch and send their ultimate twigs among the cells, without, however, uniting with them

Peripheral terminations of nerves.—Nerve-fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor nerves respectively.

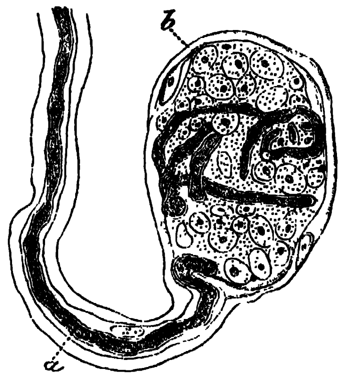
Sensory nerves would appear to terminate either in *minute primitive fibrillæ* or networks of these; or else in special terminal organs, which have been named *peripheral end-organs*, and of which there are several principal varieties, viz. the end-bulbs of Krause, the tactile corpuscles of Wagner, the Pacinian corpuscles, and the neuro-tendinous and neuro-muscular spindles.

Termination in fibrillæ.—When a medullated nerve-fibre approaches its termination the white matter of Schwann suddenly disappears, leaving only the axis cylinder surrounded by the neurilemma. After a time the fibre loses its neurilemma, and consists only of an axis cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis cylinder breaks up into its constituent primitive nerve-fibrillæ, which often present regular varicosities and anastomose with one another, thus forming a network. This network is always distributed to epithelial tissue, the nerve-fibrils lying in the interstitial substance between the epithelial cells, and there terminating, though some observers maintain that the actual terminations are

within the cells. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

The end-bulbs of Krause (fig. 64) are minute cylindrical or oval bodies, consisting of a capsule formed by the expansion of the connective tissue sheath of a medullated fibre, and containing a soft semi-fluid core in which the axis cylinder terminates either as a bulbous extremity, or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye, where they are spheroidal in shape in man, but cylindrical in most other animals, in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the genital organs of both sexes, the penis in the male and the clitoris in the female; in these situations they have a mulberry-like appearance, from being constricted by connective tissue septa into from two to six knob-like masses, and have received the name of *genital corpuscles*. Very similar corpuscles are found in the epineurium of nerve-trunks. In the synovial membranes of certain joints (e.g. those of the fingers), rounded or oval end-bulbs have been found; these are designated *articular end-bulbs*.

FIG. 64.—End-bulb of Krause.



a. Medullated nerve-fibre. b. Capsule of corpuscle. (From Klein's 'Elements of Histology.')

Tactile corpuscles have been described by Grandry as occurring in the papillæ of the beak and tongue of birds, and by Merkel as occurring in the papillæ and epithelium of the skin of man and animals, especially in those parts of the skin devoid of hair. Each consists of a capsule composed of a very delicate, nucleated membrane, and contains two or more granular, somewhat flattened cells; between these cells the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to end.

The *tactile corpuscles* (fig. 65), described by Wagner and Meissner, are oval-shaped bodies, made up of connective tissue. Each is enveloped by a capsule, and imperfect membranous septa derived from this penetrate the interior. The axis cylinder of the medullated fibre passes through the capsule, and having entered the corpuscle terminates in a small globular or pyriform enlargement, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillæ of the corium of the hand and foot, the front of the forearm, the skin of the lips, the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillæ; but from their existence in those parts in which the skin is highly sensitive, it is probable that they are specially concerned in the sense of touch, though their absence from the papillæ of other tactile parts shows that they are not essential to this sense.

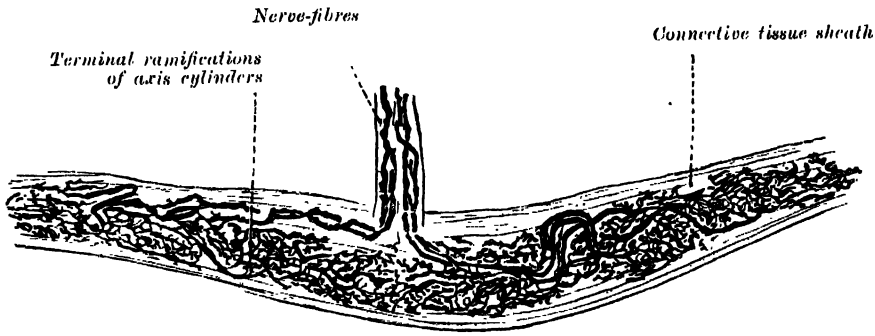
FIG. 65.—Papilla of the hand, treated with acetic acid. Magnified 350 times.

B. A tactile papilla seen from above so as to show its transverse section. *a.* Cortical layer. *b.* Nerve-fibre. *c.* Outer layer of the tactile body, with nuclei. *d.* Clear interior substance.

Ruffini has described a special variety of nerve-ending in the subcutaneous tissue of the human finger (fig. 66). These are usually known as *Ruffini's endings*. They are principally situated at the junction of the corium with the subcutaneous tissue; they are oval in shape, and consist of strong connective tissue sheaths, inside which the nerve-fibres divide into numerous branches, which show varicosities and end in small free knobs. They resemble the organs of Golgi.

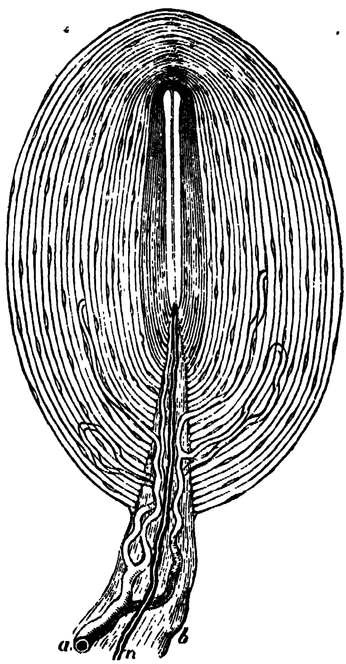
The *Pacinian corpuscles* * (fig. 67) are found in the human subject lying chiefly in the subcutaneous tissue on the nerves of the palm of the hand and

Fig. 66.—Nerve-ending of Ruffini.
(After A. Ruffini, 'Arch. ital. de Biol.,' Turin, t. xxi. 1894.)



sole of the foot and in the genital organs of both sexes; but they have also been described as connected with the nerves of the joints, and in some other situations, as in the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle, which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat), consists of a number of lamellæ or capsules arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective tissue fibres, and is lined on its inner surface by a single layer of flattened epithelioid cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar arrangement. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space. Other authors describe the artery as entering the corpuscle at the pole opposite to the nerve-fibre.

Fig. 67.—Pacinian corpuscle, with its system of capsules and central cavity.



a. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces, and one penetrates to the central capsule. *b.* The fibrous tissue of the stalk prolonged from the neurilemma. *n.* Nerve-tube advancing to the central capsule, there losing its white matter, and stretching along the axis to the opposite end, where it is fixed by a tuberculated enlargement.

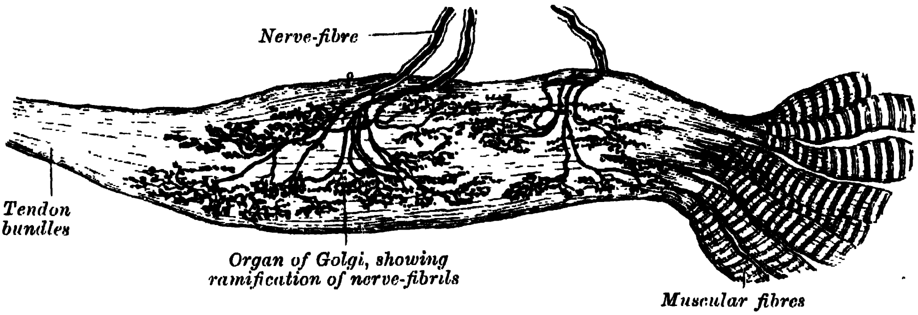
Herbst has described a nerve-ending somewhat similar to the Pacinian corpuscle, as being found in the mucous membrane of the tongue of the duck, and in some other situations. It differs, however, from the Pacinian corpuscle, in being smaller, its capsule thinner and more closely approximated, and especially in the fact that the axis cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the *corpuscles of Herbst.*

* Often called in German anatomical works 'corpuscles of Vater.'

Neuro-tendinous spindles.—The nerves supplying tendons have special modifications of the terminal fibres, especially numerous at the point where the tendon is becoming muscular. The tendon bundles become enlarged, and the nerve-fibres—one, two, or more in number—penetrate between the fasciculi of the tendon and spread out between the fibres to end in irregular discs or varicosities. A spindle-shaped body is thus formed, composed of tendon bundles and nerve-fibres; it is known as the *organ of Golgi* (fig. 68).

Neuro-muscular spindles.—In the majority of voluntary muscles there have been found special end-organs consisting of small bundles of peculiar muscular

Fig. 68.—Organ of Golgi (neuro-tendinous spindle) from the human tendo Achillis. (After Ciaccio.)



fibres (intrafusal fibres), embryonic in type, invested by capsules, within which nerve-fibres, experimentally shown to be sensory in origin, terminate. These neuro-muscular spindles vary in length from $\frac{1}{30}$ to $\frac{1}{5}$ of an inch and have a distinctly fusiform appearance. The large medullated nerve-fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule, they divide several times, and, losing their medullary sheaths, ultimately end in naked axis cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid or rounded discs (fig. 69). Neuro-muscular spindles have not yet been demonstrated in the tongue or eye muscles.

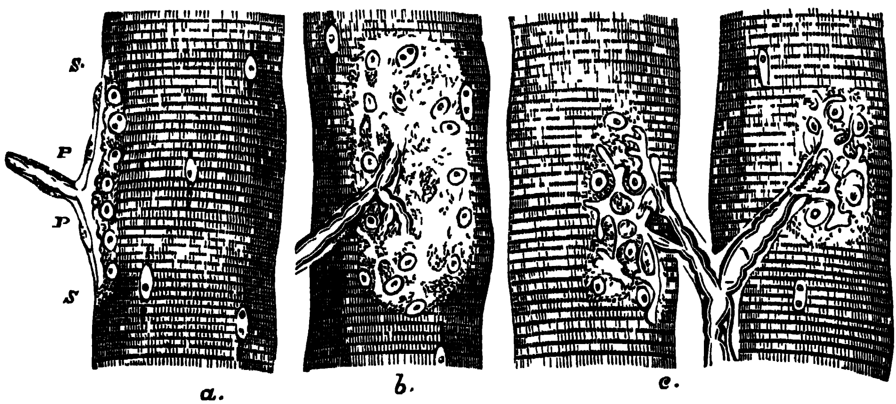
Fig. 69.—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)

In the organs of **special sense** the nerves appear to terminate in cells which belong to the epithelial class, and have received the name of ***sensory*** or ***nerve-epithelium*** cells. This is not, however, the real state of the case; the nerve-fibre is in reality a process from the epithelial cell, and terminates by branching around a ganglion-cell. The stimulus carried by it is continued onwards by an axis cylinder, derived from the ganglion, to the brain. These nerve-epithelium cells must therefore be regarded as modified forms of nerve-cells. They will be more particularly described in the chapter on the organs of special sense.

Motor nerves can be traced into either unstriped or striped muscular fibres. In the *unstriped* or *involuntary muscles* the nerves are derived from the sympathetic, and are composed mainly of the non-medullated fibres. Near their terminations they divide into numerous branches, which communicate and form intimate plexuses. At the junctions of the branches small triangular nuclear bodies (ganglion-cells) are situated. From these plexuses minute branches are given off, which divide and break up into the ultimate fibrillæ of which the nerves are composed. These fibrillæ course between the involuntary muscle-cells, and, according to Elischer, terminate on the surfaces of the cells, opposite the nuclei, in minute swellings. Arnold and Frankenhäuser believed that these ultimate fibrillæ penetrated the muscular cells, and ended in the nuclei. More recent observation has, however, tended to disprove this.

In the *striped* or *voluntary muscle*, the nerves supplying the muscular fibres are derived from the cerebro-spinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre be long, more than one nerve-fibre enters it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne, who first accurately described it, a *motor end-plat* (fig. 70).* The nerve-fibre, on approaching

FIG. 70.—Muscular fibres of *Lacerta viridis* with the terminations of nerves.



a Seen in profile P P. The nerve end-plates S S The base of the plate, consisting of a granular mass with nuclei. *b* The same as seen in looking at a perfectly fresh fibre, the nervous ends being probably still excitable. (The forms of the variously divided plate can hardly be represented in a woodcut by sufficiently delicate and pale contours to reproduce correctly what is seen in nature.) *c* The same as seen two hours after death from poisoning by curare.

the muscular fibre, suddenly loses its medullary sheath, the neurilemma becomes continuous with the sarcolemma of the muscle, and only the axis cylinder enters the muscular fibre. There it at once spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and becomes imbedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

Ganglia are small aggregations of nerve-cells. They are found on the posterior roots of the spinal nerves; on the posterior or sensory root of the fifth cranial nerve; on the facial and auditory nerves; on the glosso-pharyngeal and pneumogastric nerves. They are also found in a connected series along either side of the vertebral column, forming the trunk of the sympathetic; and on the branches of sympathetic nerves, generally in the plexuses or at the points of junction of two or more nerves with each other or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-grey substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera.

* They had, however, previously been noticed, though not accurately described, by Doyère, who named them 'nerve-hillocks'

Each ganglion is invested by a smooth and firm, closely adhering, membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior to support the blood-vessels supplying the substance of the ganglion.

In structure all ganglia are essentially similar (fig. 71), consisting of the same structural elements—viz. nerve-cells and nerve-fibres. Each nerve-cell has a nucleated sheath which is continuous with the sheath of the nerve-fibre with which the cell is connected. The nerve-cells in the ganglia of the spinal nerves are pyriform in shape, and have only single processes. A short distance from the cell and while still within the ganglion this process divides in a T-shaped manner, one limb of the cross-bar turning into the spinal cord, the other limb passing outwards to the periphery. In the sympathetic ganglia (fig. 71) the nerve-cells are multipolar and each has one axis-cylinder process and several dendrons; the axon emerges from the ganglion as a non-medullated nerve-fibre. Similar cells are found in the ganglia connected with the fifth cranial nerve, and these ganglia are therefore regarded by some as the cranial portions of the sympathetic system. The spinal and sympathetic ganglia differ somewhat in the size and disposition of the cells and in the number of nerve-fibres entering and leaving them. In the spinal ganglia (fig. 72) the nerve-cells are much larger and for the most part collected in groups near the periphery, while the fibres, which are mostly medullated, traverse the central portion of the ganglion; whereas, in the sympathetic ganglia (fig. 71) the cells are smaller and distributed in irregular groups throughout the whole ganglion; the fibres also are irregularly scattered; some of the entering ones are medullated, while many of those leaving the ganglion are non-medullated.

Fig. 71.—Section of a sympathetic ganglion.

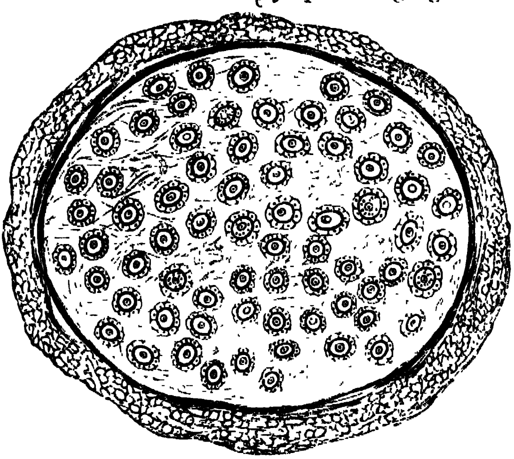


Fig. 72.—Longitudinal section of a part of a posterior root ganglion.

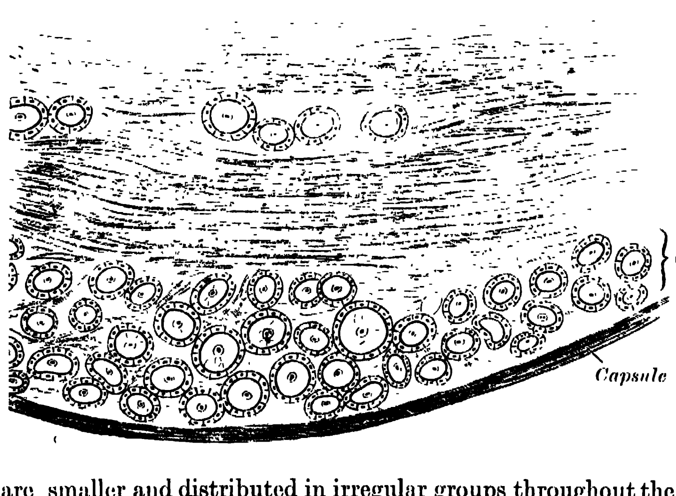


Neuron theory.—It was formerly believed that the various cells of the nervous system were anatomically in continuity by means of their processes. In 1891 Waldeyer opposed this view, and formulated the doctrine that each nerve-cell and its processes (neuron) was an independent morphological unit, and that no continuity of the processes of one neuron

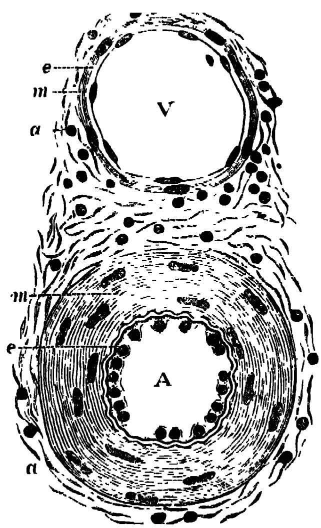
with those of another neuron existed, although the close relationship of these processes permitted physiological functional continuity. With improved methods of staining and impregnation of nerve-cells and their processes, the neuron theory has gained ground and is now accepted by the majority of anatomists. On the other hand, it is maintained by Bethe, Apathy and others that the nervous system is made up of a network of neurofibrillæ which is continuous throughout the whole nervous system, is not confined to the neurons, and can give rise to new axons independent of nerve-cells.

THE VASCULAR SYSTEM

The **Vascular system**, exclusive of its central organ the heart, is divided into four classes of vessels: the arteries, capillaries, veins, and lymphatics. The minute structure of these vessels will be briefly described here, the reader being referred to the body of the work for the details of their ordinary anatomy.

Structure of arteries (fig. 73).—The arteries are composed of three coats: internal or endothelial coat (*tunica intima* of Kölliker); middle muscular coat (*tunica media*); and external connective tissue coat (*tunica adventitia*). The two inner coats together are very easily separated from the external, as by the ordinary operation of tying a ligature round an artery. If a fine string be tied forcibly upon an artery and then taken off, the external coat will be found undivided but the two inner coats are divided in the track of the ligature and can easily be further dissected from the outer coat.

Fig. 73.—Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. Magnified about 350 diameters. (Klein and Noble Smith.)



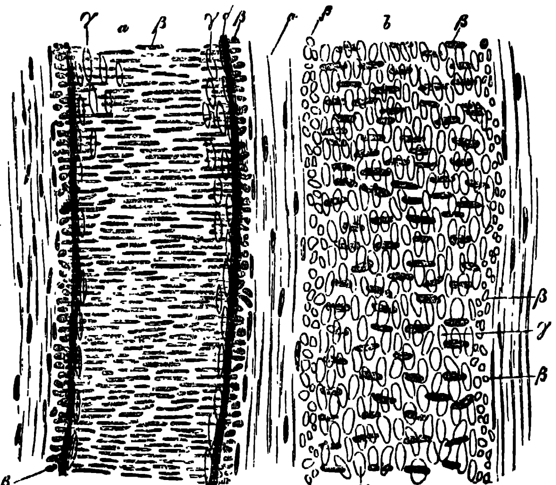
Artery, showing the nucleated endothelium, *e*, which lines it: the vessel being contracted, the endothelial cells appear very thick. Underneath the endothelium is the wavy elastic intima. The chief part of the wall of the vessel is occupied by the circular muscle-coat *m*: the staff-shaped nuclei of the muscle-cells are well seen. Outside this is *a*, part of the adventitia. This is composed of bundles of connective tissue fibres, shown in section, with the nuclei of the connective tissue corpuscles. The adventitia gradually merges into the surrounding connective tissue. V. Vein showing a thin endothelial membrane, *e*, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media *m*. This latter is composed of a few circular unstriped muscle-cells. *a*. The adventitia, similar in structure to that of an artery.

The *inner coat* (*tunica intima*) can be separated from the middle by a little maceration, or it may be stripped off in small pieces; but, on account of its friability, it cannot be separated as a complete membrane. It is a fine, transparent, colourless structure which is highly elastic, and is commonly corrugated into longitudinal wrinkles. The inner coat consists of: (1) A layer of pavement endothelium, the cells of which are polygonal, oval, or fusiform, and have very distinct round or oval nuclei. This endothelium is brought into view most distinctly by staining with nitrate of silver. (2) A sub-endothelial layer, consisting of delicate connective tissue with branched cells lying in the interspaces of the tissue; in arteries of less than a twelfth of an inch in diameter the sub-endothelial layer consists of a single stratum of stellate cells, and the connective tissue is only largely developed in vessels of a considerable size. (3) An elastic or fenestrated layer, which consists of a membrane containing a network of elastic fibres, having principally a longitudinal direction, and in which, under the microscope, small elongated apertures or perforations may be seen, giving it a fenestrated appearance. It was therefore called by Henle the *fenestrated membrane*. This membrane forms the chief thickness of the inner coat, and can be separated into several layers, some of which present the appearance of a network of longitudinal elastic fibres, and others present a more membranous character, marked by pale lines having a longitudinal direction. The fenestrated membrane in microscopic arteries is a very thin layer; but in the larger arteries, and especially in the aorta, it has a very considerable thickness.

The *middle coat* (*tunica media*) is distinguished from the inner by its colour and by the transverse arrangement of its fibres. In the smaller arteries it consists principally of plain muscle-fibres in fine bundles, arranged in lamellæ and disposed circularly around the vessel. These lamellæ vary in number according to the size of the vessel; the smallest arteries having only a single layer, and those slightly larger three or four layers. It is to this coat that the great thickness of the walls of the artery is mainly due (fig. 73, A, *m*). In the larger vessels, as the iliac, femoral, and carotid, elastic fibres unite to form lamellæ which alternate with the layers of muscular fibres; these lamellæ are united to one another by elastic fibres which pass between the muscular bundles, and are connected with the fenestrated membrane of the inner coat (fig. 75). In the largest arteries, as the aorta and innominate, the amount of elastic tissue is very considerable; in these vessels a few bundles of white connective tissue also have been found in the middle coat. The muscle-fibre cells are about $\frac{1}{500}$ of an inch in length and contain well-marked, rod-shaped nuclei, which are often slightly curved.

The *external coat* (*tunica adventitia*) consists mainly of fine and closely felted bundles of white connective tissue, but also contains elastic fibres in all but the smallest arteries. The elastic tissue is much more abundant next the tunica media, and it is sometimes described as forming here, between the adventitia and media, a special layer, the *tunica elastica externa* of Henle. This layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin; but in small arteries it is of greater proportionate thickness. In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; while in the smallest arteries, just above the capillaries, the elastic fibres are wanting, and the connective tissue of which the coat is composed becomes more nearly homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope, which finally disappears.

FIG. 74.—Longitudinal section of artery and vein.



. An artery from the mesentery of a child, ·062″, and *b*, vein ·067″ in diameter, treated with acetic acid and magnified 350 times. *α*. Tunica adventitia, with elongated nuclei. *β*. Nuclei of the contractile fibre-cells of the tunica media, seen partly from the surface, partly apparent in transverse section. *γ*. Nuclei of the endothelial cells. *δ*. Elastic longitudinal fibrous coat.

Some arteries have extremely thin coats in proportion to their size; this is especially the case in those situated in the cavity of the cranium and vertebral canal, the difference depending on the thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are included in thin fibro-areolar investments, which form their *sheaths*. In the limbs the sheath is usually formed by a prolongation of the deep fascia; in the upper part of the thigh it consists of a continuation downwards of the transversalis and iliac fasciæ of the abdomen; in the neck, of a prolongation of the deep cervical fascia. The included vessel is loosely connected with its sheath by delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are not included in sheaths.

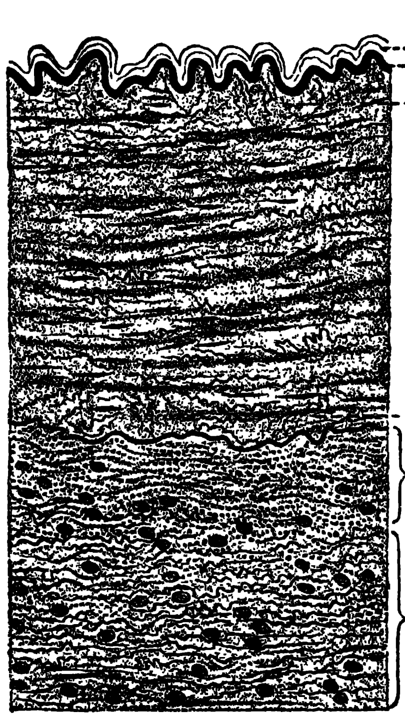
All the larger arteries, like the other organs of the body, are supplied with blood-vessels. These nutrient vessels, called the *vasa vasorum*, arise from a branch of the artery or from a neighbouring vessel, at some considerable distance from the point at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat, but do not, in man, penetrate the other coats; in some of the larger

mammals a few vessels have been traced into the middle coat. Minute veins serve to return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymphatic vessels are also present in the outer coat.

Arteries are also supplied with nerves, which are derived from the sympathetic, but may pass through the cerebro-spinal nerves. They form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller arteries as single filaments, or bundles of filaments which twist around the vessel and unite with each other in a plexiform manner. The branches derived from these plexuses penetrate the external coat and are distributed principally to the muscular tissue of the middle coat, and thus regulate, by causing the contraction and relaxation of this tissue, the amount of blood sent to any part.

The capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the spleen, and of the placenta)

Fig. 75.—Section of a medium-sized artery. (After Grünstein.)



terminate in networks of vessels which pervade nearly every tissue of the body. These vessels, from their minute size, are termed capillaries. They are interposed between the smallest branches of the arteries and the commencing veins, constituting a network, the branches of which maintain the same diameter throughout; the meshes of the network are more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The *diameters* of the capillaries vary in the different tissues of the body, the usual size being about $\frac{1}{3000}$ of an inch. The smallest are those of the brain and the mucous membrane of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as $\frac{1}{1200}$ of an inch in diameter. The *form* of the capillary net varies in the different tissues, the meshes being generally rounded or elongated.

The *rounded form of mesh* is most common, and prevails where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; the meshes are not of an absolutely circular outline, but more or less angular, sometimes nearly quadrangular, or polygonal, or more often irregular.

Elongated meshes are observed in the muscles and nerves, the meshes resembling parallelograms in form, the long axis of the mesh running parallel with the long axis of the nerve or muscle. Sometimes the capillaries have a *looped* arrangement; a single vessel projecting from the common network and returning after forming one or more loops, as in the papillæ of the tongue and skin.

The number of the capillaries and the size of the meshes determine the degree of vascularity of a part. The closest network and the smallest interspaces are found in the lungs and in the choroid coat of the eye. In these situations the interspaces are smaller than the capillary vessels themselves. In the kidney, in the conjunctiva, and in the cutis, the interspaces are from three to four times as large as the capillaries which form them; and in the brain from eight to ten times as large as the capillaries in their long diameters, and from four to six times as large in their transverse diameters. In the adventitia of arteries the width of the meshes is ten times that of the capillary vessels. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood; the meshes of the network are very narrow in all growing parts, in the glands, and in the mucous membranes; wider in bones and ligaments, which are comparatively inactive; and nearly altogether absent in tendons, in which very little organic change occurs after thei formation. In the liver the capillaries take a more or less radial course towards the intralobular vein, and are believed by some authorities to open freely into the substance of the liver, although not to such a degree as in the spleen.

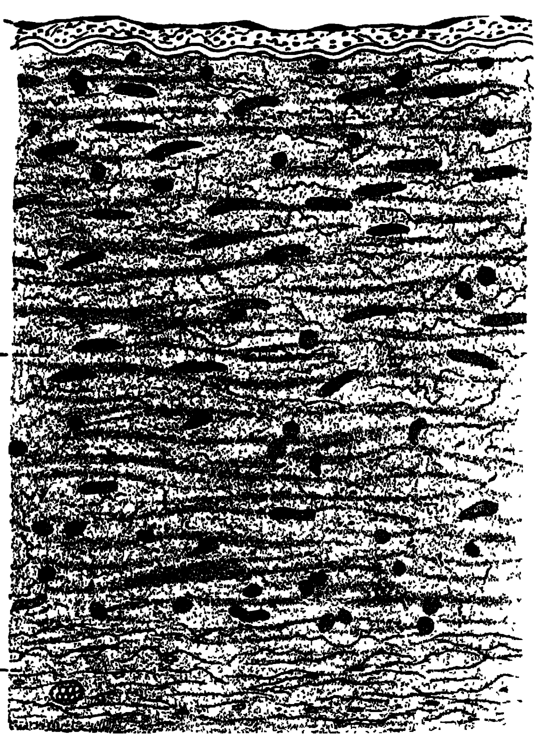
Structure.—The wall of a capillary consists of a fine transparent endothelial layer, composed of cells joined edge to edge by an interstitial cement-substance, and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver the edges which bound the epithelial cells are brought into view (fig. 76). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be brought into view by carmine or hæmatoxylin. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. They have been believed to be the situations through which the colourless corpuscles of the blood, when

migrating from the blood-vessels, emerge; but this view, though probable, is not universally accepted.

Kolossow describes these cells as having a rather more complex structure. He states that each consists of two parts: of hyaline ground-plates, and of a protoplasmic granular part, in which is imbedded the nucleus, on the outside of the ground-plates. The hyaline internal coat of the capillaries does not form a complete membrane, but consists of 'plates' which are inelastic, and though in contact with each other are not continuous; when therefore the capillaries are subjected to intravascular pressure, the plates become separated from each other; the protoplasmic portions of the cells, on the other hand, are united together.

In many situations a delicate sheath or envelope of branched nucleated connective tissue cells is found around the simple capillary tube, particularly in the larger ones; and in other places, especially in the glands, the capillaries are invested with retiform connective tissue.

FIG. 78.—Section of a medium-sized vein.



In the largest capillaries (which ought, perhaps, to be described rather as the smallest arteries or pre-capillaries) there is, outside the epithelial layer, a muscular layer consisting of contractile fibre-cells arranged transversely, as in the tunica media of the arteries (fig. 77).

Structure of veins.—The veins, like the arteries, are composed of three coats—internal, middle, and external; and these coats are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective or areolar (fig. 78). The main difference between the veins and the arteries is in the comparative weakness of the middle coat in the former.

In the smallest veins the three coats are hardly to be distinguished. The endothelium is supported on a membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (adventitia), while the inner is composed of a network of longitudinal elastic fibres (media). In the veins next above these in size (one-sixtieth of an inch in diameter), according to Kölliker a connective tissue layer containing numerous

muscle-fibres circularly disposed can be traced, forming the middle coat, while the elastic and connective tissue elements of the outer coat become more distinctly perceptible. In the middle-sized veins the typical structure of these vessels becomes clear. The endothelium is of the same character as in the arteries, but its cells are more oval and less fusiform. It is supported by a connective tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of elastic fibres disposed in the form of a network in place of the definite fenestrated membrane seen in arteries. This constitutes the *internal* coat. The *middle* coat is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a transverse layer of muscular tissue. The white fibrous element is in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The *outer* coat consists, as in the arteries, of areolar tissue, with longitudinal elastic fibres. In the largest veins the outer coat is from two to five times thicker than the middle coat, and contains a large number of longitudinal muscular fibres. These are most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the portal vein, and in the external iliac, renal, and azygos veins. In the renal and portal veins they extend through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. All the large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting—(1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater of the brain and spinal cord; (3) in the veins of the retina; (4) in the veins of the cancellous tissue of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an internal endothelial lining supported on one or more layers of areolar tissue.

Most veins are provided with valves which serve to prevent the reflux of the blood. Each valve is formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and is covered on both surfaces with endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The valves are semilunar. They are attached by their convex edges to the wall of the vein; the concave margins are free, directed in the course of the venous current, and lie in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. The wall of the vein on the cardiac side of the point of attachment of each valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially of the lower extremities; these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins, i.e. those less than $\frac{1}{12}$ of an inch in diameter, also in the venæ cavæ, the hepatic veins, portal vein and most of its branches, the renal, uterine, and ovarian veins. A few valves are found in each spermatic vein, and one also at its point of junction with the renal vein or inferior vena cava respectively. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. Valves are occasionally found, few in number, in the azygos and intercostal veins.

The veins, like the arteries, are supplied with nutrient vessels, *vasa vasorum.* Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

Structure of lymphatics.—The lymphatic vessels, including in this term the lacteal vessels which are identical in structure with them, are composed of three coats. The *internal* is an endothelial and elastic coat. It is thin, transparent, slightly elastic, and ruptures sooner than the other coats. It is composed of a layer of

elongated endothelial cells with serrated margins, by which the adjacent cells are dovetailed into one another. These are supported on an elastic membrane. The *middle* coat is composed of smooth muscular and fine elastic fibres, disposed in a transverse direction. The *external* coat consists of connective tissue, intermixed with smooth muscular fibres longitudinally or obliquely disposed. It forms a protective covering to the other coats, and serves to connect the vessel with the neighbouring structures. The above description applies only to the larger lymphatics; in the smaller vessels there is no muscular or elastic coat, and the wall consists only of a connective tissue coat, lined by endothelium. The thoracic duct has a more complex structure than the other lymphatics; it presents a distinct sub-endothelial layer of branched corpuscles, similar to that found in the arteries, and in the middle coat is a layer of connective tissue with its fibres arranged longitudinally. The lymphatics are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many non-medullated nerve-fibres in the form of a fine plexus of fibrils.

The lymphatics are very generally provided with valves, which assist materially in effecting the circulation of the fluid they contain. These valves are formed of thin layers of fibrous tissue, lined on both surfaces by endothelium, which presents the same arrangement upon the two surfaces as was described in connection with the valves of veins. In form they are semilunar; they are attached by their convex edges to the sides of the vessel, the concave edges being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of very rudimentary size and the other increased in proportion.

FIG. 79.—Pseudostomata of serous membranes.

Section through the pleura of the same animal. *a.* Pseudostomata. *b.* Free orifices of short lateral passages of the lymph-canals. (Copied from Ludwig, Schweigger-Seidel and Dybkowsky.)

The valves in the lymphatic vessels are placed at much shorter intervals than in the veins. They are most numerous near the lymphatic glands, and are found more frequently in the lymphatics of the neck and upper extremity than in those of the lower extremity. The wall of a lymphatic immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus, which gives to these vessels, when distended, the knotted or beaded appearance which they present. Valves are wanting in the vessels composing the plexiform network in which the lymphatics usually originate on the surface of the body.

Origin of lymphatics.—The finest lymphatic vessels (lymphatic capillaries) form a plexiform network in the tissues and organs, and their walls consist of a single layer of endothelial plates, with more or less sinuous margins; the vessels of the lymphatic system therefore form a series of closed tubes similar to those of the blood vascular system. The lymphatic vessels for the most part accompany the arteries or veins throughout the body; sometimes a minute artery may be seen to be ensheathed for a certain distance by a lymphatic capillary vessel, which is often many times wider than a blood capillary. These are known as perivascular lymphatics.

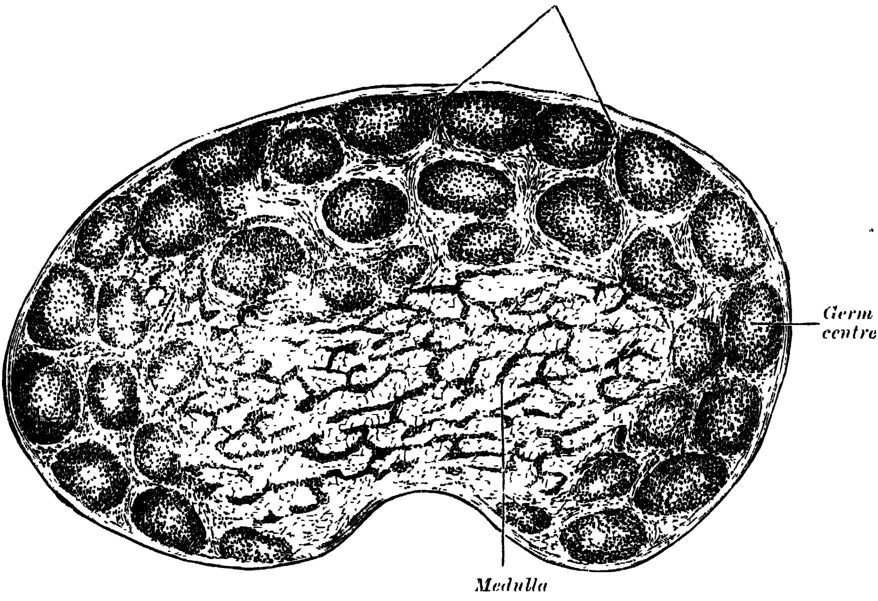
Terminations of lymphatics.—The lymphatics, including the lacteals, discharge their contents into the veins at two points: namely, at the angles of junction of the subclavian and internal jugular veins—on the left side by means of the thoracic duct, and on the right side by the right lymphatic duct. (See description of lymphatics.)

Lymphatic glands (*lymph glands*) are small oval or bean-shaped bodies, situated in the course of lymphatic and lacteal vessels so that the lymph and chyle pass

through them on their way to the blood. Each generally presents on one side a slight depression—the *hilus*—through which the blood-vessels enter and leave the interior. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter the organ at different parts of the periphery. On section (fig. 80), a lymphatic gland displays two different structures: an external, of lighter colour—the *cortical*; and an internal, darker—the *medullary*. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

A lymphatic gland consists of (1) a fibrous envelope, or *capsule*, from which a framework of processes (*trabeculæ*) proceeds inwards, imperfectly dividing the gland into open spaces freely communicating with each other; (2) a quantity of lymphoid tissue occupying these spaces without completely filling them; (3) a free supply of blood-vessels, which are supported on the trabeculæ; and (4) the *afferent* and *efferent* vessels. The nerves passing into the hilus are few in number and are chiefly distributed to the blood-vessels supplying the gland.

Fig. 80.—Section of a lymphatic gland.



The *capsule* is composed of connective tissue with some plain muscle-fibres, and from its internal surface are given off a number of membranous processes or trabeculæ, consisting, in man, of connective tissue, with a small admixture of plain muscle-fibres; but in many of the lower animals composed almost entirely of involuntary muscle. They pass inwards, radiating towards the centre of the gland, for a certain distance—that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland. In some animals they are sufficiently well marked to apparently divide the peripheral or cortical portion of the gland into a number of compartments (so-called follicles), but in man this arrangement is not obvious. The larger trabeculæ springing from the capsule break up into finer bands, and these interlace to form a meshwork in the central or medullary portion of the gland. In these spaces formed by the interlacing trabeculæ (fig. 81) is contained the proper gland-substance or lymphoid tissue. The gland-pulp does not, however, completely fill the spaces, but leaves, between its outer margin and the enclosing trabeculæ, a channel or space of uniform width throughout. This is termed the *lymph-path* or *lymph-sinus* (fig. 83). Running across it are a number of finer trabeculæ of retiform connective tissue, the fibres of which are, for the most part, covered by ramifying cells.

On account of the peculiar arrangement of the framework of the organ, the gland-pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid

FIG. 81.—Follicle from a lymphatic gland of the dog, in vertical section.

tissue, being made up of a delicate network of retiform tissue, which is continuous with that in the lymph-paths but marked off from it by a closer reticulation; it is probable, moreover, that the reticular tissue of the gland pulp and the lymph-paths is continuous with that of the trabeculæ, and ultimately with that of the capsule of the gland. In its meshes are closely packed lymph-corpuscles, traversed by a dense plexus of capillary blood-vessels. The nodules or follicles in

the cortical portion of the gland frequently show, in their centres, areas where karyokinetic figures indicate a division of the lymph corpuscles. These areas are termed *germ-centres* (fig. 80). The cells composing them are smaller than the peripheral cells, and often stain less intensely.

The *afferent vessels*, as above stated, enter at all parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule open into the lymph-sinuses of the cortical part. In doing this they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph-paths. In like manner the *efferent* vessel commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessel thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; flowing through these it enters the paths or sinuses of the medullary portion, and finally emerges from the hilus by means of the efferent vessel. The stream of lymph in its passage through the lymph-sinuses is much retarded by the presence of the reticulum, hence morphological elements, either normal or morbid, are easily arrested and deposited in the sinuses. This is a matter of considerable importance in connection with the subject of poisoned wounds and the absorption of the poison by the lymphatic system, since the causative micro-organisms of the infective processes carried along the lymphatic vessels may be arrested in the lymph-sinuses of the gland-tissue, and thus be prevented from entering the general circulation. Many lymph-corpuscles pass with the efferent lymph-stream to join the general blood-stream. The arteries of the gland enter at the hilus, and either go at once to the gland-pulp, to break up into a capillary plexus, or else run along the trabeculæ, partly to supply them and partly running across the lymph-paths, to assist in forming the capillary plexus of the gland-pulp. This plexus traverses the lymphoid tissue, but does not enter into the lymph-sinuses. From it the veins commence and emerge from the organ at the same place as that at which the arteries enter.

THE SKIN AND ITS APPENDAGES

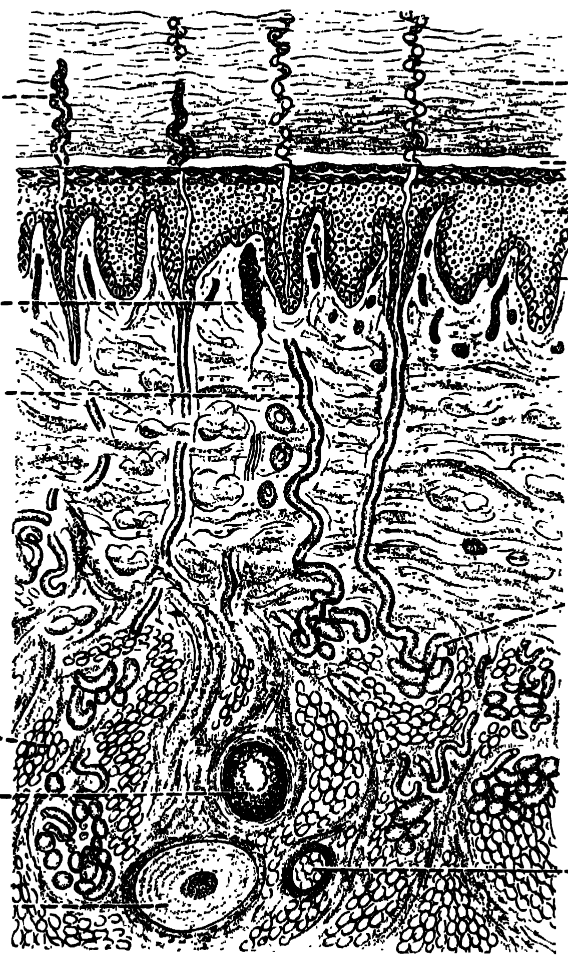
The **skin** (fig. 84) is the principal seat of the sense of touch, and may be regarded as a covering for the protection of the deeper tissues; it plays an important part in the regulation of the body temperature, and has also limited excretory and absorbing powers. It consists principally of a layer of vascular connective tissue, named the *dermis*, *corium*, or *cutis vera*, and an external covering of epithelium, termed the *epidermis* or *cuticle*. On the surface of the former layer are the sensitive *papillæ*; and within, or imbedded beneath it, are certain organs with special functions: namely, the *sweat-glands*, *hair-follicles*, and *sebaceous glands*.

The **epidermis** or **cuticle** (*scarf-skin*) is non-vascular, and consists of stratified epithelium (fig. 85). It is accurately moulded on the papillary layer of the dermis. It forms a defensive covering to the surface of the true skin, and limits the evaporation of watery vapour from its free surface. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be in a measure due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layers of cells, called the *horny* layer (*stratum corneum*), may be separated by maceration from a deeper stratum, which is called the *rete mucosum* or *stratum Malpighii*, and which consists of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, marking out the surface into a number of spaces of polygonal or lozenge-shaped form. Some of these furrows are large, as opposite the flexures of the joints, and correspond to the folds in the dermis produced by movements. In other situations, as upon the back of the hand, they are exceedingly fine, and intersect one another at various angles. Upon the palmar surface of the hand and fingers, and upon the sole of the foot, these lines are very distinct, and are disposed in curves; they depend upon the large size and peculiar arrangements of the papillæ upon which the epidermis is placed. In each individual the lines on the tips of the fingers form distinct patterns unlike those of any other person. A method of determining the identity of a criminal is based on this fact, impressions ('finger-prints') of these lines being made on paper covered with soot, or on white paper after first covering the fingers with ink. The deep surface of the epidermis is accurately moulded upon the papillary layer of the dermis, each papilla being capped by its epidermic sheath; so that when

the epidermis is removed by maceration, it presents on its under surface a number of pits or depressions corresponding to the papillæ, and ridges corresponding to the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

In structure, the epidermis consists of several layers of epithelial cells, agglutinated together and having a laminated arrangement. These several layers may be described as composed of four different strata from within outwards: (1) the *stratum Malpighii*, composed of several layers of epithelial cells; those of the deepest layer are columnar in shape and placed perpendicularly on the surface of the corium, the lower ends of the cells being denticulated, to fit into corresponding denticulations of the true skin; this deepest layer is sometimes termed the basilar

FIG. 84.—A diagrammatic sectional view of the skin (magnified).

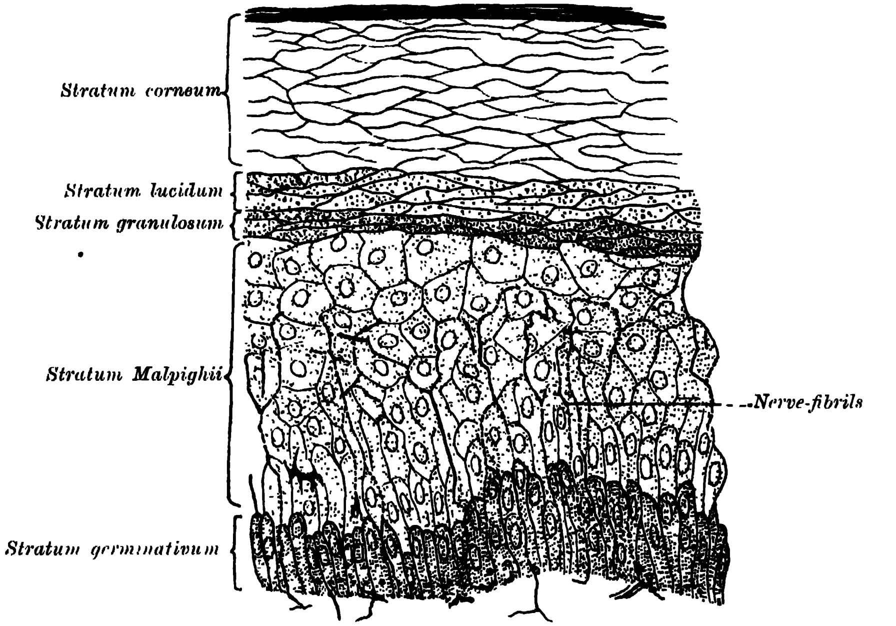


layer or *stratum germinativum*; the succeeding strata consist of cells of a more rounded or polyhedral form, the contents of which are soft, opaque, granular, and soluble in acetic acid. They are often marked on their surfaces with ridges and furrows, and are covered with numerous fibrils which connect the surfaces of the cells: these are known as *prickle-cells* (see page 15). They contain numerous epidermic fibrils, which are stained violet with hæmatoxylin and red with carmine, and form threads of union connecting adjacent cells. Between the cells are fine intercellular clefts which serve for the passage of lymph and in which lymph-corpuscles or pigment-granules may be found. (2) Immediately superficial to these are two or three layers of flattened, spindle-shaped cells, the *stratum granulosum*, which contain granules that are deeply stained by hæmatoxylin; the granules consist

of a material named *eleidin*, an intermediate substance in the formation of keratin. They are supposed to be cells in a transitional stage between the protoplasmic cells of the stratum Malpighii and the horny cells of the superficial layers. (3) Above this layer, the cells become indistinct, and appear in sections to form a homogeneous or dimly striated membrane, composed of closely packed scales in which traces of flattened nuclei may be found. It is called the *stratum lucidum*. (4) The surface layer consists of many lamellæ of horny epithelial scales in which no nuclei are discernible, forming the *stratum corneum*. These cells are unaffected by acetic acid, the protoplasm having become changed into horny material or *keratin*. According to Ranvier they contain granules of a material which has the characters of beeswax.

The deepest layer of the stratum Malpighii is separated from the papillæ by an apparently homogeneous basement membrane, which is most distinctly brought into view in specimens prepared with chloride of gold. This, according to Klein, is merely the deepest portion of the epithelium, and is 'made up of the basis of the individual cells, which have undergone a chemical and morphological alteration.' The black colour of the skin in the negro, and the tawny colour among some of the

Fig. 85.—Section of epidermis. (Ranvier.)



white races, is due to the presence of pigment in the cells of the cuticle. This pigment is more especially distinct in the cells of the deeper layer, or stratum Malpighii, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the colour becomes partially lost; the disappearance of the pigment from the superficial layers of the epidermis is, however, difficult to explain.

The **dermis, corium,** or **cutis vera** is tough, flexible, and highly elastic, in order to defend the parts beneath from violence.

It varies in thickness, from a forty-eighth to an eighth of an inch, in different parts of the body. Thus it is very thick in the palms of the hands and soles of the feet; thicker on the posterior aspect of the body than on the front, and on the outer than on the inner sides of the limbs. In the eyelids, scrotum, and penis it is exceedingly thin and delicate. The skin generally is thicker in the male than in the female, and in the adult than in the child.

The corium consists of felted connective tissue, with a varying amount of elastic fibres and numerous blood-vessels, lymphatics, and nerves. The fibro-areolar tissue forms the framework of the cutis, and is differently arranged in different parts, so that it is usual to describe it as consisting of two layers: the

deeper or *reticular* layer, and the superficial or *papillary* layer. Unstriped muscular fibres are found in the superficial layers of the corium, wherever hairs are present; and in the subcutaneous areolar tissue of the scrotum, penis, labia majora, and nipples. In the nipples the fibres are disposed in bands, closely reticulated and arranged in superimposed laminæ.

The *reticular* layer consists of strong interlacing fibrous bands, composed chiefly of the white variety of fibrous tissue, but also containing some fibres of yellow elastic tissue, which vary in number in different parts; and connective tissue corpuscles, which are often to be found flattened against the white fibrous tissue bundles. Towards the attached surface the fasciculi are large and coarse, and the areolæ which are left by their interlacement are large, and occupied by adipose tissue and sweat-glands. Below this the elements of the skin become gradually blended with the subcutaneous areolar tissue, which, except in a few situations, contains fat. Towards the free surface the fasciculi are much finer, and their mode of interlacing close and intricate.

The *papillary layer* is situated upon the free surface of the *reticular layer*; it consists of numerous small, highly sensitive, and vascular eminences, the *papillæ*, which rise perpendicularly from its surface. The papillæ are minute conical eminences, having round or blunted extremities, occasionally divided into two or more parts, and are received into corresponding pits on the under surface of the cuticle. Their average length is about $\frac{1}{100}$ of an inch, and the diameter of the base $\frac{1}{250}$ of an inch. On the general surface of the body, more especially in those parts which are endowed with slight sensibility, they are few in number, short, exceedingly minute, and irregularly scattered over the surface; but in some situations, as upon the palmar surface of the hands and fingers, upon the plantar surface of the feet and toes, and around the nipple, they are long, of large size, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of papillæ, and between the two rows the ducts of the sweat-glands pass outwards to open on the summit of the ridge. In structure each papilla consists of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres; within this tissue is a capillary loop, and in some papillæ, especially in the palms of the hands and the fingers, there are tactile corpuscles.

The *arteries* supplying the skin form a network in the subcutaneous tissue, from which branches are given off to supply the sweat-glands, the hair-follicles, and the fat. Other branches are given off which constitute a plexus immediately beneath the corium; from this, fine capillary vessels pass into the papillæ, forming, in the smaller ones, a single capillary loop, but in the larger, a more or less convoluted vessel. There are numerous *lymphatics* supplied to the skin, which form two networks, superficial and deep, communicating with each other and with those of the subcutaneous tissue by oblique branches.

The *nerves* of the skin terminate partly in the epidermis and partly in the cutis vera. The former are prolonged into the epidermis from a dense plexus in the superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in cup-shaped endings in which are lodged certain of the deeper cells of the Malpighian layer, termed tactile cells; these are especially well seen in the skin covering the pig's snout. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies, in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine the follicle in a circular manner. Other nerve-fibres are supplied to the plain muscular fibres of the hair-follicles (arrectores pilorum) and to the muscular coats of the blood-vessels. These are probably non-medullated fibres.

The **appendages of the skin** are the nails, the hairs, and the sudoriferous and sebaceous glands with their ducts.

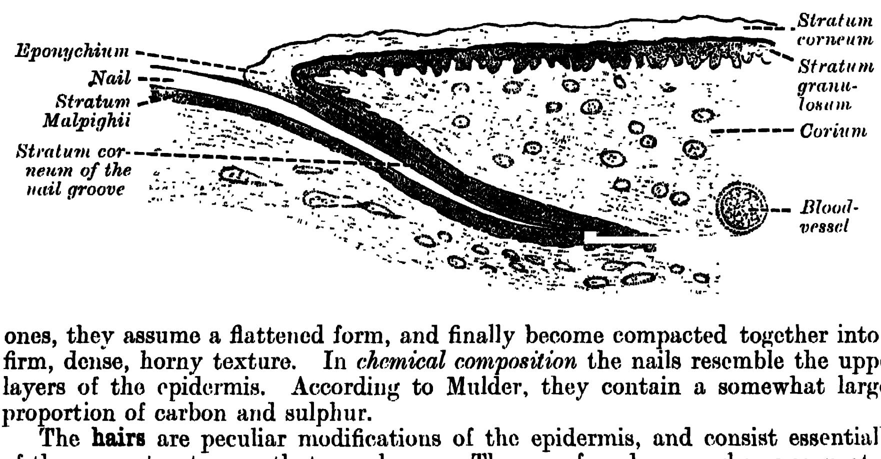
The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The **nails** (fig. 86) are flattened, elastic structures of a horny texture, placed upon the dorsal surfaces of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within, and is implanted by a portion, called the *root*, into a groove in the skin; the exposed portion is called the *body*, and the distal extremity the *free edge*. The nail is firmly adherent to the dermis, being accurately moulded upon its surface, like the epidermis in other

parts. The part beneath the body and root of the nail is called the *matrix*, because from it the nail is produced. Corresponding to the body of the nail, the *matrix is thick*, and raised into a series of longitudinal ridges which are very vascular, and the colour is seen through the transparent tissue. Behind this, near the root of the nail, there are papillæ which are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter colour, and is called the *lunula* on account of its shape.

The cuticle as it passes forwards on the dorsal surface of the finger or toe is attached to the surface of the nail a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely the thin cuticular fold (*eponychium*) which overlaps the lunula. The cells have a laminated arrangement, and are essentially similar to those composing the epidermis. The cells of the deepest layer, which lie in contact with the papillæ of the matrix, are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely packed as to make the limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forwards and maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new

FIG. 86.—Longitudinal section through human nail and its nail groove (sulcus).



ones, they assume a flattened form, and finally become compacted together into a firm, dense, horny texture. In *chemical composition* the nails resemble the upper layers of the epidermis. According to Mulder, they contain a somewhat larger proportion of carbon and sulphur.

The **hairs** are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, and the glans penis. They vary much in length, thickness, and colour in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened.

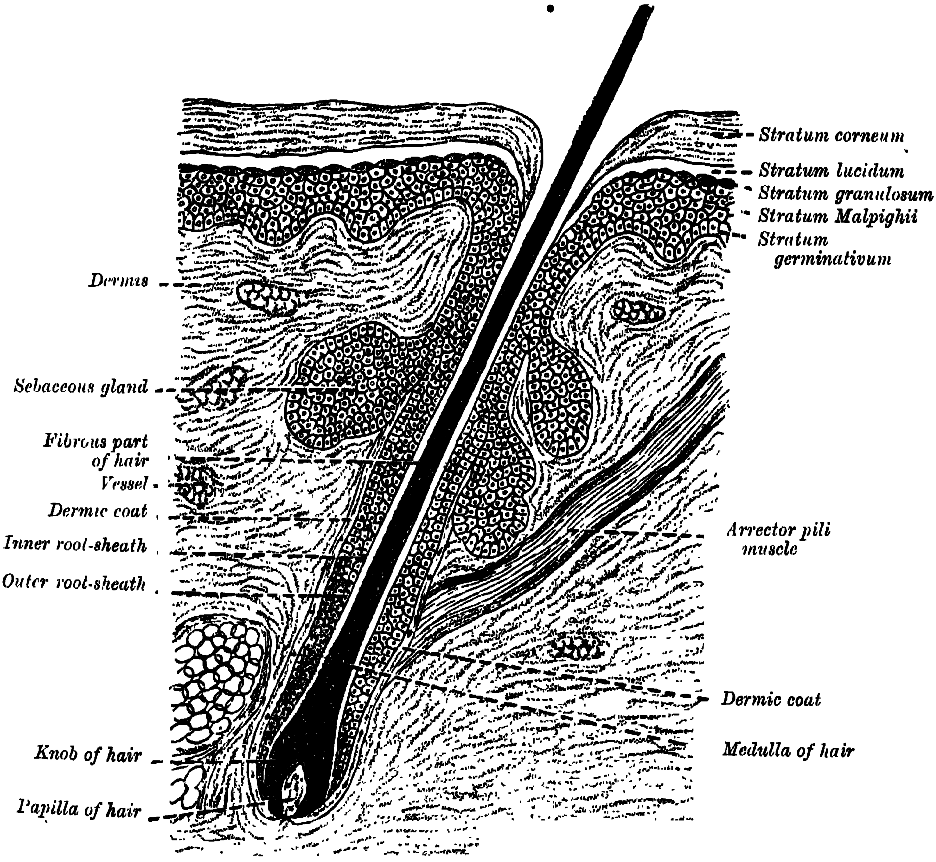
A hair consists of a *root*, the part implanted in the skin; a *shaft* or *stem*, the portion projecting from the surface: and a *point*.

The *root of the hair* presents at its extremity a bulbous enlargement, which is whiter in colour and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the *hair-follicle* (fig. 87). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inwards in an oblique or curved direction—the latter in curly hairs—to become dilated at its deep extremity, where it corresponds with the bulbous

enlargement of the hair which it contains. Opening into it, near its free extremity, are the ducts of one or more sebaceous glands. At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and probably supplied with nerve-fibrils. In structure the hair-follicle consists of two coats—an outer or *dermic*, and an inner or *epidermic*.

The *outer* or *dermic* coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (fig. 88). The most internal, next the cuticular lining of the follicle, consists of a hyaline basement membrane having a glassy, transparent appearance, which is well marked in the larger hair-follicles,

FIG. 87.—Section of skin, showing the epidermis and dermis: a hair in its follicle: the arrector pili muscle: sebaceous glands.



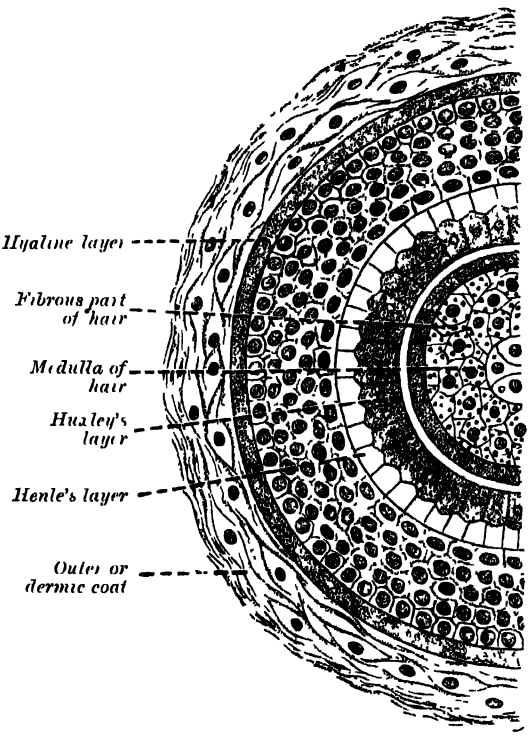
but is not very distinct in the follicles of minute hairs. It is continuous with the basement membrane of the surface of the corium. External to this is a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the blood-vessels and nerves.

The *inner* or *epidermic* layer is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the *root-sheath*. It consists of two strata named respectively the *outer* and *inner root-sheaths*; the former of these corresponds with the

Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The *inner* root-sheath consists of: (1) a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; (2) one or two layers of horny, flattened, nucleated cells, known as *Huxley's layer*; and (3) a single layer of horny oblong cells without visible nuclei, called *Henle's layer*.

The hair-follicle contains the root of the hair, which terminates in a bulbous extremity, and is excavated so as to fit exactly the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upwards into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment granules which give rise to the colour of the hair. It occasionally happens that these pigment granules completely fill the cells in the centre of the bulb; this gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

FIG. 88.—Transverse section of hair-follicle.



The *shaft of the hair* consists of a central pith or medulla, an intermediate fibrous part, and the cuticle externally. The *medulla* occupies the centre of the shaft and ceases towards the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is more opaque and deeper coloured when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air-spaces. The *fibrous* portion of the hair constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain pigment granules in dark hair, and minute air-spaces in white hair. In addition there is also a diffused pigment contained in the fibres. The cells which form the *hair-cuticle* consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales having an imbricated arrangement.

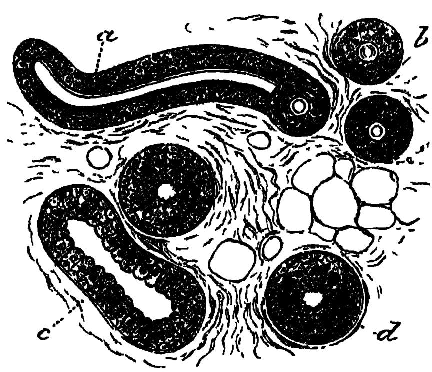
Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed the *arrectores pilorum*. They arise from the superficial layer of the corium, and are inserted into a thickened portion of the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side towards which the hair slopes, and by their action elevate the hair (fig. 87).* The sebaceous gland is situated in the angle which the arrector muscle forms with the superficial portion of the hair-follicle, and contraction of

* Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.

the muscle thus tends to squeeze the sebaceous secretion out from the duct of the gland.

The **sebaceous glands** are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which emerges from a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, as a rule, in number from two to five, but in some instances may be as many as twenty. Each saccule is composed of a transparent, colourless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity filled with their debris and a mass of fatty matter, which constitutes the sebaceous secretion. The ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margin of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

Fig. 89.—Coiled tube of a sweat-gland cut in various directions.



a Longitudinal section of the proximal part of the coiled tube. b Transverse section of the same. c Longitudinal section of the distal part of the coiled tube. d Transverse section of the same. (From Klein and Noble Smith's 'Atlas of Histology.')

The **sudoriferous or sweat glands** are the organs by which water and traces of organic material are excreted by the skin. They are found in almost every part of this structure, and are situated in small pits on the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct proceeds upwards through the corium and cuticle, becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture. The duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew in those parts where the epidermis is thick; where, however, the epidermis is thin, the spiral arrangement does not exist; the spiral course of these ducts is particularly distinct in the thick cuticle of the palms of the hands and soles of the feet. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, mammillated layer of a reddish colour, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palms of the hands, presenting, according to Krause, 2,800 orifices on a square inch of the integument, and are rather less numerous on the soles of the feet; in both of these situations the orifices of the ducts are exceedingly regular, and open on the curved ridges. In other situations the glands are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin. The wall of the duct is thick, the lumen seldom

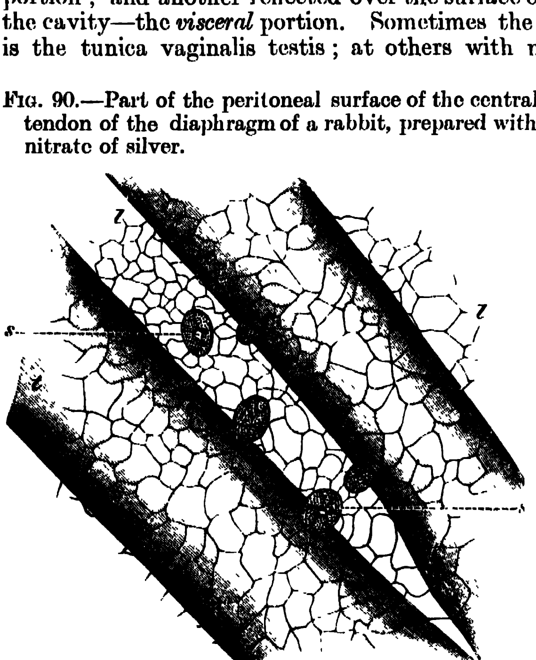
exceeding one-third of the diameter of the tubes. The tube, both in the gland and where it forms the excretory duct, consists of two layers—an outer, formed by fine areolar tissue; and an inner layer of epithelium (fig. 89). The external coat is thin, continuous with the superficial layer of the corium, and extends only as high as the surface of the true skin. The epithelial lining in the distal part of the coiled tube of the gland proper consists of a single layer of cubical epithelium, supported on a basement membrane, and beneath it, between the epithelium and the fibro-cellular coat, a layer of longitudinally or obliquely arranged fibres, composed of involuntary muscle, the contraction of which aids the expulsion of the sweat. In the duct and the proximal part of the coiled tube of the gland proper there are two or more layers of polyhedral cells, lined on the internal surface, i.e. next the lumen of the tube, by a delicate membrane or cuticle, and on the outer surface by a limiting membrana propria, but there are no muscular fibres. The epithelium is continuous with the epidermis and with the delicate internal cuticle of the epidermic portion of the tube. When the cuticle is carefully removed from the surface of the cutis, these convoluted tubes of epithelium may be drawn out in the form of short, thread-like processes on its under surface.

The contents of the smaller sweat-glands are quite fluid; but in the larger glands the contents are semi-fluid and opaque, and contain a number of coloured granules and cells which appear analogous to epithelial cells.

SEROUS MEMBRANES

The **serous membranes** form shut sacs, the walls of which are normally in contact so that the enclosed cavity is merely a potential one. The sac consists of one portion which is applied to the walls of the cavity which it lines—the *parietal* portion; and another reflected over the surface of the organ or organs contained in the cavity—the *visceral* portion. Sometimes the sac is arranged quite simply, as is the tunica vaginalis testis; at others with numerous involutions or recesses, as in the peritoneum, in which, nevertheless, the membrane can always be traced continuously around the whole circumference. The sac is completely closed, so that no communication exists between the serous cavity and the parts in its neighbourhood. An exception exists in the peritoneum of the female; for the Fallopian tubes open freely into the peritoneal cavity in the dead subject. This communication, however, is closed during life, except at the moment of the passage of the ovum out of the ovary into the tube, as is proved by the fact that no interchange of fluids ever takes place between the two cavities in dropsy of the peritoneum, or in accumulation of fluid in the Fallopian tubes. The serous membrane is sometimes supported by a firm, fibrous layer, as is the case with the pericardium, and such membranes may be spoken of as *fibro-serous*.

FIG. 90.—Part of the peritoneal surface of the central tendon of the diaphragm of a rabbit, prepared with nitrate of silver.



l. Lymph-channels. *t*. Tendon-bundles. *s*. The supposed stomata, clumps of germinating epithelial cells. (From 'Handbook for the Physiological Laboratory.' Klein.)

The various serous membranes are the peritoneum, lining the cavity of the abdomen; the two pleuræ and the pericardium, covering the lungs and heart respectively; and the tunicæ vaginales, surrounding the testicles in the scrotum. Serous membranes are thin, transparent, glistening structures, each consisting of a

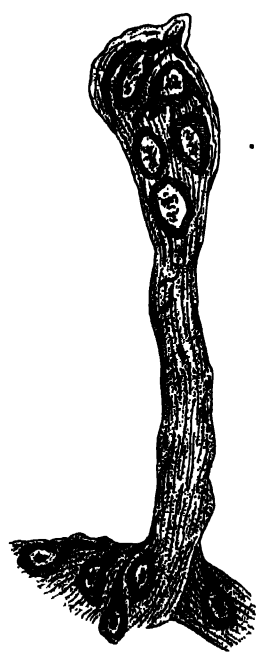
homogeneous basement membrane lined on its inner surface by a single layer of polygonal or pavement endothelial cells, supported on a matrix of fibrous connective tissue, with networks of fine elastic fibres, in which are contained numerous capillaries and lymphatics. On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. Some of these are the structures formerly described as *stomata*, each of which is composed of cubical endothelium (see fig. 90); others (*pseudostomata*) are mere interruptions in the endothelial layer, and are occupied by processes of the branched connective tissue corpuscles of the subjacent tissue or by accumulations of the intercellular cement substance.

The amount of fluid contained in these closed sacs is, in most cases, only sufficient to moisten the surface; when a small quantity can be collected, it is found to resemble lymph, and like that fluid coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a more watery fluid, yet still contains a considerable amount of protein which is coagulated on boiling.

SYNOVIAL MEMBRANES

Synovial membranes, like serous membranes, are connective tissue membranes. In some cases they form closed sacs (synovial sheaths and bursæ) directly interposed between two movable tissues so as to diminish friction; thus they may be placed between a tendon and a bone where the former glides over the latter, or between the skin and various subcutaneous bony prominences. In other cases they form incomplete linings for the capsules of movable joints; in such cases a diminution of friction between the joint-surfaces is effected by the secretion poured out from the synovial cells.

Fig. 91.—Villus of synovial membrane. (After Hammar.)



The synovial membranes are composed essentially of the typical connective tissue, cells and fibres, containing numerous vessels and nerves. It was formerly supposed that these membranes were analogous in structure to the serous membranes, and consisted of a layer of flattened cells on a basement membrane. No such continuous layer, however, exists, although here and there are patches of epithelioid cells, surrounded and held together by an albuminous ground substance. Long villus-like processes (fig. 91) are often found projecting from the surfaces of synovial membranes; they are covered by small rounded cells, and are supposed to extend the surface for the secretion of the fluid (*synovia*) which moistens the membranes. It is a rich lymph, plus a mucin-like substance, and to the latter constituent it owes its viscidity. A further description of the synovial membranes will be given with the anatomy of the joints.

MUCOUS MEMBRANES

Mucous membranes line all the passages of the internal organs, and are continuous with the skin at the various orifices by which these passages open on the surface of the body. They are soft and very vascular, and the surface is coated over by their secretion, *mucus*, which is of a tenacious consistence and serves to protect them from the foreign substances with which they are brought in contact.

They are described as lining the two tracts—the gastro-pulmonary and the genito-urinary; and all, or almost all, mucous membranes may be classed as belonging to and continuous with the one or the other of these tracts.

The deep surfaces of these membranes are attached to the parts which they line by means of connective tissue, which is sometimes very abundant, forming a loose and lax bed, so as to allow considerable movement of the opposed surfaces on each other. This is termed the *submucous tissue.* In other cases such an intervening tissue is exceedingly scanty, and the membrane is closely connected to the tissue beneath; sometimes, for example, to muscle, as in the tongue; sometimes to cartilage, as in the larynx; and sometimes to bone, as in the nasal fossæ and air sinuses of the skull.

In structure a mucous membrane is composed of *corium* and *epithelium.* The epithelium is of various forms, including the squamous, columnar, and ciliated, and is often arranged in several layers. This epithelial layer is supported by the corium, which is analogous to the dermis of the skin, and consists of connective tissue, either simply areolar, or containing a greater or lesser quantity of lymphoid tissue. The corium is usually covered on its external surface by a transparent basement membrane, generally composed of clear flattened cells placed edge to edge; on this the epithelium rests. It is only in some situations that the basement membrane can be demonstrated. The corium is an exceedingly vascular membrane, containing a dense network of capillaries, which lie immediately beneath the epithelium and are derived from small arteries in the submucous tissue.

The fibro-vascular layer of the corium contains, besides the areolar tissue and vessels, unstriped muscle-cells, which form in many situations a definite layer called the *muscularis mucosæ.* These are situated in the deepest part of the membrane, and are plentifully supplied with nerves. Other nerves pass to the epithelium and terminate between the cells. Lymphatic vessels are found in great abundance, commencing by blind extremities and communicating with plexuses in the submucous tissue.

Imbedded in the mucous membrane are found numerous glands, and projecting from it are processes (villi and papillæ) analogous to the papillæ of the skin. These glands and processes, however, exist only at certain parts, and it will be more convenient to describe them as they occur.

SECRETING GLANDS

The **secreting glands** are organs whose cells produce, by the metabolism of their protoplasm, certain substances, called 'secretions,' of a more or less definite composition; the material for the secretion being primarily selected from the blood. Each cell in the organism forms new products from the material supplied to it. Where these new substances are utilised in some of the other functions of the organism they may be referred to as *secretions* in contradistinction to substances which are merely effete products of protoplasmic activity and are discarded as *excretions.* The term secretion, however, is generally applied to all the products of glandular activity. The essential parts therefore of a secreting gland are (1) *cells,* which have the power of extracting from the blood certain matters, and in most cases of converting these into new chemical compounds; and (2) *blood-vessels,* by which the blood is brought into close relationship with these cells. The general arrangement in all secreting structures—that is to say, not only in secreting glands, but also in secreting membranes—is that the cells are arranged on one surface of an extra-vascular basement membrane, which supports them, while a minute plexus of capillary vessels ramifies on the other surface of the membrane. The cells then select from the blood certain constituents which pass through the membrane into them, and these they prepare and elaborate.

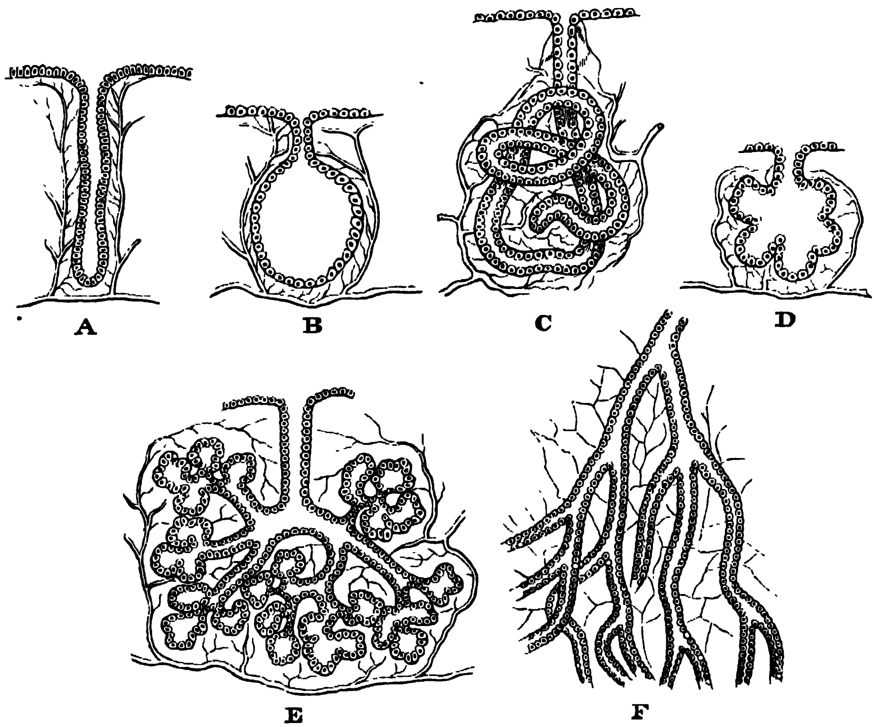
By the various modifications of this secreting surface the different glands are formed. This is generally effected by an invagination of the membrane in different ways, the object being to increase the extent of secreting surface within a given bulk.

In the simplest form a single invagination takes place, constituting a *simple* gland; this may be either in the form of an open tube (fig. 92, A), or the walls of the tube may be dilated so as to form a saccule (fig. 92, B). These are named *simple tubular* or *saccular* glands. Or, instead of a short tube, the invagination

may be lengthened to a considerable extent, and then coiled up to occupy less space. This constitutes the simple *convoluted tubular* gland, an example of which may be seen in the sweat-glands of the skin (fig. 92, C).

If, instead of a single invagination, secondary invaginations take place from the primary one (fig. 92, D and E), the gland is termed a compound one. These secondary invaginations may assume either a saccular or tubular form, and so constitute the two subdivisions—the *compound saccular* or *racemose* gland, and the *compound tubular*. The racemose gland in its simplest form consists of a primary invagination which forms a sort of duct, at the extremity of which are found a number of secondary invaginations, called saccules or alveoli, as in Brunner's glands (fig. 92, D). But, again, in other instances, the duct, instead of being simple, may divide into branches, and these again into other branches, and so on; each ultimate ramification terminating in a dilated cluster of saccules, and thus the secreting surface may be almost indefinitely extended, as in the salivary glands

FIG. 92.—Diagrammatic plan of the varieties of secreting glands.



A. Simple gland. B. Sacculated simple gland. C. Simple convoluted tubular gland. D, E. Racemose gland. F. Compound tubular gland.

(fig. 92, E). The ducts of the glands are composed of columnar epithelial cells resting on a basement membrane, outside which is a greater or lesser amount of connective tissue, depending on the size of the duct. In some cases small bundles of involuntary muscle fibres are found external to the basement membrane, and these by their contractions help to expel the contained secretion. In the *compound tubular* glands the division of the primary duct takes place in the same way as in the racemose glands, but the branches retain their tubular form, and do not terminate in saccular recesses, but become greatly lengthened out (fig. 92, F). The best example of this form of gland is to be found in the kidney. All these varieties of glands are produced by a more or less complicated invagination of a secreting membrane, and they are all identical in structure: that is to say, the saccules or tubes, as the case may be, are lined with cells, generally spheroidal or columnar in shape, and on their outer surfaces are intimate plexuses of capillary vessels. The secretion, whatever it may be, is eliminated by the cells from the blood, and is poured into the saccule or tube, and so finds its way out through the primary

invagination on to the free surface of the secreting membrane. In addition, however, to these glands, which are formed by an *invagination* of the secreting membrane, there are some few others which are formed by a *protrusion* of the same structure, as in the vascular fringes of synovial membranes. This form of secreting structure is not nearly so frequently met with.

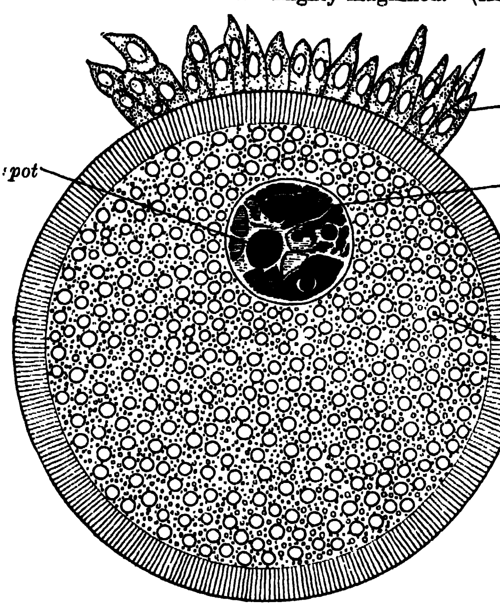
There are also certain glands which are capable of *internal secretion*, wherein are no ducts leading to any free surface, the secretion being carried either directly into the blood-stream, or indirectly through the medium of lymphatics. Such are the thyroid and suprarenal glands, but modern researches have shown that many glands which possess obvious external secretions elaborate at the same time internal secretions.

EMBRYOLOGY

THE term **Embryology**, in its widest sense, is applied to the various changes which take place during the growth of an animal from the egg to the adult condition: it is, however, usually restricted to the phenomena which occur before birth. It may be studied from two aspects: (1) that of *ontogeny*, which deals only with the development of the individual; and (2) that of *phylogeny*, which concerns itself with the evolutionary history of the animal kingdom.

In all vertebrate animals the development of a new being can only take place when a female germ-cell or *ovum* has been fertilised by a male germ-cell or *spermatozoön*. The ovum is a nucleated cell, and all the complicated changes by which the various tissues and organs of the body are formed from it, after it has been fertilised, are the result of two general processes, viz. *segmentation* and *differentiation* of cells. Thus, the fertilised ovum undergoes repeated segmentation into a number of cells which at first closely resemble one another, but are, sooner or later, differentiated into two groups: (1) *somatic cells*, the function of which is to build up the various tissues of the body; and (2) *germinal cells*, which become imbedded in the sexual glands—the ovaries in the female and the testes in the male—and are destined for the perpetuation of the species.

FIG. 93.—Ovum of rabbit. Highly magnified. (After Waldeyer.)



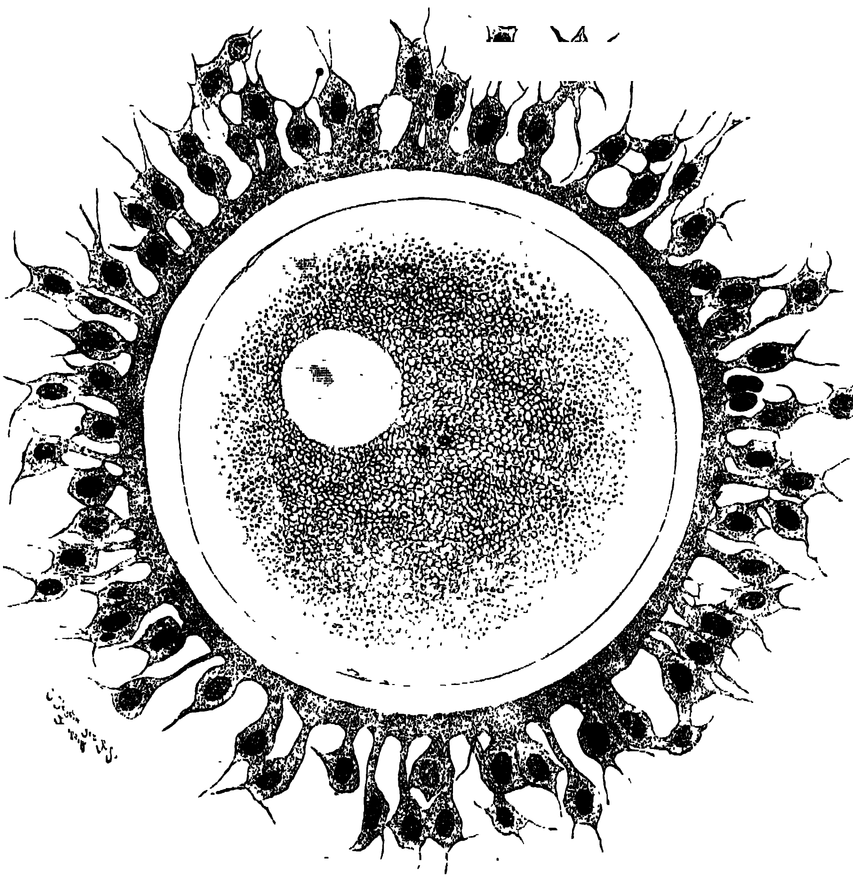
Having regard to the main purpose of this work, it is impossible, in the space available in this chapter, to describe fully, or illustrate adequately, all the phenomena which occur in the different stages of the development of the human body. The principal facts only will be given—the student being referred for further details to one or other of the text-books on human embryology.

THE OVUM

The ova are developed from the primitive germ-cells which are imbedded in the substance of the ovaries. Each of these cells gives rise, by repeated divisions, to a number of smaller cells termed *oögonia* from which the *ova* or *primary oöcytes* are developed.

Human ova are extremely minute, measuring about ·2 mm. or $\frac{1}{125}$ of an inch in diameter, and are enclosed within the egg-sacs or Graafian follicles of the ovaries.* By the enlargement and subsequent rupture of a Graafian follicle at the surface of the ovary an ovum is liberated and conveyed by the Fallopian tube or oviduct

FIG. 94.—Human ovum examined fresh in the liquor folliculi. (Waldeyer.)



The zona pellucida is seen as a thick clear girdle surrounded by the cells of the corona radiata. The egg itself shows a central granular deutoplasmic area and a peripheral clear layer, and encloses the germinal vesicle, in which is seen the germinal spot.

to the cavity of the uterus. Unless it be fertilised by a spermatozoön it undergoes no further development and is discharged from the uterus, but if fertilisation take place it is retained within the uterus and is developed into a new being.

In appearance and structure the ovum (figs. 93, 94) differs little from an ordinary cell, but distinctive names have been applied to its several parts; thus, the body of the cell is known as the *vitellus* or *yolk*, the nucleus as the *germinal vesicle*, and the nucleolus as the *germinal spot*. The ovum is enclosed within a thick, transparent envelope, the *zona pellucida* or *zona striata*, adhering to the outer surface of which are several layers of cells, derived from those of the Graafian follicle and collectively constituting the *corona radiata*.

* See description of the ovary on a future page.

The **vitellus** or **yolk** comprises (1) the *cytoplasm* of the ordinary animal cell with its reticulum and cytolymph, the cytoplasm of the ovum being frequently termed the *formative yolk*, in order to distinguish it from (2) the *nutritive yolk* or *deutoplasm*, which consists of numerous rounded granules of fatty and albuminoid substances imbedded in the cytoplasm. In the mammalian ovum the nutritive yolk is extremely small in amount, and is of service in nourishing the embryo in the early stages of its development only, whereas in the egg of the bird there is sufficient to supply the chick with nutriment throughout the whole period of incubation. The nutritive yolk not only varies in amount, but in its mode of distribution within the egg: thus, in some animals it is nearly uniformly distributed throughout the cytoplasm; in others it is centrally placed and is surrounded by the cytoplasm; in still others it is accumulated at the lower pole of the ovum, while the cytoplasm occupies the upper pole. An *attraction sphere* with its *centrosome* is present in the ova of the lower animals, and is probably represented in the ova of mammals by the *body of Balbiani*. This body is not visible during all the stages of the development of the ovum, and is 'most readily seen before the space appears in the Graafian follicle. Then the body in question lies in the immediate neighbourhood of the nucleus. It consists of a lighter central sphere enclosing one or two smaller spheres, and surrounded by a more darkly staining protoplasm.' *

The **germinal vesicle** or nucleus is a large spherical body which at first occupies a nearly central position, but becomes eccentric as the growth of the ovum proceeds. Its structure is that of an ordinary cell-nucleus, viz. it consists of a reticulum of achromatin the meshes of which are filled with nuclear sap or karyoplasm; while connected with, or imbedded in, the achromatic reticulum are a number of chromatin masses or chromosomes, which may present the appearance of a skein or may assume the form of rods or loops. The nucleus is enclosed by a delicate nuclear membrane, and contains in its interior a well-defined nucleolus or germinal spot.

COVERINGS OF THE OVUM

The **zona pellucida** or **zona striata** (figs. 93, 94) is secreted by the cells of the corona radiata, and consists of a thick, clear membrane, which, under the higher powers of the microscope, is seen to be perforated by numerous fine radially arranged channels. These give to it a striated appearance, and may suffice for the passage of nutritive materials to the ovum; they may also provide an entrance for the spermatozoa at the time of fertilisation. In some animals (e.g. insects) the zona pellucida presents one or more small perforations or *micropyles*, by which the spermatozoa are believed to enter. The zona pellucida persists for some time after fertilisation has occurred, and may serve for protection during the earlier stages of segmentation.

The **corona radiata** (fig. 94) consists of two or three strata of cells; they are derived from the cells of the Graafian follicle, and adhere to the outer surface of the zona pellucida when the ovum is set free from the follicle. The cells are radially arranged around the zona, those of the innermost layer being columnar in shape, and sending, according to some observers, delicate processes from their deep ends into the channels of the zona. The cells of the corona radiata soon disappear; in some animals they secrete, or are replaced by, a layer of adhesive protein, which may assist in protecting and nourishing the ovum.

The phenomena attending the discharge of the ova from the Graafian follicles belong more to the ordinary functions of the ovary than to the general subject of embryology, and are therefore described with the anatomy of the ovaries.†

MATURATION OF THE OVUM

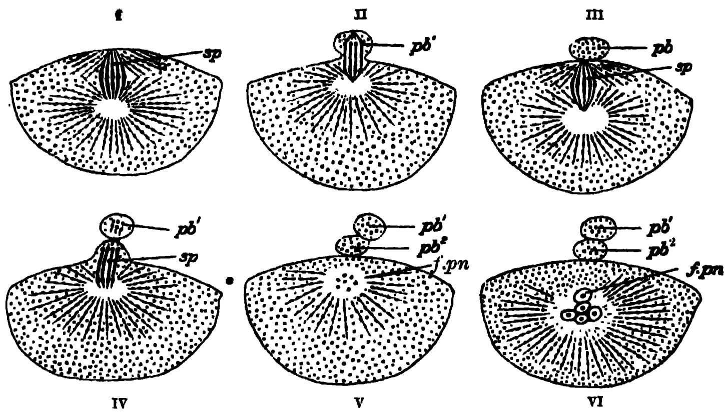
Before an ovum can be fertilised it must undergo a process of *maturation* or *ripening*. This takes place previous to, or immediately after, its escape from the Graafian follicle, and consists essentially of an unequal subdivision of the ovum (fig. 95) first into two and then into four cells. Three of the four are small, incapable

* Robinson, 'Hunterian Lectures on the Mammalian Ovum and Placenta.' *Journal of Anatomy and Physiology*, vol. xxxviii.

† See description of the ovary on a future page.

of further development, and are termed *polar bodies*, while the fourth is much larger, and constitutes the *mature ovum*. The process of maturation has not been observed

FIG. 95.—Formation of polar bodies in Asterias glacialis. (Slightly modified from Hertwig.)

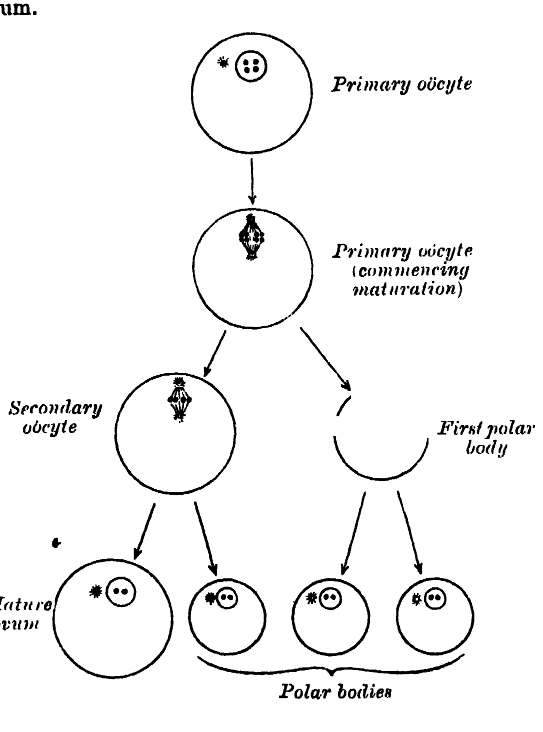


In fig. I the polar spindle (*sp*) has advanced to the surface of the egg. In fig. II a small elevation (*pb'*) is formed which receives half of the spindle. In fig. III the elevation is constricted off, forming the first polar body (*pb'*), and a second spindle is formed. In fig. IV is seen a second elevation which in fig. V has been constricted off as the second polar body (*pb²*). Out of the remainder of the spindle (*f.pn* in fig. VI) the female pronucleus is developed.

in the human ovum, but has been carefully studied in the ova of some of the lower animals, to which the following description applies.

It was pointed out on page 5 that the number of chromosomes found in the nucleus is constant for all the cells in an animal of any given species. This applies not only to the somatic cells but to the primitive ova and their descendants. For the sake of illustration a species may be taken in which the number of nuclear chromosomes is four (fig. 96). If an ovum from such be observed at the beginning of the maturation process it will be seen that the number of its chromosomes is apparently reduced to two. In reality, however, the number is doubled, since each chromosome consists of four granules grouped to form a *tetrad*. During the metaphase (see page 5) each tetrad divides into two *dyads*, which are equally distributed between the nuclei of the two cells formed by the first division of the ovum. One of the two cells is almost as large as the original ovum, and is named the *secondary oöcyte*; the other is small, and is termed the *first polar body*. The secondary oöcyte now undergoes subdivision, during which each dyad divides and contributes a single chromosome to the nucleus of each

FIG. 96.—Diagram showing the reduction in number of the chromosomes in the process of maturation of the ovum.

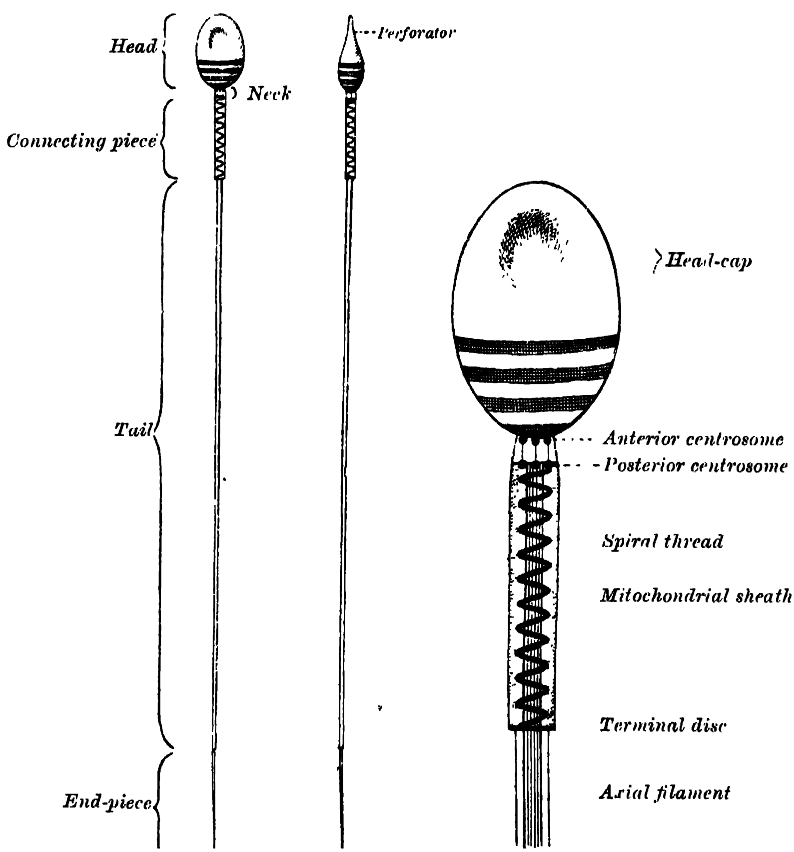


of the two resulting cells. This second division is also unequal, producing a large cell which constitutes the *mature ovum*, and a small cell, the *second polar body*. The first polar body frequently divides while the second is being formed, and as a final result four cells are produced, viz. the mature ovum and three polar bodies, each of which contains two chromosomes, i.e. one half the number present in the nuclei of the somatic cells of members of the same species. The nucleus of the mature ovum is termed the *female pronucleus*. The number of polar bodies varies in the ova of different animals; typically three are formed, but in some animals there is only one, in others there are two—the last condition being probably explained by the fact that the first polar body has not undergone subdivision by the time the second is separated from the ovum.

THE SPERMATOZOÖN

The spermatozoa or male germ-cells are developed within the tubuli seminiferi of the testes. They are present in enormous numbers in the seminal fluid, and consist of small but greatly modified cells. The human spermatozoön possesses a head, a neck, a connecting piece or body, and a tail (fig. 97).

FIG. 97.—Human spermatozoön. (Diagrammatic.)



A. Surface view. B. Profile view. In C the head, neck, and connecting piece are highly magnified.

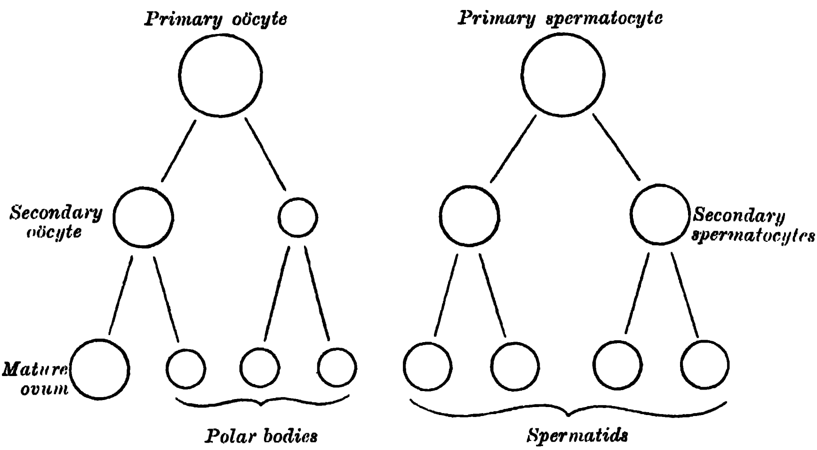
The **head** is oval or elliptical, but flattened, so that when viewed in profile it is pear-shaped. Its anterior two-thirds are covered by a layer of modified protoplasm, which is named the *head-cap*. This, in some animals (e.g. the salamander), is prolonged into a barbed spearlike process or *perforator*, which probably facilitates

the entrance of the spermatozoön into the ovum. von Bardeleben and E. Nelson have described spearlike perforators as being present in the human spermatozoa, but other observers deny their présence. Waldeyer inclines to the view that in man the perforator consists of the anterior sharp margin of the head-cap, and acts as a cutting rather than a boring apparatus. The posterior part of the head exhibits an affinity for certain reagents, and presents a transversely striated appearance, being crossed by three or four dark bands. In some animals a central rodlike filament extends forwards for about two-thirds of the length of the head, while in others a rounded body is seen near its centre. The head contains a mass of chromatin, and is generally regarded as the nucleus of the cell surrounded by a thin envelope.

The **neck** is less constricted in the human spermatozoön than in those of some of the lower animals. The *anterior centrosome*, represented by two or three rounded particles, is situated at the junction of the head and neck, and behind it is a band of homogeneous substance.

The **connecting piece** or **body** is rodlike, and is limited behind by a ring or *terminal disc*. The *posterior centrosome* is placed at the junction of the body and neck and, like the anterior, consists of two or three rounded particles. From this centrosome an *axial filament*, surrounded by a sheath, runs backwards through the body and tail. In the body the sheath of the axial filament is encircled by a

FIG. 98.—Scheme showing analogies in the process of maturation of the ovum and the development of the spermatids (young spermatozoa).



spiral thread, around which is an envelope of finely granular substance termed the *mitochondrial sheath*.

The **tail** is of great length, and consists of the axial thread or filament, surrounded by its sheath which may contain a spiral thread or may present a striated appearance. Further, in some animals there is attached to the connecting piece and tail a thin undulatory membrane, along the free edge of which there is a marginal filament. The terminal portion of the tail is named the *end-piece*, and consists of the axial filament only.

By virtue of their tails, which act as propellers, the spermatozoa, in the fresh condition, are capable of free movement, and if placed in favourable surroundings (e.g. in the female passages) may retain their vitality for several days.

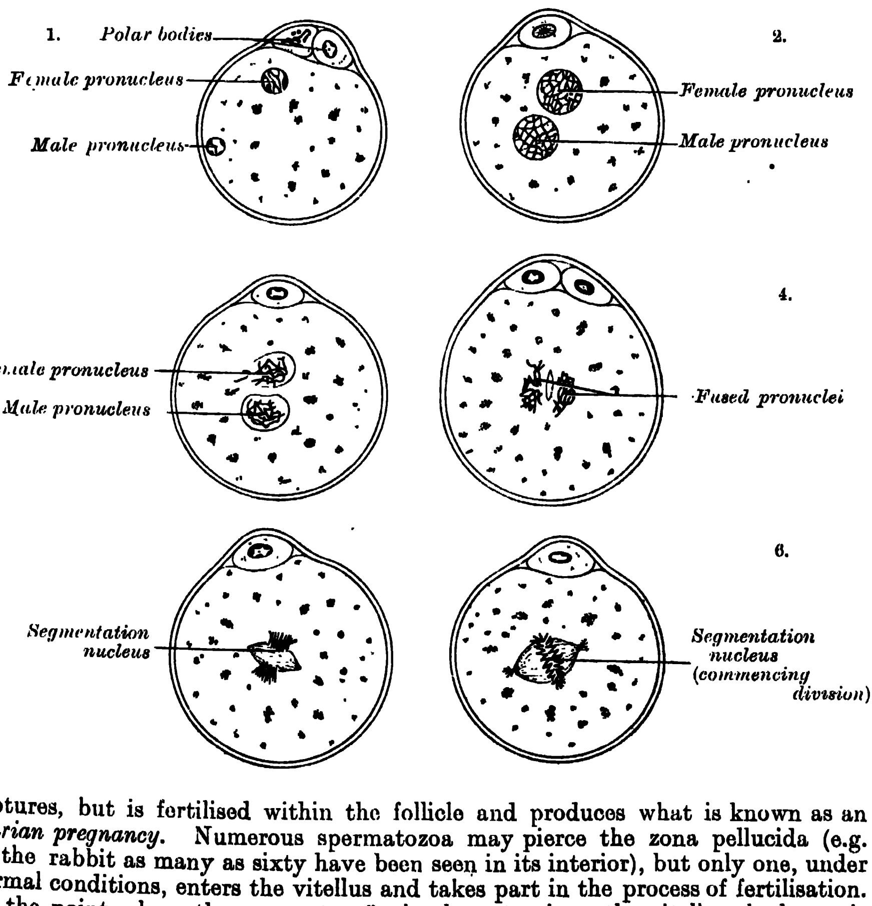
The spermatozoa are developed from the primitive germ-cells which have become imbedded in the testes, and the stages of their development are very similar to those of the maturation of the ovum. The primary germ-cells undergo division and produce a number of cells termed *spermatogonia*, and from these the *primary spermatocytes* are derived. Each primary spermatocyte divides into two *secondary spermatocytes*, and each secondary spermatocyte into two *spermatids* or young spermatozoa; from this it will be seen that a primary spermatocyte gives rise to *four* spermatozoa. On comparing this process with that of the maturation of the ovum (fig. 98) it will be observed that the primary spermatocyte gives rise to two cells, the secondary spermatocytes, and the primary oöcyte to two cells, the secondary oöcyte and the

first polar body. Again, the two secondary spermatocytes by their subdivision give origin to four spermatozoa, and the secondary oöcyte and first polar body to four cells, the mature ovum and three polar bodies. In the development of the spermatozoa, as in the maturation of the ovum, there is a reduction of the nuclear chromosomes to one half of those present in the primary germ cells. But here the similarity ends, for it must be noted that the four spermatozoa are of equal size, and each is capable of fertilising a mature ovum, whereas the three polar bodies are not only very much smaller than the mature ovum but are incapable of further development, and may be regarded as abortive ova.

FERTILISATION OF THE OVUM

Fertilisation consists in the union of the spermatozoön with the mature ovum (fig. 99). This usually takes place in the upper part of the Fallopian tube, and the ovum is then conveyed to the cavity of the uterus—a journey which probably occupies two or three days. Sometimes the fertilised ovum is arrested in the Fallopian tube and there undergoes development, giving rise to a *tubal pregnancy*; or it may fall into the abdominal cavity and produce an *abdominal pregnancy*. Occasionally the ovum is not expelled from the Graafian follicle when the latter

FIG. 99.—The process of fertilisation in the ovum of a mouse. (After Sobotta.)



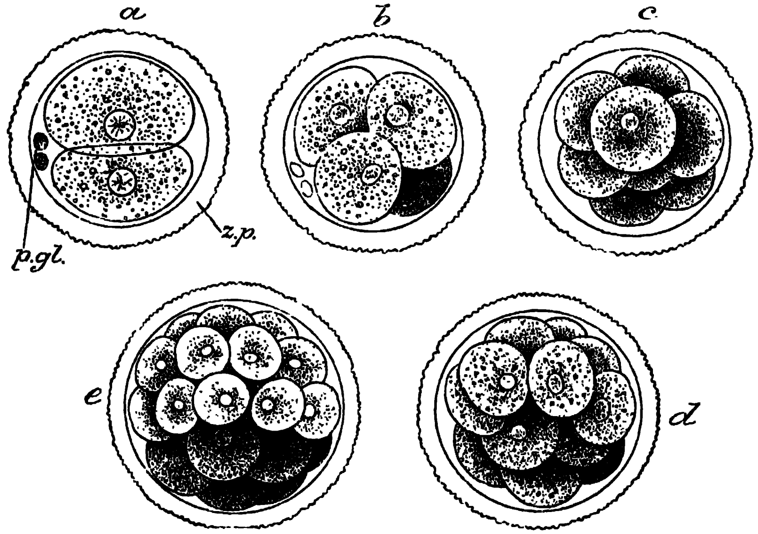
ruptures, but is fertilised within the follicle and produces what is known as an *ovarian pregnancy*. Numerous spermatozoa may pierce the zona pellucida (e.g. in the rabbit as many as sixty have been seen in its interior), but only one, under normal conditions, enters the vitellus and takes part in the process of fertilisation. At the point where the spermatozoön is about to pierce the vitellus the latter is drawn out into a conical elevation, termed the *cone of attraction*. As soon as the spermatozoön has entered at this point the peripheral portion of the vitellus is transformed into a membrane, the *vitelline membrane*, which prevents the passage of

additional spermatozoa. Occasionally a second spermatozoön may enter the vitellus, thus giving rise to a condition of *polyspermy*: when this occurs the ovum usually develops in an abnormal manner and gives rise to a monstrosity. Having pierced the vitellus, the spermatozoön loses its tail, while its head and connecting piece assume the form of a nucleus containing a cluster of chromosomes. This constitutes the *male pronucleus*, and associated with it there are a centrosome and attraction sphere. The male pronucleus passes more deeply into the vitellus, and coincident with this the granules of the cytoplasm surrounding it become radially arranged. The male and female pronuclei migrate towards each other, and, meeting near the centre of the vitellus, fuse to form a new nucleus, the *segmentation nucleus*, which therefore contains both male and female nuclear substance; the former transmits the individualities of the male ancestors, the latter those of the female ancestors, to the future embryo. By the union of the male and female pronuclei the number of chromosomes is restored to that which is present in the nuclei of the somatic cells.

SEGMENTATION OF THE FERTILISED OVUM

After it has been fertilised the ovum undergoes repeated subdivision into a number of small cells (figs. 100, 101). The segmentation nucleus exhibits the usual mitotic changes, and these are succeeded by a division of the ovum into two cells of nearly equal size.* The process is repeated again and again, so that the two

FIG. 100.—First stages of segmentation of a mammalian ovum: semi-diagrammatic. (From a drawing by Allen Thomson.)



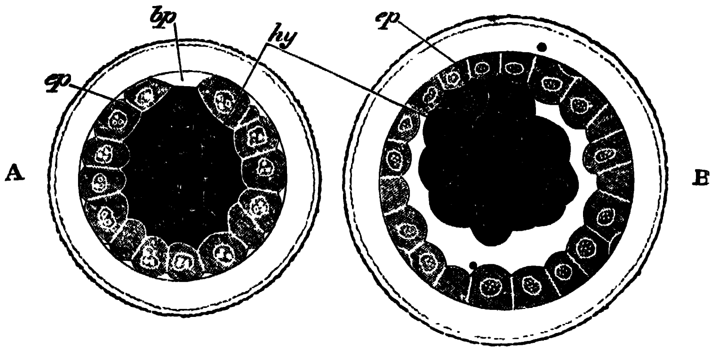
z.p. Zona pellucida. *p.gl.* Polar bodies. *a.* Two-cell stage. *b.* Four-cell stage. *c.* Eight-cell stage. *d, e.* Morula stage.

cells are succeeded by four, eight, sixteen, thirty-two, and so on, with the result that a mass of cells is found within the zona pellucida (which itself takes no share in the process, but ultimately disappears), and to this mass the term *morula* is applied.

* In the mammalian ova the nutritive yolk or deutoplasm is small in amount and uniformly distributed throughout the cytoplasm; such ova undergo *complete* division during the process of segmentation, and are therefore termed *holoblastic*. In the ova of birds, reptiles, and fishes where the nutritive yolk forms by far the larger portion of the egg the cleavage is limited to the formative yolk, and is therefore only *partial*; such ova are termed *meroblastic*. Again, it has been observed, in some of the lower animals, that the pronuclei do not fuse but merely lie in apposition. At the commencement of the segmentation process the chromosomes of the two pronuclei group themselves around the equator of the nuclear spindle and then divide; an equal number of male and female chromosomes travel to the opposite poles of the spindle, and thus the male and female pronuclei subscribe equal shares of chromatin to the nuclei of the two cells which result from the subdivision of the fertilised ovum.

The segmentation of the mammalian ovum may not take place in the regular sequence of two, four, eight, &c., since one of the two first-formed cells may subdivide more rapidly than the other, giving rise to a three- or a five-cell stage.

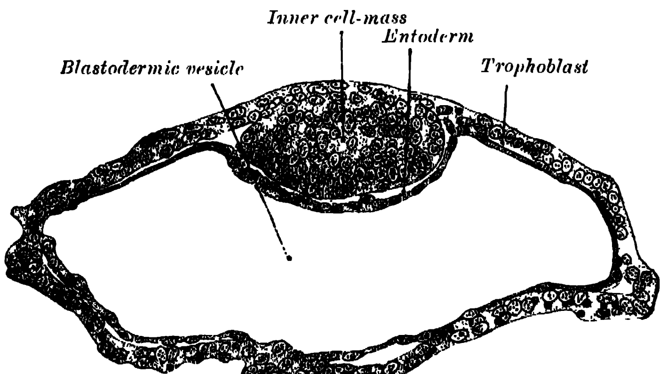
FIG. 101.—Ovum of the rabbit at the end of the process of segmentation.



ep. Primitive ectoderm. *hy.* Primitive entoderm. *bp.* Place where the ectoderm has not yet grown over the entoderm. (From Balfour, after Ed. van Beneden.)

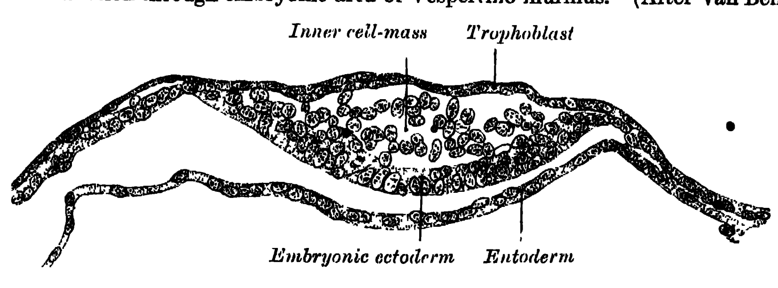
The cells of the morula are at first closely aggregated inside the zona pellucida; but soon they become arranged into an outer or peripheral layer, the *primitive ectoderm* or *trophoblast*, which does not contribute to the formation of the embryo

FIG. 102.—Blastodermic vesicle of Vespertilio murinus. (After van Beneden.)



proper, and an *inner cell-mass*, from which the embryo is developed (figs. 101, B, and 102). Fluid collects between the trophoblast and the greater part of the inner cell-mass, and thus the morula is converted into a vesicle, the *blastodermic vesicle.*

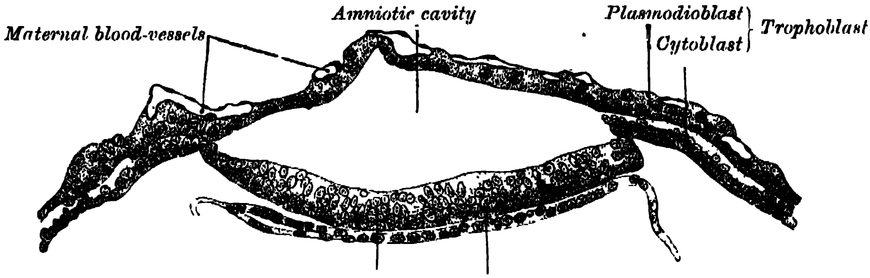
FIG. 103.—Section through embryonic area of Vespertilio murinus. (After van Beneden.)



The inner cell-mass remains in contact, however, with the trophoblast at one pole of the ovum; this is named the *embryonic pole*, since it indicates the situation where the future embryo will be developed. The cells of the trophoblast become

differentiated into two strata : an outer, termed the *syncytium* or *plasmodioblast*, so named because it consists of a layer of protoplasm studded with nuclei, but showing no evidence of subdivision into cells ; and an inner layer of prismatic epithelium, which is named the *cytoblast* or *layer of Langhans*. As already stated, the cells of the trophoblast do not contribute to the formation of the embryo proper ; they form the ectoderm of the chorion and play an important part in the development of the placenta. On the inner surface of the inner cell-mass a layer of flattened cells, the *entoderm*, is differentiated and quickly assumes the form of a

FIG. 104.—Section through embryonic area of Vespertilio murinus (after van Beneden) to show the formation of the amniotic cavity.



small sac, the *yolk-sac*. Spaces appear between the remaining cells of the mass (fig. 103), and by the enlargement and coalescence of these spaces a cavity, termed the *primitive amniotic cavity* (fig. 104), is gradually developed. This cavity persists in certain of the bats, and probably also in man and monkeys, to form the permanent amniotic cavity. The floor of this cavity is formed by a layer of prismatic cells, the *embryonic ectoderm*, derived from the inner cell-mass and lying in apposition with the entoderm. The formation of the amnion will be again referred to (page 93).

THE EMBRYONIC AREA

In reptiles, birds, and mammals, only a part of the ovum is utilised in the development of the embryo proper, the remainder being used up in the formation of membranes and other appendages which are concerned with its protection and nutrition ; the ovum therefore may be divided into *embryonic* and *extra-embryonic areas* (figs. 105, 106). If the ovum, at this stage, be viewed from the surface it will be seen to exhibit a centrally placed, circular, opaque area surrounded by a more transparent portion. The central opaque part is the embryonic area, and is equal in extent to the embryonic ectoderm already mentioned ; the peripheral clearer portion is the extra-embryonic area. The circumference of the embryonic region 'remains as a relatively slow-growing area, while the embryonic and extra-embryonic portions of the wall of the ovum rapidly increase in extent. Under these circumstances it follows that the margin of the embryonic area will soon appear as a ring between the upper embryonic and the lower or extra-embryonic parts of the ovum, both of which have expanded beyond it in all directions' (Robinson).* The circumference of the embryonic area corresponds with the future umbilicus.

The primitive streak; formation of the mesoderm.—The embryonic area becomes oval and then pear-shaped, the wider end being directed forwards. At the narrow, posterior end an opaque, crescent-shaped patch makes its appearance, and gradually extends forwards as a dark streak, the *primitive streak*, along the middle line of the area for about one-half of its length (figs. 105, 106). A shallow groove, the *primitive groove*, appears on the surface of the streak, and the anterior end of this groove communicates by means of an aperture, the *blastopore*, with the primitive alimentary canal. The primitive streak is produced by a thickening of the axial part of the ectoderm, the cells of which multiply, grow downwards, and blend with those of the subjacent entoderm (fig. 107). From the sides of the primitive

* 'The Early Stages of the Development of the Pericardium,' by Professor Arthur Robinson. *Journal of Anatomy and Physiology*, vol. xxxvii.

streak a third layer of cells, the *mesoderm* or *mesoblast*, extends outwards between the ectoderm and entoderm. Although the mesoderm is mainly derived from the primitive streak, possibly the entoderm also contributes to it.

The extension of the mesoderm takes place throughout the whole of the embryonic and extra-embryonic areas of the ovum, except in certain regions. One of these is seen immediately in front of the neural tube. Here the mesoderm extends forwards in the form of two crescentic masses, which curve inwards and meet in

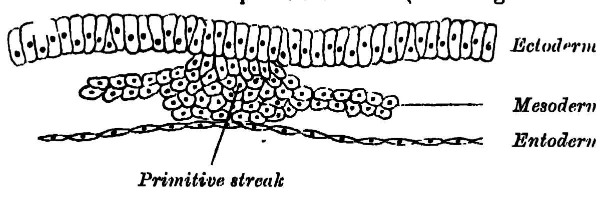
the middle line so as to enclose behind them an area which is devoid of mesoderm and is named the *bucco-pharyngeal area*, since it afterwards forms the septum between the primitive mouth and primitive pharynx. In front of the bucco-pharyngeal area, where the lateral crescents of mesoderm have fused in the middle line, the pericardium is afterwards developed, and this region is therefore designated the *pericardial area*. A second region where the mesoderm is absent, at least for a time, is that immediately in front of the pericardial area. This is termed the *pro-amniotic area*, and is the region where the *pro-amnion* is developed; in man however, a pro-amnion is apparently never formed. Other regions are: a band on the ventral aspect of the neural tube in the site of the future vertebral column, and an area at the hinder end of the embryo in the position of the cloaca.

FIG. 107.—Section across primitive streak (semi-diagrammatic).



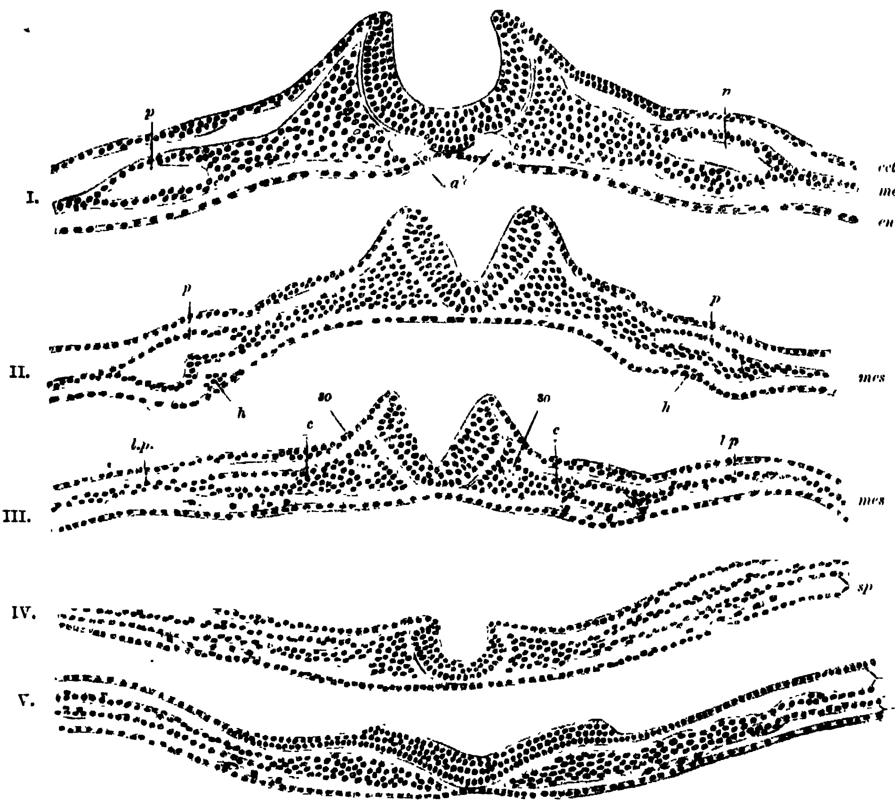
The blastoderm now consists of three layers, named from without inwards, ectoderm, mesoderm and entoderm. Each has distinctive characteristics and gives rise to certain tissues of the body.

The **ectoderm** consists of columnar cells, which are, however, somewhat flattened or cubical towards the margin of the embryonic area. It forms the whole of the nervous system, the epidermis of the skin, the lining cells of the sebaceous, sweat and mammary glands, the hairs and nails, the epithelium of the nose and adjacent air-sinuses, and that of the cheeks and roof of the mouth. From it also

are derived the enamel of the teeth, and the anterior lobe of the pituitary body, the epithelium of the cornea, conjunctiva, and lachrymal glands, and the neuro-epithelium of the sense organs.

The **entoderm** consists at first of flattened cells, which subsequently become columnar. It forms the epithelial lining of the whole of the alimentary canal excepting part of the mouth and pharynx and the terminal part of the rectum (which are lined by involutions of the ectoderm), the lining cells of all the glands

Fig. 108.—A series of transverse sections through an embryo of the dog. (After Bonnet.) Section I. is the most anterior. In V. the neural plate is spread out nearly flat. The series shows the uprising of the neural folds to form the neural canal.



a, aortæ; *c*, intermediate cell-mass; *ect*, ectoderm; *ent*, entoderm; *h*, *h*, rudiments of endothelial heart-tubes. In III., IV., and V. the scattered cells represented between the entoderm and splanchnic layer of mesoderm are the vaso-formative cells which give origin in front, according to Bonnet, to the heart-tubes *h*; *l.p.*, lateral plate still undivided in I., II., and III.: in IV. and V. split into somatic (*sm*) and splanchnic (*sp*) layers of mesoderm; *mes*, mesoderm; *p*, pericardium; *so*, primitive segment.

which open into the alimentary canal, including those of the liver and pancreas, the epithelium of the Eustachian tube and tympanic cavity, of the trachea, bronchi, and air-cells of the lungs, of the urinary bladder and part of the urethra, and that which lines the follicles of the thyroid and thymus glands.

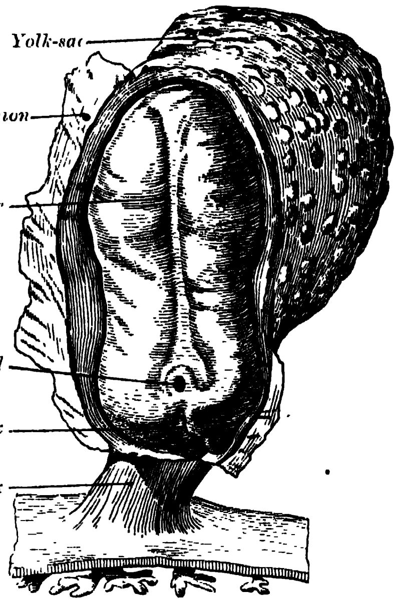
The **mesoderm** consists of loosely arranged branched cells surrounded by a considerable amount of intercellular fluid. From it the remaining tissues of the body are developed. The epithelial lining of the heart and blood-vessels is, however, regarded by some as being of entodermal origin.

THE NEURAL GROOVE AND TUBE

In front of the primitive streak two longitudinal ridges, caused by a looping or folding up of the ectoderm, make their appearance, one on either side of the middle line (fig. 106). These are named the *neural* or *medullary folds*; they commence some distance behind the anterior end of the embryonic area, where they are

continuous with each other, and from there gradually extend backwards, one on either side of the primitive streak. Between these folds is seen a mesial, longitudinal groove, the *neural groove* (figs. 108, 109), which gradually deepens as the medullary folds become elevated. Ultimately the folds meet and coalesce in the middle line, converting the neural groove into a closed tube, the *neural tube* or *canal* (fig. 111), the surrounding ectodermal wall of which forms the rudiment of the nervous system. By the coalescence of the medullary folds over the anterior end of the primitive streak, the blastopore no longer opens on the surface but into the closed canal of the neural tube, and thus a transitory communication, the *neurenteric canal*, is established between the neural tube and the primitive alimentary canal. The coalescence of the medullary folds occurs first in the region of the hind-brain, and from there extends forwards and backwards; the hinder part of the neural groove presents for a time a rhomboidal shape, and to this expanded portion the term *sinus rhomboidalis* has been applied (fig. 110). Before the neural groove is closed to form the neural tube a ridge of ectodermal cells appears along the prominent margin of each medullary fold; this is termed the *neural crest* or *ganglion ridge* (fig. 150), and from it the spinal and cranial nerve ganglia and the ganglia of the sympathetic nervous system are developed.

Fig. 109.—Human embryo—length 2 mm. Dorsal view, with the amnion laid open. × 30. (After Graf Spee; reconstruction.)



The cephalic end of the neural groove exhibits several dilatations, which, when the tube is closed, assume the form of three vesicles; these constitute the three primary cerebral vesicles, and correspond respectively to the future *fore-brain*, *mid-brain*, and *hind-brain* (fig. 110). Their walls are developed into the nervous tissue and neuroglia of the brain, while their cavities become modified to form its ventricles. The remainder of the tube forms the central canal of the spinal cord, whilst from its ectodermal wall the nervous and neuroglial elements of the spinal cord are developed.

THE NOTOCHORD

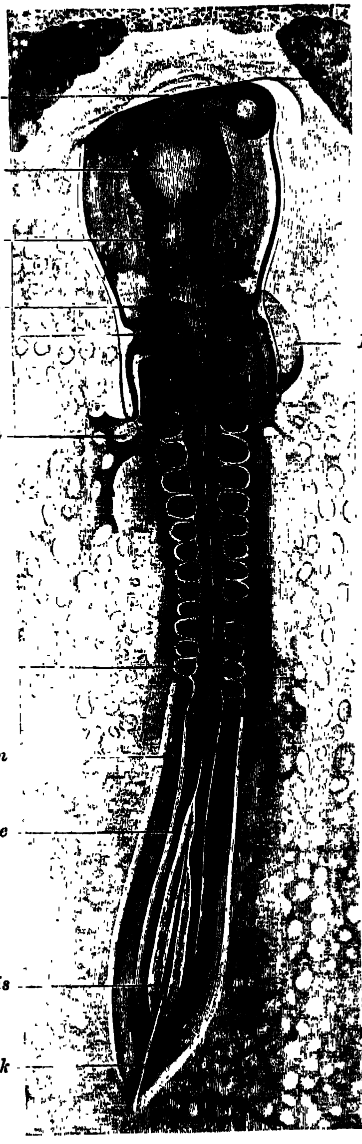
The **notochord** (fig. 111) consists of a rod of cells situated on the ventral aspect of the neural tube; it constitutes the foundation of the axial skeleton, since around it the segments of the vertebral column are formed. Its appearance synchronises with that of the neural tube. On the ventral aspect of the neural groove an axial thickening of the entoderm takes place; this thickening assumes the appearance of a furrow—the *chordal furrow*—the margins of which come into contact, and so convert it into a solid rod of cells—the *notochord*—which is then separated from the entoderm. It extends throughout the entire length of the future vertebral column, and reaches as far as the anterior end of the mid-brain. Its cephalic extremity lies immediately behind the pituitary invagination of the stomatodæum, where it ends in a hook-like extremity in the region of the future dorsum sellæ of the sphenoid bone. It lies at first between the neural tube and the entoderm of the primitive alimentary canal, but soon becomes separated from them by the mesoderm, which grows inwards and

surrounds it. From this surrounding mesoderm the vertebral column, the basi-occipital and basi-sphenoidal portions of the skull and the membranes of the brain and spinal cord are developed.

FORMATION OF THE BODY CAVITY OR CŒLOM

As the mesoderm develops between the ectoderm and entoderm it is separated into lateral halves by the neural tube and notochord. A longitudinal groove appears on the dorsal surface of either half and divides it into an inner column, the

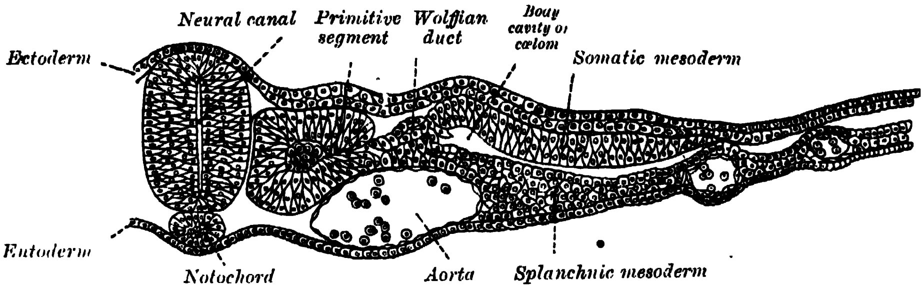
Fig. 110.—Chick embryo of thirty-three hours' incubation, viewed from the dorsal aspect. × 30. (From Duval's 'Atlas d'Embryologie.')



paraxial mesoderm, lying on the side of the neural tube, and an outer portion, the *lateral mesoderm*, which is not confined to the embryonic area but extends beyond it into the extra-embryonic region. The mesoderm lying in the floor of the groove connects the paraxial with the lateral mesoderm and is known as the *intermediate*

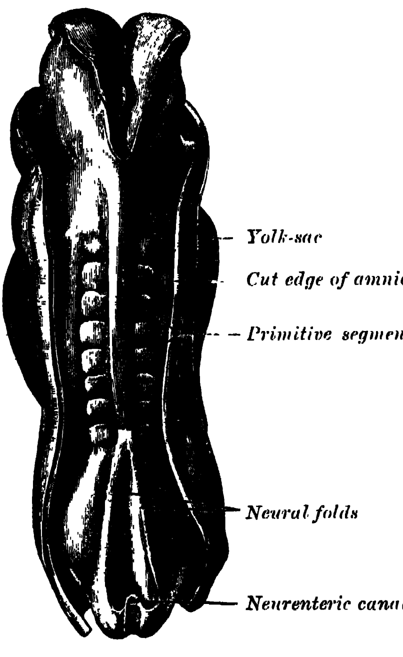
ll-mass; in it the genito-urinary organs are developed. The lateral mesoderm splits into two layers, an outer or *somatic*, which becomes applied to the inner surface of the ectoderm, and with it forms the *somatopleure*; and an inner or

Fig. 111.—Section across the dorsal part of a chick embryo of forty-five hours' incubation. (Balfour.)



splanchnic, which adheres to the entoderm, and with it forms the *splanchnopleure* (fig. 111). The space between the two layers of the lateral mesoderm is termed the *body cavity* or *cœlom*. A portion of this space is enclosed within the embryo and is named the *embryonic cœlom*; it forms the rudiment of the pleural, pericardial, and peritoneal cavities, while the portion left outside the embryo, the *extra-embryonic cœlom*, envelops the yolk-sac.

Fig. 112.—Dorsum of human embryo, 2·11 mm. in length. (After Eternod.)



THE PRIMITIVE SEGMENTS OR PROTOVERTEBRAL SOMITES

Towards the end of the second week the paraxial mesoderm becomes segmented and converted into a series of well-defined, more or less cubical areas, the *primitive segments* or *protovertebral somites* (figs. 110, 111, and 112), which extend from the occipital region of the head along the entire length of the trunk on either side of the middle line.

They lie immediately under the ectoderm on the lateral aspect of the neural tube and notochord, and are connected to the lateral mesoderm by the *intermediate cell-mass*. The cells of each somite encircle a central cavity—the *myocœl*—which, however, soon becomes filled with angular and spindle-shaped cells. The somites of the trunk may be arranged in the following groups, viz.: cervical 8, thoracic 12, lumbar 5, sacral 5, and coccygeal from 5 to 8. Those of the occipital region of the head are usually described as being four in number. In mammals primitive segments can only be recognised in the occipital region of the head, but a study of the lower vertebrates leads to the belief that they are present also in the anterior part of the head, and that altogether nine segments are represented in the cephalic region.

DELIMITATION OF THE EMBRYO

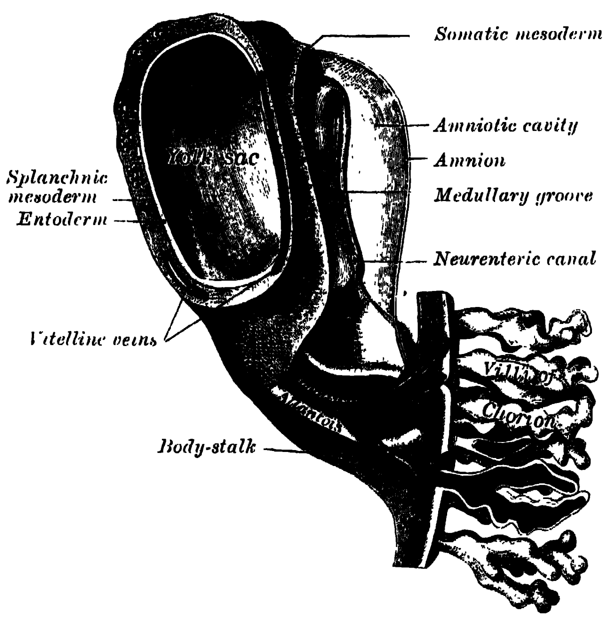
As has been pointed out, the margin of the embryonic area is of relatively slow growth, and thus it comes to form a ring of constriction between the embryo and the yolk-sac, and a part of the latter is enclosed within the embryo to form

the primitive alimentary canal (fig. 114). At the same time a part of the cœlom is enclosed within the embryo and forms the rudiment of the pleural, pericardial, and peritoneal cavities. Although the embryo grows in all directions, it increases much more rapidly in length than in width, and its cephalic and caudal extremities are bent downwards to form the *cephalic* and *caudal folds* respectively (figs. 198 and 199). The pro-amniotic area, lying immediately in front of the pericardial area (see page 87), forms the anterior limit of the slow-growing embryonic margin. The forward growth of the head therefore carries with it the posterior end of the pericardial area so that this area becomes inverted; its posterior border becomes anterior and its dorsal surface ventral. When the cephalic and caudal flexures have been formed, the primitive alimentary canal presents the appearance of a nearly straight tube, closed at its two extremities. This tube is divided into three portions, viz.: (*a*) the *fore-gut*, between the pericardium and the notochord; (*b*) the *mid-gut*, opening directly into the yolk-sac; and (*c*) the *hind-gut*, contained within the caudal fold (fig. 199). The passage between the mid-gut and the yolk-sac is at first relatively wide, but it is gradually narrowed and at the same time lengthened to form a tubular duct, the *vitelline duct.*

MEMBRANES AND APPENDAGES OF THE EMBRYO.*

These are concerned with the protection and nourishment of the embryo, and comprise (1) the yolk-sac, the amnion, the allantois, the chorion, and the umbilical cord, which are of embryonic origin; (2) the decidua, which is produced by a modification of the mucous membrane of the uterus; and (3) the placenta, which is derived partly from embryonic and partly from maternal tissues.

Fig. 113.—Model of human embryo 1·3 mm. long. (After Eternod.)

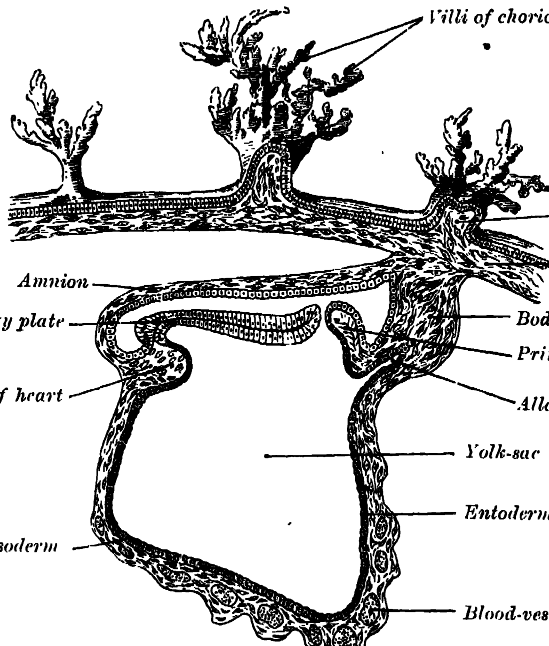


The **yolk-sac** (figs. 113, 114, 115) is an appendage of the alimentary canal and, like that tube, it is lined by entoderm, outside of which is a layer of mesoderm. Situated on the ventral aspect of the embryo, it is at first comparatively large, and communicates with the mid-gut by means of a relatively wide opening. It is filled with fluid, the *vitelline fluid*, which possibly may be utilised for the nourishment of the embryo during the earlier stages of its existence. Blood is conveyed to the

* The term embryo is often confined to a developing ovum up to the age of four months; generally, however, the terms embryo and fœtus are interchangeable.

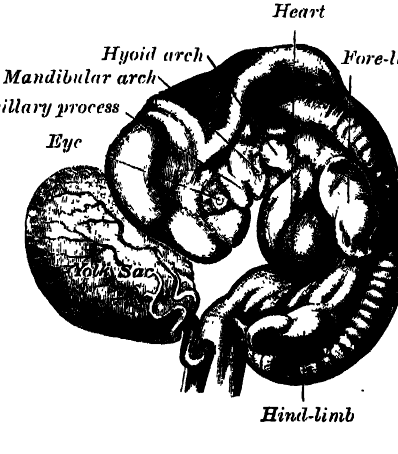
wall of the sac by the primitive aortæ, and after circulating through a wide-meshed capillary plexus, termed the *vascular area*, is returned by the vitelline veins to the tubular heart of the embryo. This constitutes the *vitelline* circulation, and by means

FIG. 114.—Section through the embryo which is represented in fig. 109. (After Graf Spee.)



of it nutritive material is absorbed from the yolk-sac and conveyed to the embryo. At the end of the fourth week the yolk-sac presents the appearance of a small pear-shaped vesicle opening into the alimentary canal by a long narrow tube, the *vitelline duct*. The vesicle may be seen at birth as a small sac near the placenta, but the duct is soon obliterated; its proximal part, however, sometimes persists in the adult as a diverticulum from the small intestine. It is known as *Meckel's diverticulum*, is situated from two to four feet above the ileo-colic junction, and may be attached by a fibrous cord to the abdominal wall at the umbilicus.

FIG. 115.—Human embryo from thirty-one to thirty-four days. (His.)



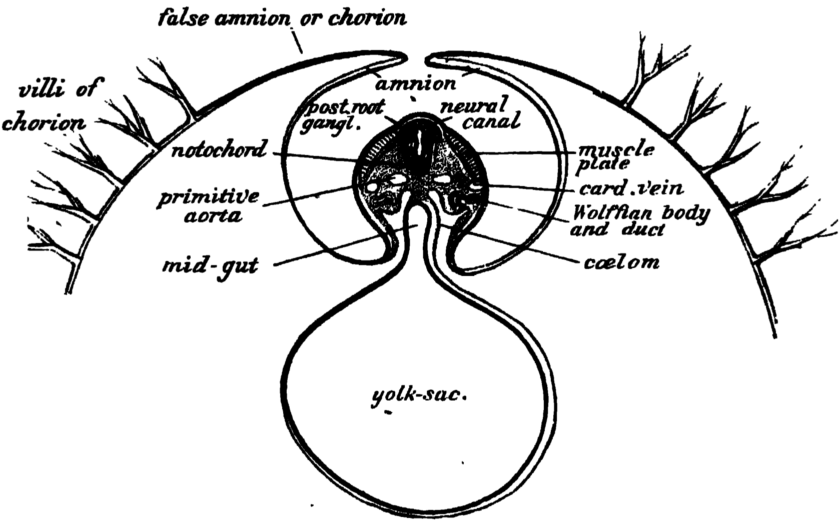
The **amnion** is a membranous sac which surrounds and protects the embryo. It is developed in reptiles, birds, and mammals, which are hence called 'Amniota'; but not in amphibia and fishes, which are consequently termed 'Anamnia.'

In reptiles, birds, and many mammals it is developed in the following manner. At the point of constriction where the primitive alimentary canal of the embryo joins the yolk-sac—i.e. in the region of the future umbilicus—a reflection or folding upwards of the somatopleure takes place. This, the *amniotic fold* (fig. 116), first makes its appearance at the cephalic extremity, and subsequently at the caudal end and sides of the embryo, and gradually rising more and more, its different parts meet and fuse over the dorsal aspect of the embryo, and enclose a cavity, the *amniotic*

cavity. After the fusion of the edges of the amniotic fold, the two layers of the fold become completely separated, the inner forming the *amnion*, the outer the *false amnion* or *serosa* (fig. 116). The space between the amnion and the serosa constitutes the extra-embryonic cœlom, already referred to, and for a time communicates with the embryonic cœlom or primitive pleuro-peritoneal cavity.

In the human embryo the earliest stages of the formation of the amnion have not been observed ; in the youngest embryo which has been studied the amnion was already present as a closed sac (figs. 117, 123). As indicated on page 86, the primitive amniotic cavity which appears in the inner cell mass is probably retained in the human embryo, as in that of the bat, to form the permanent amniotic cavity. This cavity is roofed in by a single stratum of flattened ectodermal cells, the *amniotic ectoderm*, and its floor consists of the prismatic ectoderm of the embryonic disc—the continuity between the prismatic embryonic ectoderm and the flattened amniotic ectoderm being established at the margin of the embryonic area. Outside the amniotic ectoderm is a thin layer of mesoderm, which separates it from the chorionic ectoderm or trophoblast and is continuous with the mesoderm of the body-stalk and with the somatic mesoderm of the embryo. Mall suggests that the human amnion may be formed by an inversion of the blastoderm.

Fig. 116.—Diagram of a transverse section, showing the mode of formation of the amnion in the chick. The amniotic folds have nearly united in the middle line. (From Quain's 'Anatomy,' vol. i. pt. 1, 1890.)



Ectoderm, blue ; mesoderm, red ; entoderm and notochord, black.

When first formed the amnion is in close contact with the body of the embryo, but about the fourth or fifth week fluid begins to accumulate within it. This fluid constitutes the *liquor amnii*, and, increasing in quantity, causes the amnion to expand and ultimately to adhere to the inner surface of the chorion, so that the extra-embryonic part of the cœlom is obliterated. The amnion therefore covers the inner surface of the chorion and the fœtal aspect of the placenta. The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, after which it diminishes somewhat in amount. It allows of the free movements of the fœtus during the later stages of pregnancy, and also protects it by diminishing the risk of injury from without. It contains less than two per cent. of solids, which consist of urea and other extractives, inorganic salts, a small amount of protein, and frequently a trace of sugar. That part of the liquor amnii is swallowed by the fœtus is proved by the fact that epidermal debris and hairs have been found among the contents of the fœtal alimentary canal.

The **allantois** (figs. 114, 119, 120).—The allantois arises as a diverticulum from that part of the hind-gut which later forms the cloaca : it grows out into the body-stalk, a mass of mesoderm which lies below and around the tail end of the embryo. The diverticulum is lined by entoderm and covered by mesoderm, and in the latter are carried the allantoic or umbilical vessels.

In reptiles, birds, and many mammals the allantois becomes expanded into a vesicle (fig. 199) which projects into the extra-embryonic cœlom, i.e. into the space between the amnion and the serosa. If its further development be traced in the bird, it is seen to project to the right side of the embryo, and, gradually expanding, it spreads over its dorsal surface as a flattened sac between the amnion and the serosa, and, extending in all directions, ultimately surrounds the yolk. Its outer wall becomes applied to, and fuses with, the serosa, which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by the two allantoic or umbilical arteries, which are continuous with the primitive aortæ, and, after circulating through the allantoic capillaries, is returned to the primitive heart by the two umbilical veins. In this way the allantoic circulation, which is of the utmost importance in connection with the respiration and nutrition of the chick, is established. Oxygen is taken from, and carbonic acid is given up to the atmosphere through the egg-shell, while nutritive materials are at the same time absorbed by the blood from the yolk.

In man and other primates the nature of the allantois is entirely different from that just described. Here it exists merely as a narrow, tubular diverticulum of the hind-gut, and never assumes the form of a vesicle outside the embryo. With the formation of the amnion the embryo is, in most animals, entirely separated from the chorion, and is only again united to it when the allantoic mesoderm spreads over and becomes applied to its inner surface The human embryo, on the other hand, as was pointed out by His, is never wholly separated from the chorion, its tail end being from the first connected with the chorion by means of

FIG. 117.—Diagram showing earliest observed stage of human ovum.

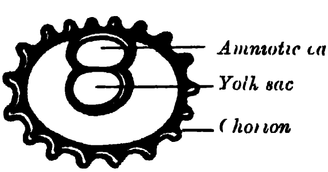


FIG. 118.—Diagram illustrating early formation of allantois and differentiation of body-stalk.

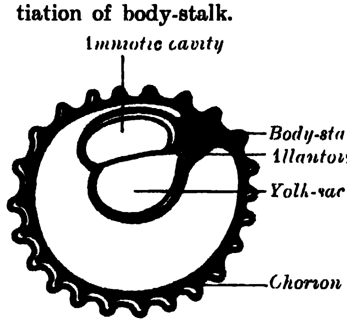

a thick band of mesoderm, named the *body-stalk* (*Bauchstiel*) (figs. 118 and 119); into this stalk the tube of the allantois extends (fig. 113). Moreover, in the human embryo the allantoic diverticulum is seen before the hind-gut is formed, and appears as a tubular protrusion from the yolk-sac (fig. 114). The body-stalk is at first attached to the hind-end of the embryo, but with the growth of the tail and the formation of the caudal flexure it assumes a ventral position, and the tubular allantois is then seen to open from the cloacal part of the hind-gut. The umbilical orifice divides the allantois into two portions—an intra-abdominal and an extra-abdominal. The latter persists till birth in a rudimentary condition; the proximal part of the intra-abdominal portion takes part in the formation of the cloaca. After the subdivision of the cloacal part of the hind-gut into bladder and rectum has taken place the distal part of the intra-abdominal portion of the allantois becomes obliterated and forms a fibrous cord, the *urachus*, which reaches from the summit of the bladder to the umbilicus.

The **umbilical cord** and **body-stalk** (figs. 119, 120, 121).—The rudiment of the umbilical cord is represented by the tissue which separates the rapidly growing embryo from the extra-embryonic area of the ovum. Included in this tissue are the body-stalk and the vitelline duct—the former containing the allantoic diverticulum and the umbilical vessels, the latter forming the communication between the alimentary canal and the yolk-sac. The *body-stalk* is the posterior segment of the embryonic area, and is attached to the chorion. It consists of a plate of mesoderm covered by thickened ectoderm on which a trace of the neural groove can be seen, indicating its continuity with the embryo. Running through its mesoderm are the two umbilical arteries and the two umbilical veins, together with the canal

of the allantois—the last being lined by entodermal epithelium. Its dorsal surface is covered by the amnion, while its ventral surface is bounded by the extra-embryonic cœlom, and is in contact with the vitelline duct and yolk-sac. With the rapid elongation of the embryo and the formation of the tail fold, the body-stalk

FIG. 119.—Diagram showing later stage of allantoic development with commencing constriction of the yolk sac.

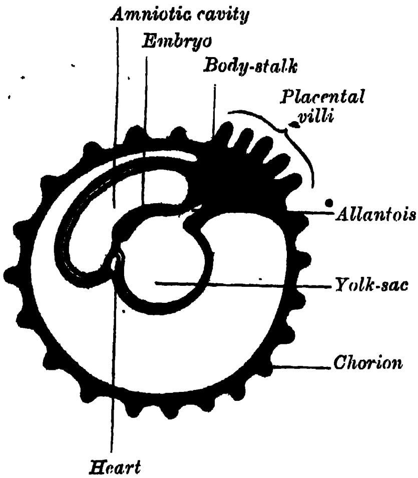

FIG. 120.—Diagram showing the expansion of amnion and delimitation of the umbilicus.

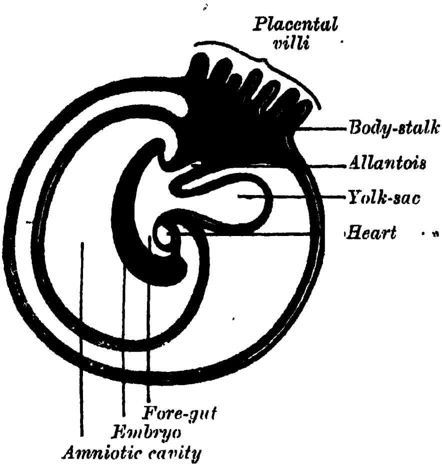
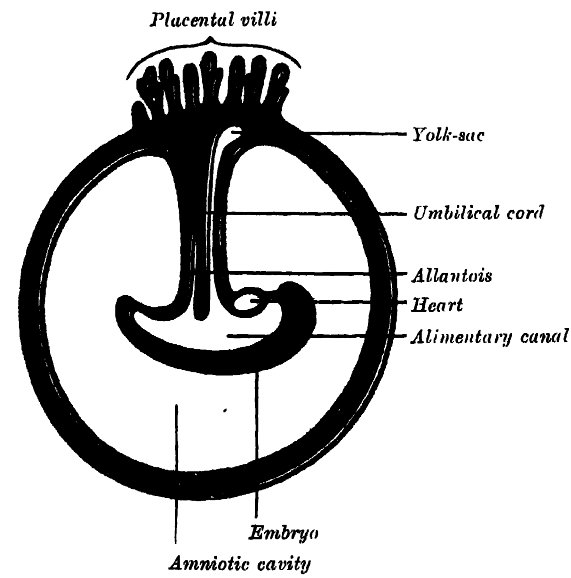


comes to lie on the ventral surface of the embryo, where its mesoderm blends with that of the yolk-sac and the vitelline duct. The lateral leaves of somatopleure then grow round on each side, and, meeting on the ventral aspect of the allantois, enclose the vitelline duct and vessels, together with a part of the embryonic

FIG. 121.—Diagram illustrating a later stage in the development of the umbilical cord.

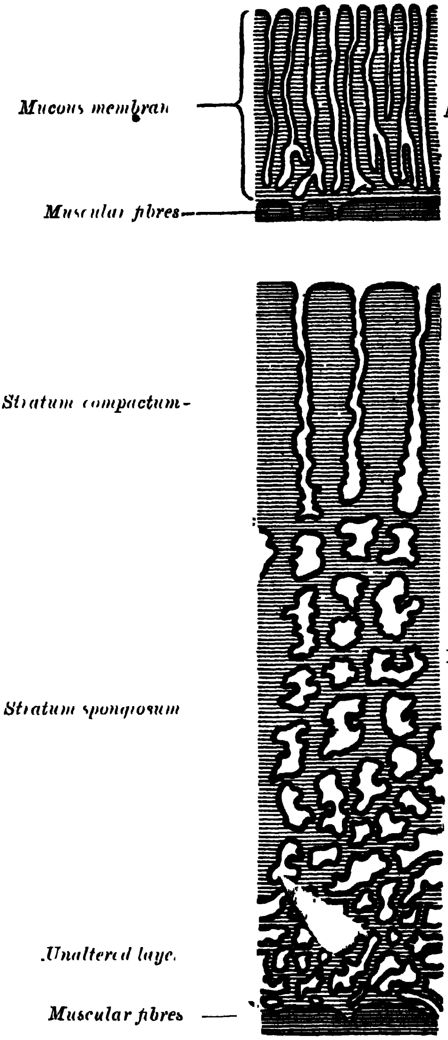


cœlom; the latter is ultimately obliterated. The cord, therefore, is not covered by the amnion, but by a layer of ectoderm which is continuous with that of the amnion at the placental end of the cord, around which the amnion is attached. The various constituents of the cord are enveloped by embryonic gelatinous tissue (jelly of Wharton). The vitelline vessels and duct, together with the right

umbilical vein, undergo atrophy, and disappear; and thus the cord, at birth, contains a pair of umbilical arteries and one (the left) umbilical vein.

The chorion (figs. 117 to 121).—The chorion is developed from the wall of the blastodermic vesicle, and consists of two layers: an outer formed by the primitive ectoderm or trophoblast, and an inner by the somatic mesoderm (figs. 119 and 120). The trophoblast is made up of an internal layer of cubical or prismatic cells, the *cytoblast* or *layer of Langhans*, and an external layer of richly nucleated protoplasm devoid of cell boundaries, the *syncytium*. It undergoes rapid proliferation and forms numerous processes, the *chorionic villi*, which invade and destroy the uterine decidua and at the same time absorb from it nutritive materials for the growth of the embryo. The chorionic villi are at first small and non-vascular, and consist of trophoblast only, but they increase in size and ramify, while the mesoderm, carrying branches of the umbilical vessels, grows into them, and in this way they are vascularised. Blood is carried to the villi by the branches of the umbilical arteries, and after circulating through the capillaries of the villi, is returned to the embryo by the umbilical veins. Until about the end of the second month of pregnancy the villi cover the entire chorion and are almost uniform in size (fig. 119), but after this they develop unequally. The greater part of the chorion is in contact with the decidua capsularis (fig. 121), and over this portion the villi, with their contained vessels, undergo atrophy, so that by the fourth month scarcely a trace of them is left, and hence this part of the chorion becomes smooth, and is named the *chorion læve*; as it takes no share in the formation of the placenta, it is also named the non-placental part of the chorion. On the other hand, the villi on that part of the chorion which is in contact with the decidua placentalis increase greatly in size and complexity, and hence this part is named the *chorion frondosum*. Since it forms the fœtal portion of the placenta, it is appropriately named the placental part of the chorion, and its villi, the placental villi (fig. 124).

FIG. 122.—Diagrammatic sections of the uterine mucous membrane: (A) of the non-pregnant uterus; (B) of the pregnant uterus, showing the thickened mucous membrane and the altered condition of the uterine glands. (Kundrat and Engelmann.)



The decidua.—Changes take place in the mucous membrane of the uterus in order to render it fit for the reception of the fertilised ovum. It becomes congested and thickened, its connective tissue cells are increased in number, and its glands are expanded; this altered mucous membrane is termed the *decidua*. When the fertilised ovum enters the uterus it becomes imbedded in the decidua, which then undergoes the following changes: its thickness and its vascularity are greatly increased; its glands are elongated and open on its free surface by funnel-shaped

orifices, while their deeper portions are tortuous and dilated into irregular spaces. The interglandular tissue is also increased in quantity, and is crowded with large round, oval, or polygonal cells, termed *decidual cells*. These changes are well advanced by the second month of pregnancy, when the mucous membrane consists of the following strata (fig. 122): (1) *stratum compactum*, next the free surface; in this the uterine glands are only slightly expanded, and are lined by columnar cells; (2) *stratum spongiosum*, in which the gland tubes are greatly dilated and very tortuous, and ultimately come to be separated by only a small amount of interglandular tissue, while their lining cells are flattened or cubical; (3) a thin *unaltered layer*, next the uterine muscular fibres, containing the deepest parts of the uterine glands, which are not dilated, and are lined with columnar epithelium; it is from this epithelium that the epithelial lining of the uterus is regenerated

Fig. 123.—Section through ovum imbedded in the uterine decidua. Semi-diagrammatic. (After Peters.)

after pregnancy. The decidua lines the whole of the *body* of the uterus, without, however, occluding the orifices of the Fallopian tubes.

Imbedding of the ovum.—When the fertilised ovum enters the cavity of the uterus it adheres to the decidua, generally in the neighbourhood of the fundus uteri. It destroys the uterine epithelium over the area of contact and excavates and sinks into the decidua. It expands rapidly and imbeds itself in the decidua, the portion of the latter which overlaps it being named the *decidua capsularis.** The point at which the ovum entered is at first closed by a mushroom-shaped blood clot, but soon all trace of the aperture is lost and the ovum is then completely enveloped by the decidua (fig. 123). The portion of the decidua which

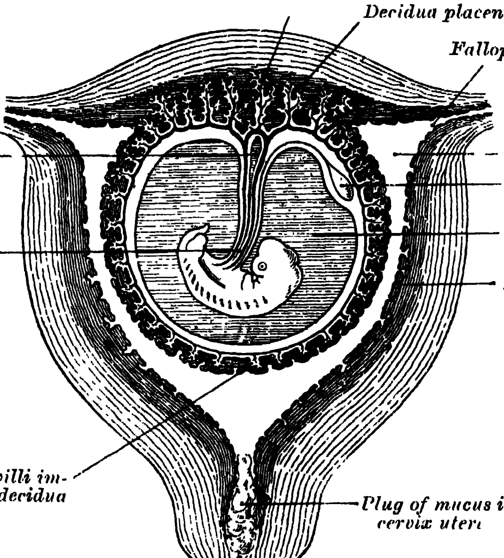
* The decidua capsularis was formerly named the *decidua reflexa*; this name was applied to it because it was supposed to be produced by the upgrowth of folds of the surrounding decidua over the ovum—these folds gradually overlapping and ultimately fusing so as to completely cover the ovum.

intervenes between the ovum and the uterine wall is named the *decidua basalis* or *decidua placentalis*: it is here that the placenta is subsequently developed. The part of the decidua which lines the remainder of the uterus is known as the *decidua vera*.

The trophoblast of the ovum proliferates rapidly and forms numerous branching villous processes which cover the entire surface of the ovum and invade and destroy the surrounding decidua. They embrace and erode the uterine capillaries so that blood spaces containing maternal blood are formed around the villi and in the trophoblast. These spaces become greatly distended and constitute the *maternal blood sinuses* or *intervillous spaces*. The villi are at first non-vascular and consist of trophoblast only; processes of mesoderm, however, soon invade them and carry into them branches of the umbilical vessels.

Coincidently with the growth of the embryo, the decidua capsularis is thinned and extended (fig. 124). Its vascular supply is diminished, and it undergoes degeneration, and at the same time the non-placental villi atrophy and disappear. The space between the decidua capsularis and decidua vera is gradually obliterated, so that by the third month of pregnancy the two are in contact. By the fifth month

FIG. 124.—Sectional plan of the gravid uterus in the third and fourth month. (Modified from Wagner.)



the decidua capsularis has practically disappeared, and, as a consequence, the chorion læva comes directly into contact with the decidua vera. During the succeeding months of pregnancy the decidua vera also undergoes atrophy, owing to the increased pressure. The glands of the stratum compactum are obliterated, and their epithelium is lost. In the stratum spongiosum the glands are compressed and present the appearance of slit-like fissures, while their epithelium undergoes degeneration. In the deepest or unaltered layer, however, the glandular epithelium retains a columnar or cubical form.

The **placenta**.—The placenta connects the fœtus to the uterine wall, and is the organ by means of which the nutritive, respiratory, and excretory functions of the fœtus are carried on. It is composed of fœtal and maternal portions.

The *fœtal portion of the placenta* consists of the villi of the placental part of the chorion. It has already been pointed out that the chorionic villi consist at first of trophoblast (ectoderm) only (fig. 125), and that they become vascularised by the growth into them of the mesoderm which conveys branches of the umbilical vessels (fig. 126). Further, it has been shown that, for a time, they cover the entire surface of the ovum and invade the whole of the surrounding decidua, but owing to the growth of the ovum and consequent extension of the decidua capsularis the

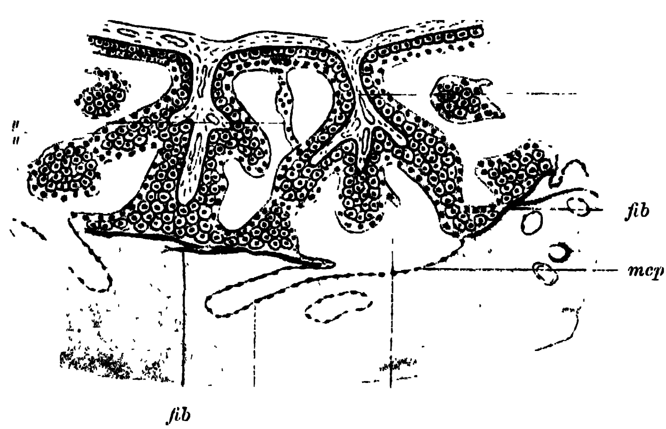
vessels of the latter become atrophied and the villi over the corresponding part of the chorion disappear. On the other hand the placental villi, which invade the decidua placentalis, branch repeatedly, increase enormously in size, and constitute the fœtal part of the placenta (fig. 124). These greatly ramified villi are suspended in the maternal blood sinuses, and are therefore bathed in maternal blood, which is conveyed to the sinuses by the uterine arteries and carried away by the uterine veins. A branch of an umbilical artery enters each villus and ends in a capillary plexus from which the blood is drained by a tributary of the umbilical vein. The vessels of the villus are surrounded by a thin layer of mesoderm consisting of gelatinous connective tissue, which is covered by two strata of ectodermal cells derived from the trophoblast: the deeper stratum, next the mesodermic tissue, represents the layer of Laughans; the superficial, in contact with the maternal blood, the syncytium.*

FIG. 125.—Diagram to illustrate the first phase of the placenta. (After Peters.)

b.l., blood-lacuna; *ca*, maternal capillary; *de*, decidua; *mes*, mesoderm; *sy*, syncytium; *tr*, trophoblast.

The *maternal portion of the placenta* is formed by the decidua placentalis containing the maternal blood sinuses. As already explained, these sinuses are produced partly by the erosion and opening out of the uterine vessels by the trophoblast and partly by the channels which make their appearance in the trophoblast itself. The destructive changes involve the greater portion of the stratum

FIG. 126.—Diagram to illustrate the second phase of the placenta. (After Peters.)



The mesodermic core has now invaded the strands of the trophoblast, and is beginning to branch. *ca*, maternal capillary; *core*, core of villus; *fib*, fibrinous material deposited at junction of trophoblast with decidua; *mcp*, endothelium of maternal capillary; *mes*, mesoderm; *sy*, syncytium; *vs*, intervillous space.

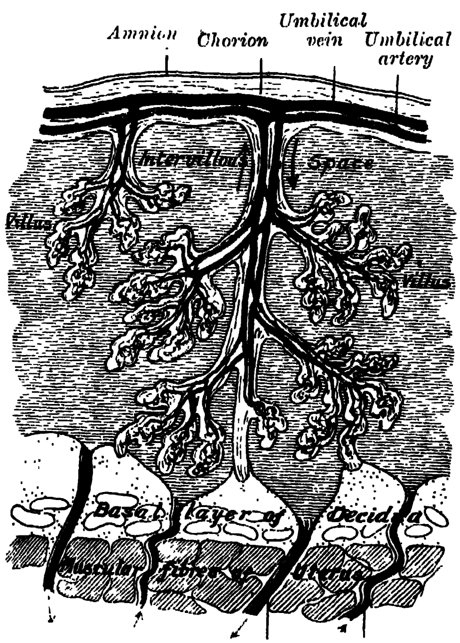
compactum, but the deeper part of this layer persists and is condensed to form what is known as the *basal plate*. Between this plate and the uterine muscular fibres are the stratum spongiosum and the unaltered layer; through these and the basal plate the uterine arteries and veins pass to and from the maternal blood sinuses. The endothelial lining of the uterine vessels ceases at the point where they terminate in the sinuses; the sinuses themselves are lined by the syncytium of the trophoblast. Portions

* This outer layer was regarded by some authorities as being of maternal origin, but recent observations have proved that it is derived from the syncytium. The whole of the structures of the villi, therefore, consist of embryonic tissues.

of the stratum compactum persist and are condensed to form a series of septa, which extend from the basal plate through the thickness of the placenta and subdivide it into the lobes or *cotyledons* seen on the uterine surface of the detached placenta.

The fœtal and maternal blood currents traverse the placenta, the former passing through the blood-vessels of the placental villi and the latter through the maternal blood sinuses or intervillous spaces (fig. 127). The two currents do not intermingle, being separated from each other by the delicate walls of the villi. Nevertheless, the fœtal blood is able to absorb, through the thin walls of the villi, oxygen and nutritive materials from the maternal blood, and give up to the latter its waste products. The blood, so purified, is carried back to the fœtus by the umbilical vein. It will thus be seen that the placenta not only establishes a mechanical connection between the mother and the fœtus, but subserves for the latter the purposes of nutrition, respiration, and excretion. In favour of the view that the placenta possesses certain selective powers may be mentioned the fact that glucose is more plentiful in the maternal than in the fœtal blood. It is interesting to note also that the proportion of iron, and of lime and potash, in the fœtus is increased during the last months of pregnancy. Further, there is evidence that the maternal leucocytes may migrate into the fœtal blood, since leucocytes are much more numerous in the blood of the umbilical vein than in that of the umbilical arteries.

FIG. 127.—Scheme of placental circulation.



The placenta is usually attached near the fundus uteri, and more frequently on the posterior than on the anterior wall of the uterus. It may, however, occupy a lower position and, in rare cases, its site is close to the os uteri internum, which it may occlude, thus giving rise to the condition known as *placenta prævia.*

Separation of the placenta.—After the child is born, the placenta and membranes are expelled from the uterus as the *after-birth.* The separation of the placenta from the uterine wall takes place through the stratum spongiosum, and necessarily causes rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction of the uterine muscular fibres, and thus *post-partum hæmorrhage* is prevented. The epithelial lining of the uterus is regenerated by the proliferation and extension of the epithelium which lines the persistent portions of the uterine glands in the unaltered layer of the decidua.

The expelled placenta appears as a discoid mass which weighs about a pound, and has a diameter of from six to eight inches. Its average thickness is about an inch and a quarter, but this diminishes rapidly towards the circumference of the disc, which is continuous with the membranes. Its uterine surface is divided by a series of fissures into lobules or *cotyledons*, the fissures containing the remains of the septa which extended between the maternal and fœtal portions. Most of these septa end in irregular or pointed processes; others, especially those near the edge of the placenta, pass through its thickness and are attached to the chorion. In the early months these septa convey branches of the uterine arteries which open into the maternal sinuses on the surfaces of the septa. The fœtal surface of the placenta is smooth, being closely invested by the amnion. Seen through the latter, the chorion presents a mottled appearance, consisting of grey, purple,

or yellowish areas. The umbilical cord is usually attached near the centre of the placenta, but may be inserted anywhere between the centre and the margin. In some cases it is inserted into the membranes, i.e. the *velamentous* insertion. From the attachment of the cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper and larger than the arteries. The remains of the vitelline duct and yolk-sac may be sometimes observed beneath the amnion, close to the cord, the former as an attenuated thread, the latter as a minute sac.

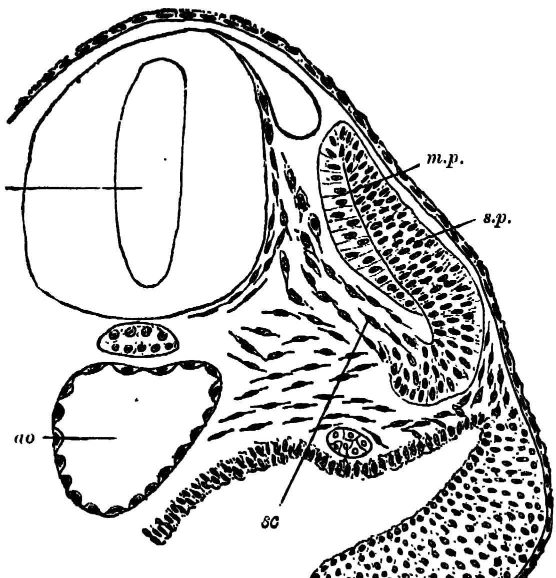
On section, the placenta presents a soft, spongy appearance, caused by the greatly branched villi; surrounding them is a varying amount of maternal blood giving the dark red colour to the placenta. Many of the larger villi extend from the chorionic to the decidual surface, while others are attached to the septa which separate the cotyledons; but the great majority hang free in the maternal sinuses, like the branches of a tree.

The further growth of the embryo will be best understood from a description of the principal facts relating to the development of the chief parts of which the body consists.

DEVELOPMENT OF THE PARIETES

The Skeleton.—The skeleton is of mesodermal origin, and may be divided into (*a*) that of the trunk (axial skeleton), comprising the vertebral column, skull, ribs, and sternum, and (*b*) that of the limbs (appendicular skeleton).

FIG. 128.—Transverse section of a human embryo of the third week to show the differentiation of the primitive segment. (Kollmann.)



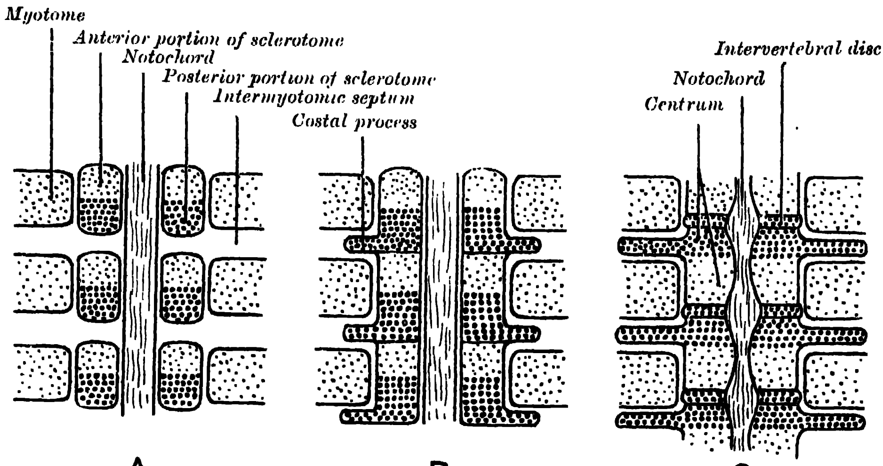
ao, aorta ; *m.p.*, muscle-plate ; *n.c.*, neural canal ; *sc*, sclerotome *s.p.*, cutis-plate.

The vertebral column.—The notochord (fig. 111) is a temporary structure and forms a central axis, around which the segments of the vertebral column are developed.* It is derived from the entoderm, and consists of a rod of cells, which lies on the ventral aspect of the neural tube and reaches from the anterior end of the mid-brain to the extremity of the tail. On either side of it is a column of paraxial mesoderm which divides into a number of more or less cubical segments, the *primitive segments* or *protovertebral somites* (figs. 110, 111, 112). These are separated from one another by *intersegmental septa* and are arranged symmetrically on either side of the neural tube and notochord: to every segment a spinal nerve is distributed. At first each segment contains a central cavity, the *myocœl*, but this is soon filled with a core of angular and spindle-shaped cells. The cells of the segment become differentiated into three groups, which form respectively the cutis-plate or dermatome, the muscle-plate or myotome, and the sclerotome (fig. 128). The *cutis-plate* is placed on the outer and dorsal aspect of the myocœl, and from it the true skin of the corresponding segment is derived; the *muscle-plate* is situated on the inner aspect of the myocœl and furnishes the muscles of the segment. The

* In the amphioxus the notochord persists and forms the only representative of a skeleton in that animal.

cells of the *sclerotome* are largely derived from those which form the core of the myocœl, and lie next the notochord. Fusion of the individual sclerotomes in an antero-posterior direction soon takes place, and thus a continuous strand of cells, the *scleratogenous layer*, is formed along the ventro-lateral aspects of the neural tube. The cells of this layer proliferate rapidly, and extending inwards surround the notochord; at the same time they grow backwards on the lateral aspects of the neural tube and eventually surround it, and thus the notochord and neural tube are enveloped by a continuous sheath of mesoderm, which is termed the *membranous vertebral column*. In this mesoderm the original segments are still distinguishable, but each is now differentiated into two portions, an anterior, consisting of loosely arranged cells, and a posterior, of more condensed tissue (fig. 129, A and B). Between the two portions the rudiment of the intervertebral disc is laid down (fig. 129, C). Cells from the posterior mass grow out into the intervals between the myotomes (fig. 129, B and C) of the corresponding and succeeding segments to form an arch or bow, the *primitive vertebral bow*. The mesial portion of this bow lies on the ventral aspect of the notochord, and is termed the *hypochordal bar* or *brace*. Its lateral portions extend both dorsally and ventrally; the dorsal extensions surround the neural tube and represent the future neural arch of the vertebra, while the ventral extend into

FIG. 129.—Scheme showing the manner in which each vertebral centrum is developed from portions of two adjacent segments.



the body-wall as the costal processes. The hinder part of the posterior mass joins the anterior mass of the succeeding segment to form the vertebral body. Each vertebral body is therefore a composite of two segments, being formed from the posterior portion of one segment and the anterior part of that immediately behind it. The neural and costal arches are derivatives of the posterior part of the segment in front of the intersegmental septum with which they are associated.

This stage is succeeded by that of the *cartilaginous vertebral column*. In the fourth week two cartilaginous centres make their appearance on the dorsal aspect of the hypochordal bar, one on either side of the notochord; these extend round the notochord and form the body of the cartilaginous vertebra. A second pair of cartilaginous foci appear in the lateral parts of the vertebral bow, and grow backwards on either side of the neural tube to form the cartilaginous neural arch. By the eighth week the cartilaginous arch has fused with the body, and in the fourth month the two halves of the arch are joined on the dorsal aspect of the neural tube. The spinous process is developed from the junction of the two halves of the neural arch. The transverse process grows out from the neural arch immediately behind the costal process.

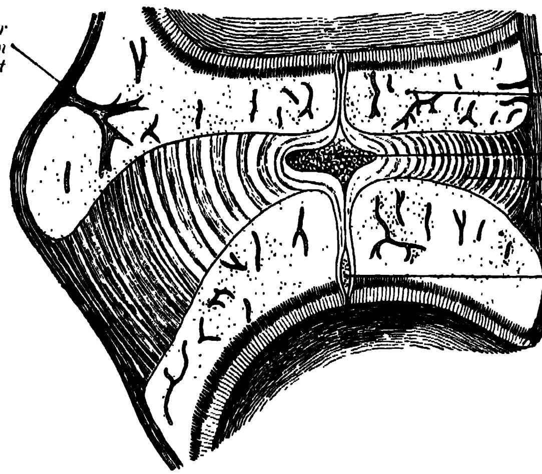
Except in the case of the first cervical vertebra, the hypochordal bar of the primitive vertebral bow disappears by fusing with the intervertebral disc. In this vertebra, however, the entire bow persists and remains separate from the

cartilaginous body. The hypochordal bar becomes developed into the anterior arch of the bone, while the cartilaginous body forms the odontoid process which fuses with the body of the second cervical vertebra.

The portions of the notochord which are surrounded by the bodies of the vertebræ atrophy, and ultimately disappear, while the parts which lie in the centres of the intervertebral discs undergo enlargement, and persist throughout life as the central *nucleus pulposus* of the discs (fig. 130).

The **ribs.**—The ribs are formed from the ventral or costal processes of the primitive vertebral bows, the processes extending outwards between the muscle-plates. In the *thoracic region* of the vertebral column the costal processes of the vertebral bows grow outwards to form a series of arches, the *primitive costal arches.* As already described, the transverse process grows out behind the vertebral end of each arch. It is at first connected to the costal process by continuous mesoderm, but this becomes differentiated later to form the costo-transverse ligaments: between the costal process and the tip of the transverse process the costo-transverse joint is formed by absorption. The costal process becomes separated from the vertebral bow by the development of the costo-central joint. In the *cervical vertebræ* the transverse process forms the posterior boundary of the foramen transversarium, while the costal process corresponding to the head and neck of the rib fuses with the body of the vertebra, and forms the antero-

FIG. 130.—Sagittal section through the intervertebral disc and adjacent parts of two vertebræ of an advanced sheep's embryo. (Kölliker.)

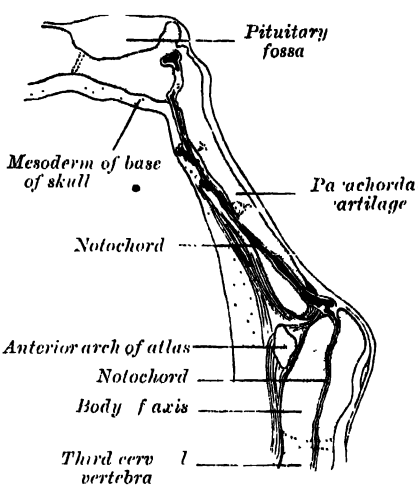


lateral boundary of the foramen. The distal portions of the primitive costal arches remain undeveloped; occasionally the arch of the seventh cervical vertebra undergoes greater development, and by the formation of costo-vertebral joints is separated off as a rib. In the *lumbar region* the distal portions of the primitive costal arches fail; the proximal portions remain undifferentiated and fuse with the transverse processes to form the transverse processes of descriptive anatomy. Occasionally a movable rib is developed in connection with the first lumbar vertebra. In the *sacral region* costal processes are developed only in connection with the upper three, or it may be four, vertebræ; the processes of adjacent segments fuse with one another to form the lateral masses of the sacrum. The *coccygeal vertebræ* are devoid of costal processes.

The **sternum.**—The view generally held regarding the development of the sternum is that it arises as a paired structure from the ventral ends of the upper nine ribs which join on either side of the middle line to form a cartilaginous strip. The two strips are at first connected by membrane, but they become united in the middle line from before backwards, and so give rise to a longitudinal piece of cartilage, which represents the manubrium and gladiolus. The ventral ends of the eighth and ninth cartilages fuse to form the xiphoid appendix, and subsequently lose their connection with the sternum. Sometimes the eighth retains its original connection, and constitutes an eighth true rib

which occurs more frequently on the right than on the left side. This bilateral condition of the primitive sternum would serve to explain the occurrence of fissures or holes in the bone, as well as that rare anomaly, a completely divided sternum. Paterson,* on the other hand, after reviewing the literature on this subject, and giving the results of his own observations on the embryonic and adult conditions of the sternum in man and some of the lower animals, says: 'The weight of evidence is all on the side of the primary association of the sternum with the shoulder girdle and its secondary connection with the ribs.' There is reason to believe that the upper part of the manubrium sterni represents the precoracoid element of the shoulder girdle.

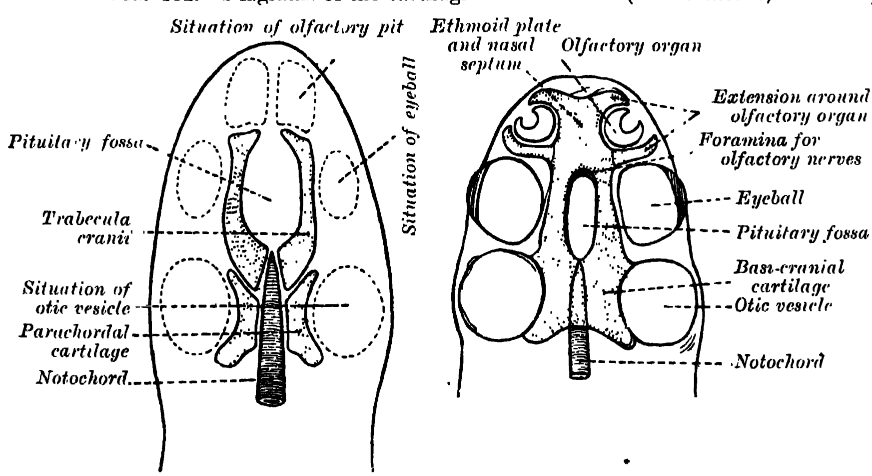
FIG. 131.—Sagittal section of cephalic end of notochord. (Keibel.)



The **skull.**—Up to a certain stage the development of the skull corresponds with that of the vertebral column; but it is modified later in association with the expansion of the brain-vesicles, the formation of the organs of smell, sight, and hearing, and the development of the mouth and pharynx.

The notochord extends as far forwards in the base of the future skull as the anterior end of the mid-brain, and becomes partly surrounded by mesoderm (fig. 131). The posterior part of this mesodermal investment corresponds with the future basi-occiput, and shows a subdivision into four segments, which are separated by the roots of the hypoglossal nerve. The mesoderm then extends over the brain-vesicles, and thus the entire brain is enclosed by a mesodermal investment, which is termed the *membranous primordial cranium.* From the inner layer of this the bones of

FIG. 132.—Diagrams of the cartilaginous cranium. (Wiedersheim.)



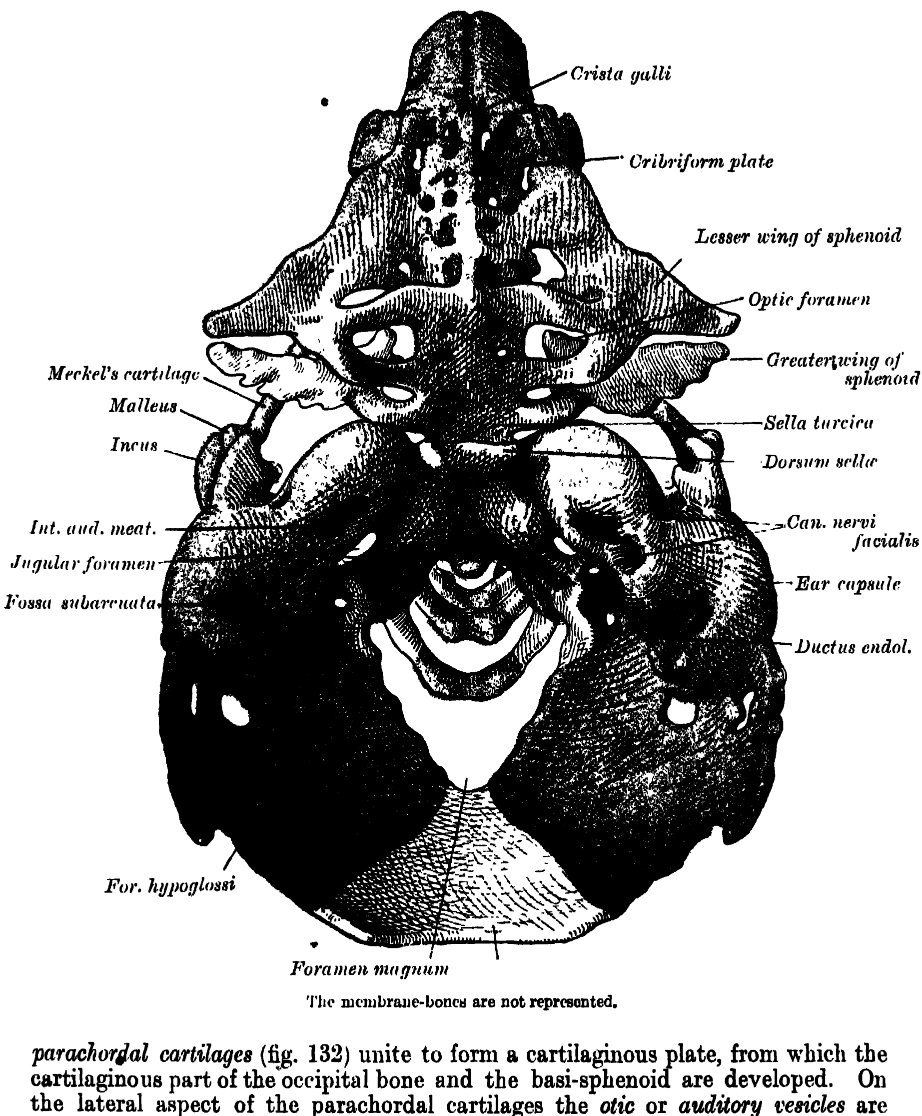
the skull and the membranes of the brain are developed; from the outer layer the muscles, blood-vessels, true skin, and subcutaneous tissues of the scalp. In the shark and dog-fish this membranous cranium undergoes complete chondrification, and forms the cartilaginous skull or ***chondrocranium*** of these animals. In mammals, on the other hand, the process of chondrification is limited to the base of the skull—the roof and sides being covered in by membrane. Thus

* *The Human Sternum*, by A. Melville Paterson, 1904.

the bones of the base of the skull are preceded by cartilage, those of the roof and sides by membrane. The posterior part of the base of the skull is developed around the notochord, and exhibits a segmented condition analogous to that of the vertebral column, while the anterior part arises in front of the notochord and shows no regular segmentation. The base of the skull may therefore be divided into (*a*) a *chordal* or *vertebral*, and (*b*) a *prechordal* or *prevertebral* portion.

In the lower vertebrates two pairs of cartilages are developed: viz. a pair of parachordal cartilages, one on either side of the notochord; and a pair of prechordal cartilages, the *trabeculæ cranii*, in front of the notochord (fig. 132). The

FIG. 133.—Model of the chondrocranium of a human embryo, 8 cm. long. (From Hertwig's 'Handbuch der Entwickelungslehre.')

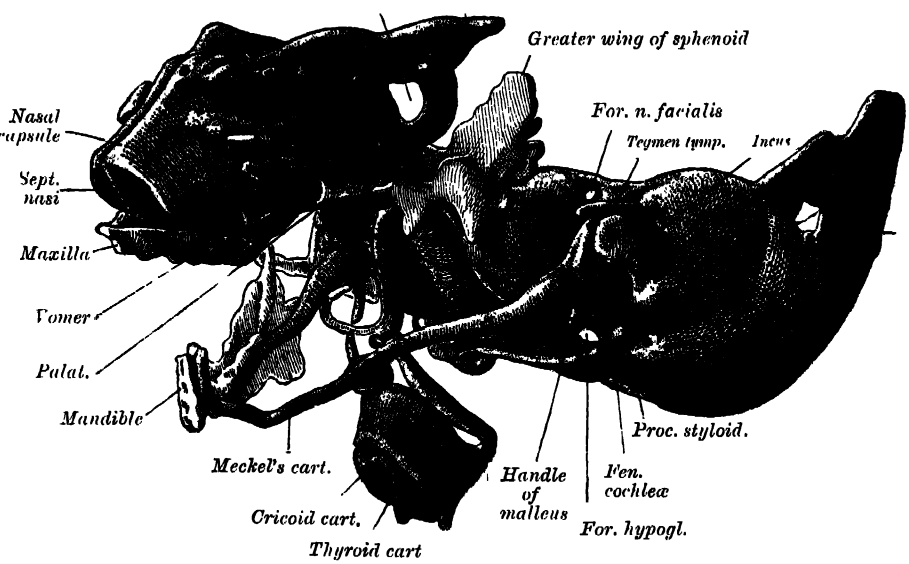


The membrane-bones are not represented.

parachordal cartilages (fig. 132) unite to form a cartilaginous plate, from which the cartilaginous part of the occipital bone and the basi-sphenoid are developed. On the lateral aspect of the parachordal cartilages the *otic* or *auditory vesicles* are situated, and the mesoderm enclosing them is soon converted into cartilage, forming the *cartilaginous ear-capsules*. These cartilaginous ear-capsules, which are of an oval shape, fuse with the lateral aspects of the basilar plate, and from them arise the petro-mastoid portions of the temporal bones. The *trabeculæ cranii* (fig. 132) are two curved bars of cartilage which embrace the pituitary body; their posterior ends soon unite with the basilar plate, while their anterior ends join to form the *ethmoidal plate*, which extends forwards between the fore-brain and the

olfactory pits. Later, the trabeculæ meet and fuse below the pituitary body, forming the floor of the pituitary fossa, and so cutting off the anterior lobe of the pituitary body from the stomatodæum. The mesial part of the ethmoidal plate forms the bony and cartilaginous parts of the nasal septum. From the lateral margins of the trabeculæ cranii three processes grow out on either side. The anterior forms the lateral mass of the ethmoid and the alar cartilages of the nose; the middle gives rise to the lesser wing of the sphenoid, while from the posterior the greater wing and external pterygoid plate of the sphenoid are developed (figs. 133, 134). The bones of the vault are of membranous formation, and are termed *dermal* or *covering bones.* They are partly developed from the mesoderm of the primordial cranium, and partly from that which lies outside the entoderm of the fore-gut. They comprise the upper part of the tabular portion of the occipital (interparietal), the squamous-temporals and tympanic plates, the parietals, the frontal, the vomer, the internal pterygoid plates, and the bones of the face. Some of them remain distinct throughout life (e.g. parietal and frontal), while others join with the bones of the chondrocranium (e.g. interparietal, squamous-temporals, and internal pterygoid plates).

FIG. 134.—The same model as shown in fig. 133 from the left side.



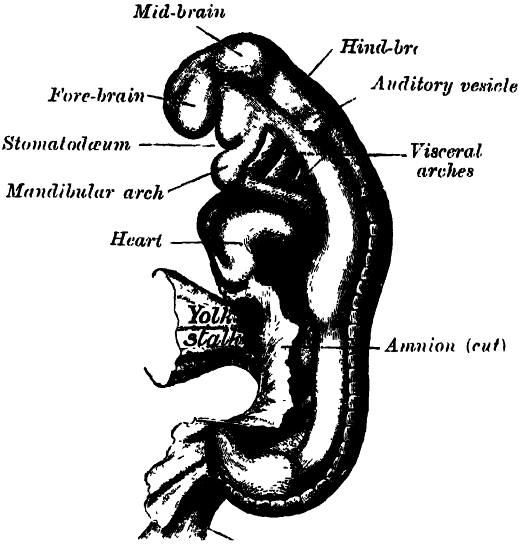
Certain of the membrane-bones of the right side are represented in yellow.

Recent observations have shown that, in mammals, the basi-cranial cartilage, both in the chordal and prechordal regions of the base of the skull, is developed as a single plate which extends from behind forwards. In man, however, its posterior part shows an indication of being developed from two chondrifying centres which fuse rapidly in front and below. The relation of this cartilaginous plate to the notochord differs in different animals. In the rat embryo it lies beneath the notochord (Robinson); in the sheep, pig, calf, and ferret, the cranial part of the notochord is enclosed within it; in man, the anterior and posterior thirds of the cartilage surround the notochord, but its middle third lies on the dorsal aspect of the notochord, which in this region is placed between the cartilage and the wall of the pharynx.

The visceral arches.—In the lateral walls of the anterior part of the fore-gut a series of furrows or incomplete clefts appears (fig. 135). These are named the *visceral clefts*, and take origin as paired grooves or pouches in the sides of the fore-gut; over each groove a corresponding indentation of the ectoderm occurs, so that the latter comes into contact with the entodermal lining of the fore-gut, and the two layers unite along the floors of the grooves to form thin septa between the

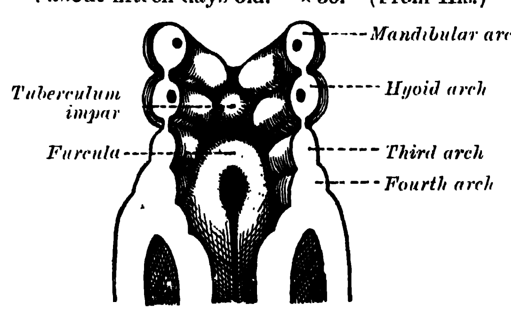
fore-gut and the exterior. In gill-bearing animals these septa disappear, and the grooves become complete clefts—the gill-clefts—opening from the pharynx on to the exterior; perforation, however, does not occur in birds or mammals. The clefts separate a series of rounded bars or arches, the *visceral arches*, in which thickening of the mesoderm takes place (figs. 135, 136, 137). The dorsal ends of these arches are attached to the sides of the head, while the ventral extremities ultimately meet in the middle line of the neck. In all, five arches make their appearance, but of these only the first four are visible externally, the fifth never being elevated above the surface. The first arch is named the *mandibular*; the second, the *hyoid*; the third, the *thyro-hyoid* (fig. 137); while the others have no distinctive names, but are referred to as the fourth and fifth visceral arches. In each arch a cartilaginous bar, consisting of right and left halves, is developed, and with each of these there is one of the primitive aortic arches.

Fig. 135.—Embryo between eighteen and twenty-one days. (His.)



The mandibular arch lies between the first visceral cleft and the stomatodæum, and is developed into the lower lip and mandible. Its cartilaginous bar is formed by what are known as *Meckel's cartilages* (right and left, fig. 138). The dorsal ends of these cartilages are connected with the periotic capsules and are ossified to form two of the bones of the middle ear, the malleus and incus;* the ventral ends meet each other in the region of the symphysis menti, and are usually regarded as undergoing ossification to form that portion of the mandible which contains the incisor teeth. The intervening part of the cartilage disappears; the portion immediately adjacent to the malleus and incus is replaced by fibrous membrane, and constitutes the spheno-mandibular ligament, while from the connective tissue covering the remainder of the cartilage the greater part of the mandible is ossified. The second or hyoid arch assists in forming the side and front of the neck. From its cartilage are developed the styloid process, stylo-hyoid ligament, and lesser cornu of the hyoid bone.

Fig. 136.—The floor of the pharynx of a human embryo about fifteen days old. × 50. (From His.)



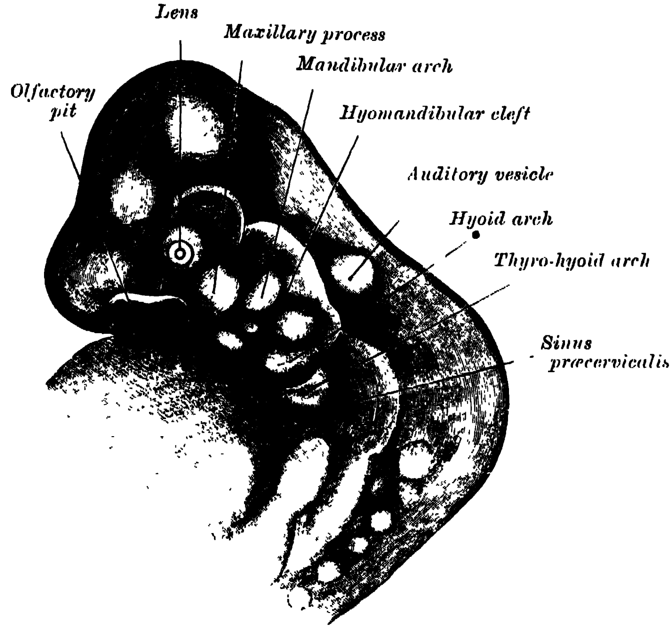
The cartilage of the third or thyro-hyoid arch gives origin to the great cornu of the hyoid bone. The ventral ends of the second and third arches unite with those of the opposite side, and form a transverse band, from the cartilages of which the body of the hyoid bone is developed. The ventral

* Some regard the incus as arising from the dorsal end of the hyoid bar, while Gadow (*Phil. Trans.* vol. clxxix.) inclines to the view that the malleus, incus, and stapes arise from a cartilaginous plate, the hyomandibula, which binds the proximal ends of the mandibular and hyoid bars together.

portions of the cartilages of the fourth and fifth arches unite to form the thyroid cartilage.

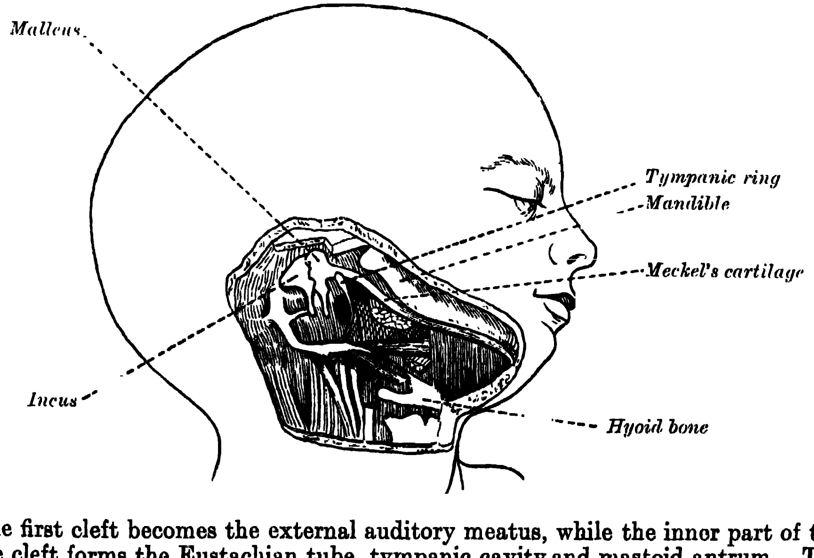
The first and second arches grow more rapidly than those behind them, with the result that the latter become, to a certain extent, telescoped within the former,

FIG. 137.—Profile view of the head of a human embryo, estimated as twenty-seven days old. (After His.)



and a deep depression, the *sinus præcervicalis* (fig. 140) is formed on the side of the neck. This sinus is bounded in front by the hyoid arch, and behind by the thoracic wall; it is ultimately obliterated by the fusion of its walls. The outer part

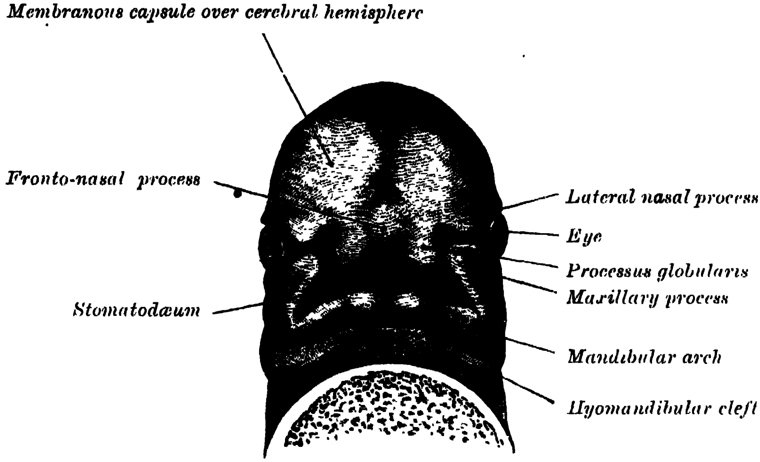
FIG. 138.—Head and neck of a human embryo eighteen weeks old, with Meckel's cartilage and hyoid bar exposed. (After Kölliker.)



of the first cleft becomes the external auditory meatus, while the inner part of the same cleft forms the Eustachian tube, tympanic cavity and mastoid antrum. The septum between the outer and inner parts of this cleft is invaded by mesoderm, and

forms the membrana tympani. No traces of the outer parts of the second, third, and fourth clefts persist. The inner part of the second cleft is subdivided into an upper and lower portion by the palate. The former persists as the fossa of Rosenmüller. or lateral recess of the naso-pharynx; in the latter is developed the tonsil, above which a trace of the cleft persists as the supra-tonsillar fossa. From the pharyngeal

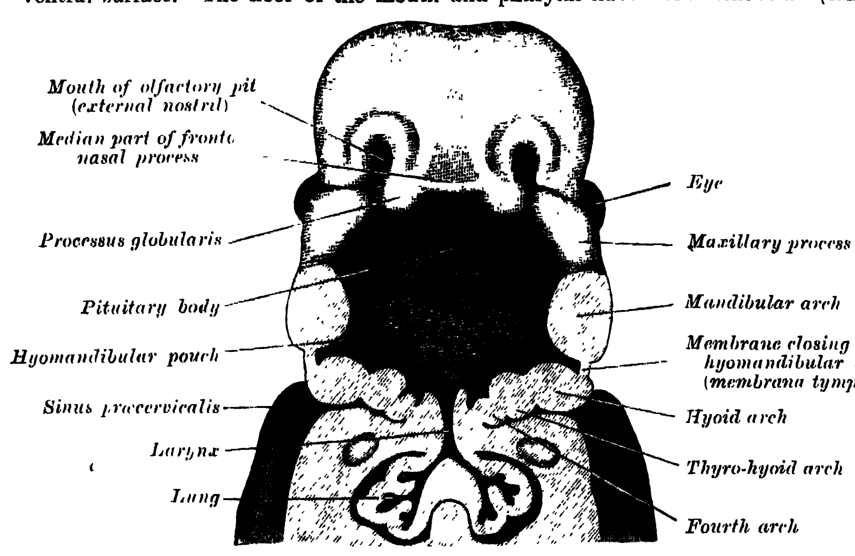
FIG. 139.—Under surface of the head of a human embryo about twenty-nine days old. (After His.)



aspect of the third cleft the thymus gland arises as an entodermal diverticulum on either side, and from the corresponding part of the fourth clefts similar diverticula give origin to the lateral parts of the thyroid body (see page 154).

The **face and nose** (figs. 139 to 144).—The nasal cavities are formed from the stomatodæum, while the outer nose is derived from its antero-lateral

FIG. 140.—The head and neck of a human embryo thirty-two days old, seen from the ventral surface. The floor of the mouth and pharynx have been removed. (His.)

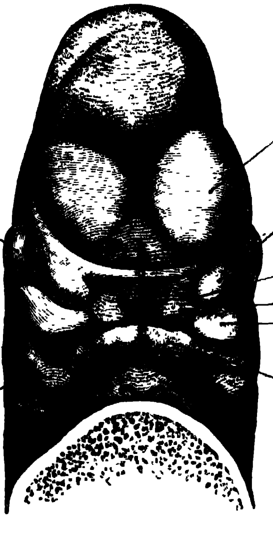


boundaries. Two areas of thickened ectoderm, the *olfactory areas*, appear immediately under the fore-brain in the anterior wall of the stomatodæum, one on either side of the *fronto-nasal process*. By the upgrowth of the surrounding parts these areas are converted into pits, the *olfactory pits* (fig. 140), which divide the fronto-nasal process into a *mesial* and two *lateral nasal processes* (fig. 141).

The rounded lateral angles of the mesial nasal process constitute the *globular processes* of His (figs. 140, 141). The olfactory pits form the rudiments of the nasal cavities, and extend backwards between the mesial and lateral nasal processes into the roof of the stomatodæum. From their ectodermal lining the olfactory epithelium and part of the olfactory bulb are derived. The globular processes are prolonged backwards as plates, termed the *nasal laminæ*: these laminæ are at first some distance apart, but, gradually approaching, they ultimately fuse, and form the nasal septum; the processes themselves meet in the middle line, and form the premaxillæ and the philtrum or central part of the upper lip (fig. 142).

The depressed part of the fronto-nasal process between the globular processes forms the lower part of the nasal septum or *columella*; while above this is seen a prominent angle, which becomes the future point, and still higher a flat area, the future bridge, of the nose (fig. 144). The lateral nasal processes form the alæ of the nose. Continuous with the dorsal end of the mandibular arch, and growing forwards from its cephalic border, is a triangular process—the *maxillary process*—the ventral extremity of which is separated from the mandibular arch by a >-shaped notch (fig. 139). The maxillary process grows forwards to form the outer wall and floor of the orbit, and meets with the lateral nasal process, from

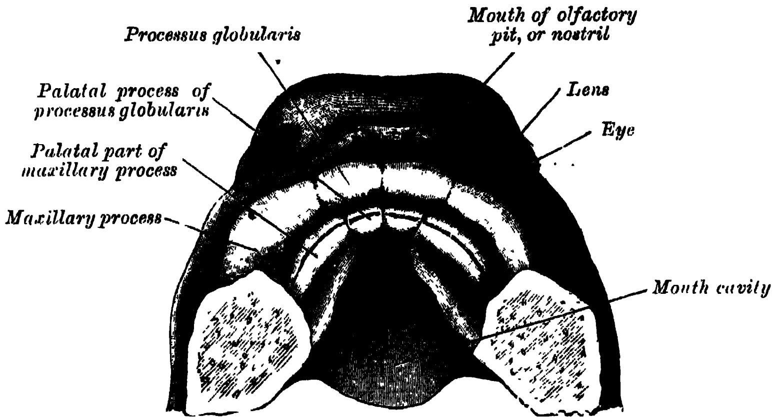
FIG. 141.—Under surface of the head of a human embryo about thirty days old. (After His.)



which, however, it is separated for a time by a groove—the *oculo-nasal sulcus*—that extends from the furrow encircling the eyeball to the olfactory pit. The maxillary processes ultimately fuse with the lateral nasal and globular processes, converting the oculo-nasal sulci into the lachrymal sacs and nasal ducts, and at the same time forming the lateral parts of the upper lip and the posterior boundaries of the anterior nares. The maxillary process also gives rise to the lower portion of the lateral wall of the nasal cavity—the upper part of this wall, together with the roof, being developed from the ethmoid plate of the cartilaginous chondrocranium. The nasal cavity is shut off from the buccal part of the stomatodæum by the development of the palate, the greater part of which is formed by a pair of shelf-like *palatal processes* which extend inwards from the maxillary processes (figs. 142, 143); these coalesce with each other in the middle line, and constitute the entire palate, except a small part in front which is formed by the premaxillary bones. The union of the palatal processes with the premaxillæ is deficient in the middle line, where an aperture remains—the naso-palatine canal. The union of the parts which form the palate commences in front, the premaxillary and palatal processes joining in the eighth week, while the region of the future hard palate is completed by the ninth, and that of the soft palate by the eleventh week. The deformity known as cleft palate results from a non-union of the palatal processes,

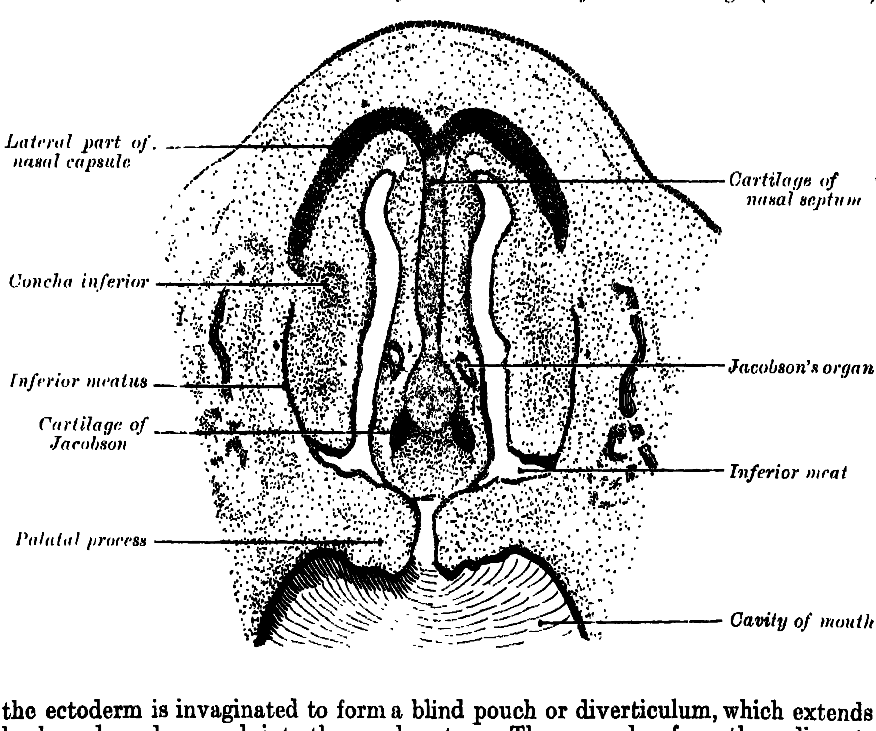
and that of hare-lip through a non-union of the maxillary and globular processes (see page 285). The nasal cavity becomes divided into the two nasal fossæ by a vertical septum, which extends downwards and backwards from the fronto-nasal process and nasal laminæ, and unites below with the palatal processes. Into

FIG. 142.—The roof of the mouth of a human embryo about two and a half months old, showing the mode of formation of the palate. (His.)



this a plate of cartilage extends from the under aspect of the ethmoid plate of the chondrocranium. The anterior part of this persists as the septal cartilage of the nose, but the posterior and upper parts are replaced by the vomer and mesethmoid. On each side of the nasal septum, at its lower and anterior part,

FIG. 143.—Frontal section of nasal cavity of a human embryo, 28 mm. long. (Kollmann.)



the ectoderm is invaginated to form a blind pouch or diverticulum, which extends backwards and upwards into the nasal septum. These pouches form the rudiments of *Jacobson's organs*, which open below, close to the junction of the premaxillary and maxillary bones.

The Limbs.—The limbs begin to make their appearance in the third week as small elevations or buds at the side of the trunk (fig. 145). Prolongations from the muscle- and cutis-plates of several primitive segments extend into each bud, and carry with them the anterior divisions of the corresponding spinal nerves.

FIG. 144.—Head of a human embryo of about eight weeks, in which the nose and mouth are formed. (His.)

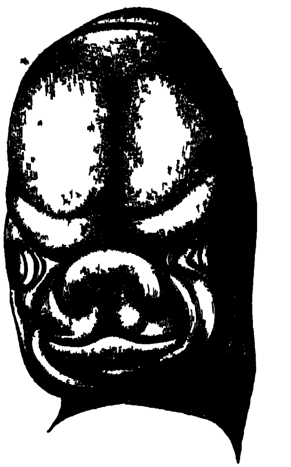


FIG. 145.—Human embryo from thirty-one to thirty four days. (His.)

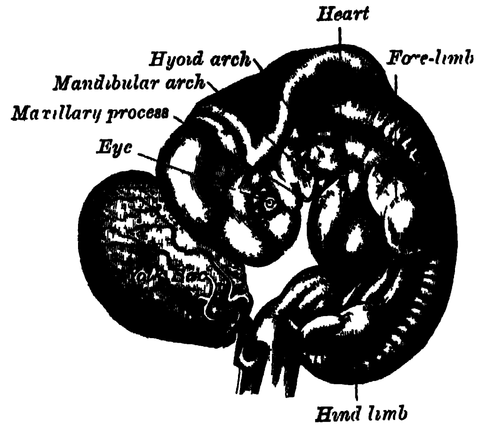
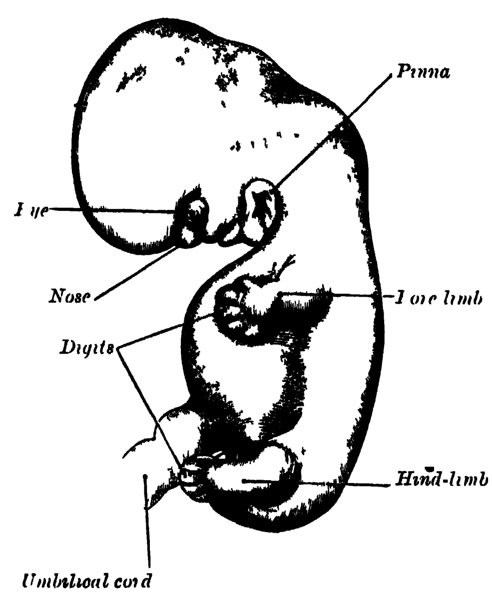


The axial part of the mesoderm of the limb bud becomes condensed and converted into its cartilaginous skeleton, and by the ossification of this the bones of the limbs are formed. By the sixth week the three chief divisions of the limb are marked off by furrows—the upper into arm, forearm, and hand, the lower into thigh, leg, and foot (fig 146) The limbs are at first directed backwards nearly parallel to the long axis of the trunk, and each presents two surfaces and two borders. Of the surfaces, one—the future *flexor* surface of the limb—is directed ventrally, the other, the *extensor* surface, dorsally; while one border, the *pre-axial*, looks forward towards the cephalic end of the embryo, and the other, the *post-axial*, backwards towards the caudal end. The external condyle of the humerus, the radius and the thumb lie along the pre-axial border in the case of the upper limb, and the internal condyle of the femur, the tibia and the great toe along the corresponding border of the lower limb. The pre-axial part is derived from the anterior segments, the post-axial from the posterior segments of the limb bud, and this explains, to a large extent, the innervation of the adult limb, the nerves of the more anterior segments being distributed along the pre-axial (radial or tibial), and those of the more posterior along the post-axial (ulnar or fibular) border of the limb. The limbs next undergo a rotation or torsion through an angle of 90° around their long axes, the rotation

FIG. 146.—Embryo of about six weeks. (His.)



being effected almost entirely at the limb girdles. In the upper limb the rotation is outwards and forwards; in the lower limb, inwards and backwards. In this manner the pre-axial (radial) border of the fore-limb is directed outwards, while the pre-axial (tibial) border of the hind-limb is directed inwards; thus the flexor surface of the fore-limb is turned forwards, and that of the hind-limb backwards.

The Joints.—The mesoderm from which the different parts of the skeleton are formed at first shows no differentiation into masses corresponding with the individual bones. Thus continuous cores of mesoderm form the axes of the limb-buds and a continuous column of mesoderm the future vertebral column. The first indications of the bones and joints are circumscribed condensations of the mesoderm; these condensed parts become chondrified and finally ossified to form the bones of the skeleton. The intervening non-condensed portions consist at first of undifferentiated mesoderm, which may develop in one of three directions. It may be converted into fibrous tissue as in the case of the skull bones, a synarthrodial joint being the result, or it may become partly cartilaginous, in which case an amphiarthrodial joint is formed. Again, it may become looser in texture and a cavity ultimately appear in its midst; the cells lining the sides of this cavity form a synovial membrane and thus a diarthrodial joint is developed.

The tissue surrounding the original mesodermal core forms fibrous sheaths for the developing bones, i.e. periosteum and perichondrium. which are continued between the ends of the bones over the synovial membrane as the capsules of the joints. These capsules are not of uniform thickness, so that in them may be recognised specially strengthened bands which are described as ligaments. This, however, is not the only method of formation of ligaments. In some cases by modification of, or derivations from, the tendons surrounding the joint, additional ligamentous bands are provided to further strengthen the articulations. In other cases (e.g. ligamentum teres of the hip joint) a portion of muscle may be enclosed within the articulation and become modified to form a ligament.

In several of the movable joints the mesoderm which originally existed between the ends of the bones does not become completely absorbed—a portion of it persists and forms an interarticular fibro-cartilage. These interarticular fibro-cartilages may be intimately associated in their development with the muscles surrounding the joint (e.g. the semilunar cartilages of the knee-joint) or with cartilaginous elements, representatives of skeletal structures, which are vestigial in human anatomy (e.g. the fibro-cartilage of the sterno-clavicular joint).

The Muscles.—The voluntary muscles are developed from the myotomes of the primitive segments. Portions of the myotomes retain their position on the side of the neural tube, where they may remain distinct from each other and form the short muscles of the vertebral column, or fuse with corresponding portions of neighbouring myotomes to form the superficial portions of the Erector spinæ. Other portions of the myotomes extend into the trunk wall, where again they may retain their segmental condition, as in the Intercostal muscles, or may fuse with adjacent segments to form the flat muscles of the abdominal wall. Finally, portions of the myotomes wander into the limb buds and there undergo fusions and alterations in form to produce the limb muscles. The original segmental character of the limb muscles is therefore soon lost, but their segmental nerve supplies are retained. Some of the limb muscles expand and migrate secondarily towards the mid-dorsal line (e.g. Trapezius and Latissimus dorsi) or towards the mid-ventral line (e.g. Pectoralis major). Again, muscles may migrate in a cephalic direction (e.g. the facial muscles which are derived from the hyoid arch), or in a caudal direction (e.g. the Serratus magnus). In all cases the muscles carry with them the segmental nerves of the myotomes, from which they were originally derived; two examples of this will suffice, viz.: the Diaphragm, which is derived from the third and fourth, and the Serratus magnus, from the fifth, sixth, and seventh cervical segments as is indicated by their nerves of supply. In man and the higher vertebrates many of the derivatives of the myotomes degenerate and are converted into aponeuroses (e.g. epicranial aponeurosis, or the aponeuroses of the abdominal muscles), or ligaments (e.g. great sacro-sciatic ligament and external lateral ligament of the knee).

The involuntary muscles are derived from the splanchnopleure mesoderm.

The Skin, Glands, and Soft Parts.—The epidermis and its appendages, consisting of the hairs, nails, sebaceous and sweat glands, are developed from the

ectoderm, while the corium or true skin is of mesodermal origin, being derived from the cutis-plates of the primitive segments. About the fifth week the epidermis consists of two layers of cells, the deeper one corresponding to the rete mucosum. The subcutaneous fat appears about the fourth month, and the papillæ of the true skin about the sixth. A considerable desquamation of epidermis takes place during fœtal life, and this desquamated epidermis, mixed with a sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of fœtal life. The nails are formed at the third month, and begin to project from the epidermis about the sixth. The hairs appear between the third and fourth months in the form of solid downgrowths of the deeper layer of the epidermis, the growing extremities of which become inverted by papillary projections from the corium. The central cells of the solid downgrowth undergo alteration to form the hair, while the peripheral cells are retained to form the lining cells of the follicle. About the fifth month, the fœtal hairs (*lanugo*) appear, first on the head and then on the other parts; they drop off after birth, and give place to the permanent hairs. The cellular structures of the sudoriferous and sebaceous glands are formed from the ectoderm, while the connective tissue and blood-vessels are derived from the mesoderm.

The *mammary gland* is also formed partly from mesoderm and partly from ectoderm—its blood-vessels and connective tissue being derived from the former, its cellular elements from the latter. Its first rudiment is seen about the third month, in the form of a number of small inward projections of the ectoderm, which invade the mesoderm; from these, secondary tracts of cellular elements radiate and subsequently give rise to the glandular follicles and ducts. The development of the follicles, however, remains imperfect, except in the adult female.

DEVELOPMENT OF THE NERVOUS SYSTEM AND SENSE ORGANS

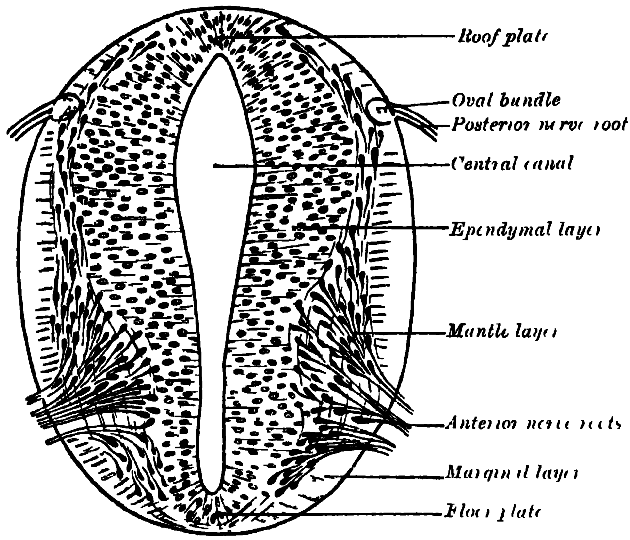
The entire nervous system is of ectodermal origin, and its first rudiment is seen in the neural groove which extends along the dorsal aspect of the embryo (fig. 109). By the elevation and ultimate fusion of the medullary folds, the groove is converted into the neural tube (fig. 111). The anterior end of the neural tube becomes expanded to form the three primary brain-vesicles which are subsequently modified to form the ventricular cavities of the brain (except the fifth); the remainder of the tube forms the central canal of the spinal cord (fig. 147). From its surrounding wall the nervous elements and the neuroglia of the brain and spinal cord are developed.

The Spinal Cord.—At first the wall of the neural tube is composed of a single layer of columnar ectodermal cells. Soon the lateral parts of the wall become thickened, while the dorsal and ventral parts remain thin, and are named the *roof* and *floor plates* (figs. 147, 149). A transverse section of the tube at this stage presents an oval outline, while its lumen has the appearance of a slit. The cells which constitute the wall of the tube are differentiated into two sets: viz. (a) *spongioblasts* or young neuroglia-cells, and (b) *germinal cells*, which are the parents of the *neuroblasts* or young nerve-cells (fig. 148). The spongioblasts are elongated and columnar, and extend from the lumen of the tube to its peripheral wall—their inner and outer ends being modified to form the inner and outer limiting membranes of the cord. The parts of the spongioblasts abutting against the central canal retain their columnar character, and ultimately form the layer of columnar ciliated epithelium which lines this canal. Their outer parts, on the other hand, undergo ramification and form a sponge-like network, termed the *myelospongium*, from which the neuroglia or sustentacular tissue of the cord is developed. The branching of the spongioblasts is most marked near the periphery of the cord, and this outer part, in consequence, assumes the appearance of a fine reticulum.

The germinal cells are large, round or oval, and first make their appearance between the inner ends of the neuroglia-cells on the lateral aspects of the central canal. They increase rapidly in number, so that by the fourth week they form an almost continuous layer on each side of the tube. No germinal cells are found in the roof or floor-plates; the roof-plate retains, in certain regions of the brain, its epithelial character; elsewhere, its cells become spongioblasts. The nuclei of many of the germinal cells exhibit mitotic changes, indicating that the cells

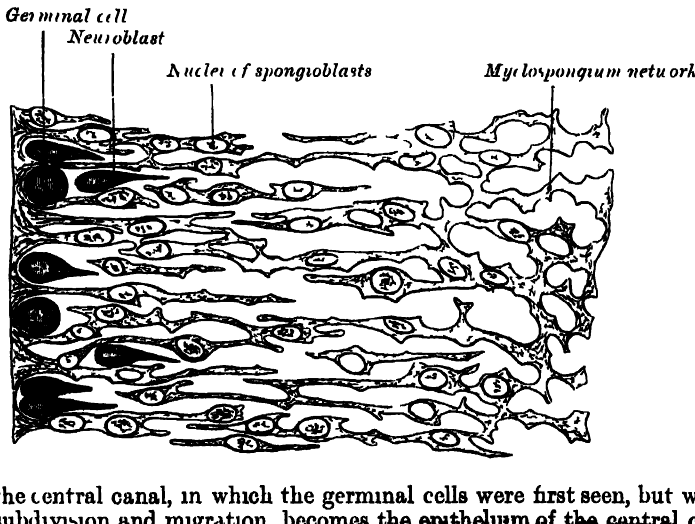
are undergoing rapid subdivision. By such subdivision they give rise to the neuroblasts or young nerve-cells. The neuroblasts migrate outwards from the sides of the central canal, and at the same time they become pear-shaped; the tapering part of the cell undergoes still further elongation, and forms the axis-cylinder or axon of the cell.

FIG. 147.—Section of spinal cord of a four weeks' embryo. (His.)



A transverse section of the cord now exhibits three layers (fig. 147), viz. (1) a *marginal layer* or *marginal veil*, consisting of a fine neuroglial network, in which the future white matter of the cord is developed (2) An intermediate layer, the representative of the future grey matter of the cord This is crowded with neuroblasts, and is sometimes termed the *mantle layer* (3) An internal or *ependymal*

FIG. 148.—Transverse section of the spinal cord of a human embryo at the beginning of the fourth week (After His) The left edge of the figure corresponds to the lining of the central canal



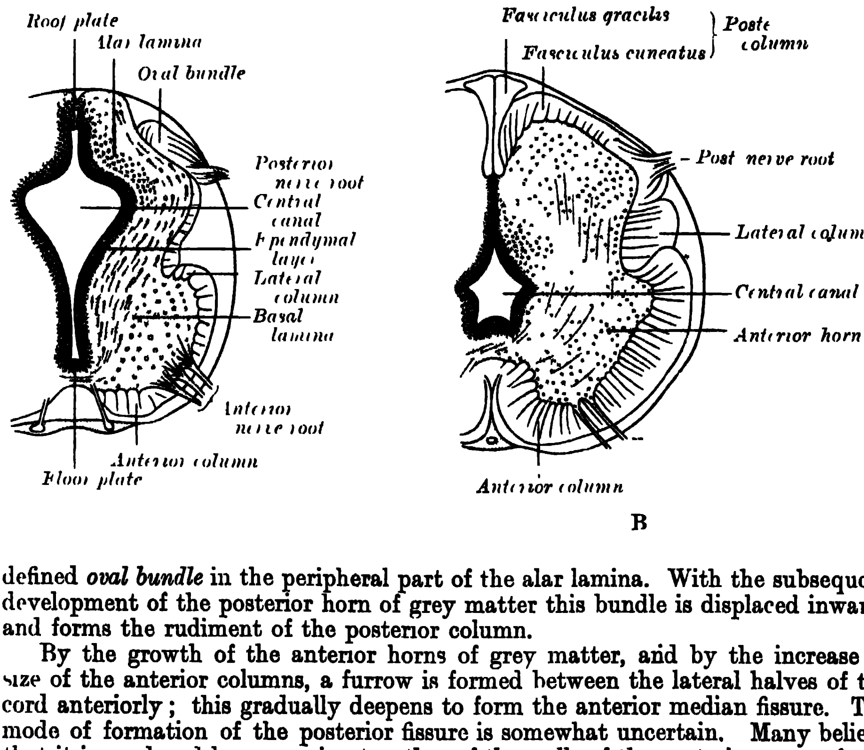
layer, next the central canal, in which the germinal cells were first seen, but which, after their subdivision and migration, becomes the epithelium of the central canal. The lateral walls of the slit-like canal increase in thickness, and the canal itself widens out near its dorsal extremity, and assumes a somewhat lozenge shaped

appearance. The widest part of the canal serves to subdivide the lateral wall of the neural tube into a *dorsal* or *alar*, and a *ventral* or *basal lamina* (fig. 149), a subdivision which extends forwards into the brain.

The ventral part of the mantle layer becomes thickened, and on cross-section appears as a triangular patch between the marginal and ependymal layers. This thickening is the rudiment of the anterior horn of grey matter, and contains many neuroblasts, the axis-cylinders of which pass out through the marginal layer and form the anterior roots of the spinal nerves (figs. 147, 149). The thickening of the mantle layer gradually extends in a dorsal direction, and forms the posterior horn of grey matter. The axons of many of the neuroblasts in the alar lamina pass forward, and cross in the floor-plate to the opposite side of the cord; these form the rudiment of the anterior white commissure of the cord.

The anterior and lateral white columns of the spinal cord consist at first of the axons of the neuroblasts; they are, however, at a later stage, largely augmented by the pyramidal tracts which descend from the cerebral cortex. The fibres of the posterior nerve-roots grow inwards into the spinal cord from the cells of the spinal ganglia; in the spinal cord of a six months fœtus they form a well-

FIG. 149.—Transverse sections through the spinal cords of human embryos; A, about four and a half weeks old. B, about three months old. (His.)



defined *oval bundle* in the peripheral part of the alar lamina. With the subsequent development of the posterior horn of grey matter this bundle is displaced inwards and forms the rudiment of the posterior column.

By the growth of the anterior horns of grey matter, and by the increase in size of the anterior columns, a furrow is formed between the lateral halves of the cord anteriorly; this gradually deepens to form the anterior median fissure. The mode of formation of the posterior fissure is somewhat uncertain. Many believe that it is produced by a growing together of the walls of the posterior part of the central canal. Robinson * traverses this view, and points out that the so-called posterior fissure is occupied by a fibrillated tissue, which is probably of a spongioblastic origin, since its fibrils can be traced directly into the posterior grey commissure.

Up to the fourth month of fœtal life the spinal cord occupies the entire length of the spinal canal, and the spinal nerves pass outwards at right angles from the cord. From this time onwards, the vertebral column grows more rapidly than the cord, and the latter, being fixed above through its continuity with the brain, gradually assumes a higher position within the canal. By the sixth month its lower end reaches only as far as the upper end of the sacral canal; at birth it is

* *Studies in Anatomy*, Owens College, 1891

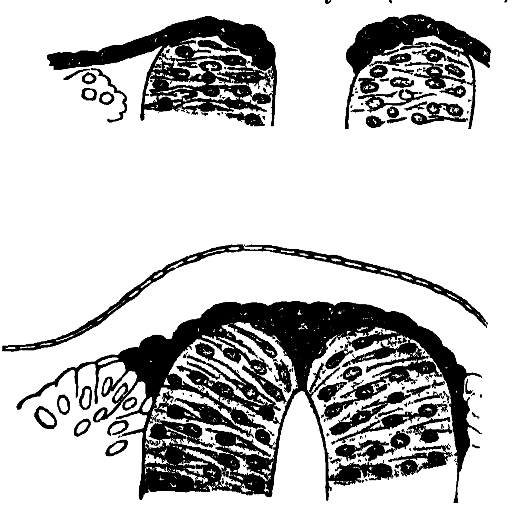
on a level with the third lumbar vertebra, and in the adult it terminates at the lower border of the first or upper border of the second lumbar vertebra. A delicate filament, the *filum terminale*, extends from its lower end as far as the coccyx.

The Spinal Nerves.—Each spinal nerve is attached to the cord by an anterior or ventral and a posterior or dorsal root.

The fibres of the anterior roots are formed by the axons of the neuroblasts which lie in the ventral part of the mantle layer; these axons grow out through the overlying marginal layer and become grouped to form the anterior nerve-roots (fig. 147).

The fibres of the posterior roots are developed from the cells of the spinal ganglia. Before the neural groove is closed to form the neural tube a ridge of ectodermal cells, the *ganglion ridge* or *neural crest* (fig. 150), appears along the prominent margin of each medullary lamina. When the laminæ meet in the middle line the two ganglion ridges fuse and form a wedge-shaped area along the line of closure of the tube. The cells of this area proliferate rapidly opposite the primitive segments and then migrate in an outward and ventral direction to the sides of the neural tube, where they form a series of oval-shaped masses, the future spinal ganglia. These ganglia are arranged symmetrically on the two sides of the neural tube and, except in the region of the tail, are equal in number to the primitive segments. The cells of the ganglia are at first round or oval in shape, but soon assume the form of spindles the extremities of which gradually elongate into central and peripheral processes. The central processes grow inwards and, becoming connected with the neural tube, constitute the fibres of the posterior nerve-roots, while the peripheral processes grow outwards to mingle with the fibres of the anterior root in the spinal nerve. As development proceeds the original bipolar form of the cells changes; the two processes become approximated until they ultimately arise from a single stem in a T-shaped manner. Only in the ganglia of the auditory nerve is the bipolar form retained.

Fig. 150.—Two stages in the development of the neural crest in the human embryo. (Lenhossék.)



The anterior or ventral and the posterior or dorsal nerve-roots join immediately beyond the spinal ganglion to form the *spinal nerve*, which then divides into anterior, posterior, and visceral divisions. The anterior and posterior divisions proceed directly to their areas of distribution without further association with ganglion cells. The visceral divisions are distributed to the thoracic, abdominal, and pelvic viscera, to reach which they pass through the sympathetic cord, and many of the fibres form arborisations around the ganglion cells of this cord. Visceral branches are not given off from all the spinal nerves; they form two groups, viz.: (*a*) *thoracico-lumbar*, from the first or second thoracic to the second or third lumbar nerves; and (*b*) *pelvic*, from the second and third, or third and fourth sacral nerves.

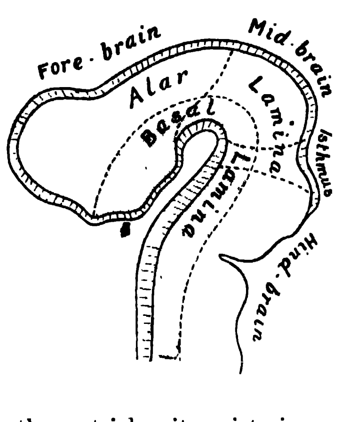
The ganglia of the sympathetic system are generally regarded as being developed as offshoots from the ganglia on the roots of the cranial and spinal nerves.

The Brain.—The brain is developed from the anterior end of the neural tube, which at an early period becomes expanded into three vesicles, the primary cerebral vesicles (figs. 110 and 135). These are marked off from each other by intervening constrictions, and are named the *fore-brain*, the *mid-brain*, and the *hind-brain* (fig. 154)—the last being continuous with the spinal cord. As the result of unequal growth of these different parts three flexures are formed and the

embryonic brain becomes bent on itself in a somewhat zigzag fashion; the two earliest flexures are concave ventrally and are associated with corresponding flexures of the whole head. The first flexure appears in the region of the mid-brain, and is named the *primary cephalic flexure* (fig. 155). By means of it the fore-brain is bent in a ventral direction around the anterior end of the notochord and fore-gut, with the result that the floor of the fore-brain comes to lie almost parallel with that of the hind-brain (fig. 155). This flexure causes the mid-brain to become, for a time, the most prominent part of the brain, since its dorsal surface corresponds with the convexity of the curve. The second bend appears at the junction of the hind-brain and spinal cord. This is termed the *cervical flexure* (fig. 157), and increases from the third to the end of the fifth week, when the hind-brain forms nearly a right angle with the spinal cord; after the fifth week erection of the head takes place and the cervical flexure diminishes and disappears. The third bend is named the *pontine flexure* (fig. 157), because it is found in the region of the future pons Varolii. It differs from the other two in that (*a*) its convexity is forwards, and (*b*) it does not affect the head. The lateral walls of the brain-tube, like those of the spinal cord, are divided by internal furrows into alar or dorsal and basal or ventral laminæ.

The **hind-brain or rhombencephalon.**—The cavity of the hind-brain becomes the fourth ventricle. At the time when the primary cephalic flexure makes its appearance, the length of the hind-brain exceeds the combined lengths of the other two vesicles. Immediately behind the mid-brain it exhibits a marked constriction, the *isthmus rhombencephali* (fig. 154, Isthmus), which is best seen when the brain is viewed from the dorsal aspect. From the isthmus the valve of Vieussens or superior medullary velum and the superior peduncles of the cerebellum are formed. It is customary to divide the rest of the hind-brain into two parts: viz. an upper, called the *metencephalon*, and a lower, the *myelencephalon*. The cerebellum is developed by a thickening of the roof, and the pons by a thickening in the floor and lateral walls of the metencephalon. The floor and lateral walls of the myelencephalon are thickened to form the medulla oblongata; its roof remains thin, and, retaining to a great extent its epithelial nature, is expanded in a lateral direction. Later, by the growth and backward extension of the cerebellum, the roof is folded inwards towards the cavity of the fourth ventricle; it assists in completing the dorsal wall of this cavity, and is also invaginated to form the epithelial covering of its choroid plexuses. Above it is continuous with the inferior medullary velum; below, with the obex and ligulæ.

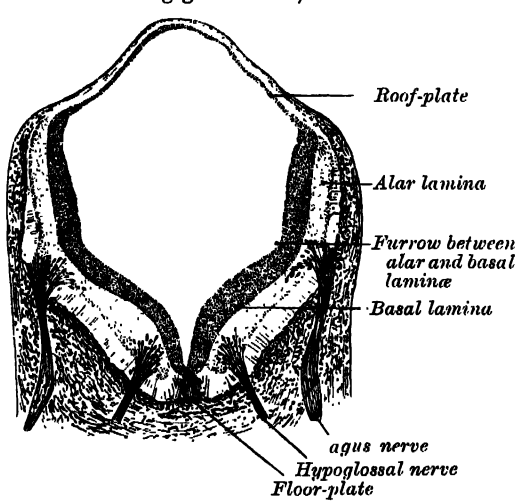
FIG. 151.—Diagram to illustrate the alar and basal laminæ of brain vesicles. (His.)



The development of the *medulla oblongata* resembles that of the spinal cord, but at the same time exhibits one or two interesting modifications. On transverse section the myelencephalon at an early stage is seen to consist of two lateral walls, connected across the middle line by floor and roof plates, as in the cord (figs. 152 and 153). Each lateral wall consists of an alar and a basal lamina, separated by an internal furrow, the remains of which are represented in the adult brain by the foveæ on the floor of the fourth ventricle. The contained cavity is more or less triangular in outline, the base being formed by the roof-plate, which is thin and greatly expanded transversely. Pear-shaped neuroblasts are developed in the alar and basal laminæ, and their narrow stalks are elongated to form the axis-cylinders of the nerve-fibres. Opposite the furrow or boundary between the alar and basal laminæ a bundle of nerve-fibres attaches itself to the outer surface of the alar lamina. This is named the *tractus solitarius* (fig. 153), and is formed by the sensory fibres of the glosso-pharyngeal and vagus nerves. It is the homologue of the *oval bundle* seen in the cord, and, like it, is developed by an ingrowth of fibres from the ganglia of the neural crest. At first it is applied to the outer surface of the alar lamina, but it soon becomes buried, owing to the growth over

it of the neighbouring parts. By the fifth week the dorsal part of the alar lamina bends in an outward direction along its entire length, to form what is termed the *rhombic lip* (figs. 153, 156). Within a few days this lip becomes applied to, and unites with, the outer surface of the main part of the alar lamina, and so covers in the tractus solitarius and also the spinal root of the fifth nerve.

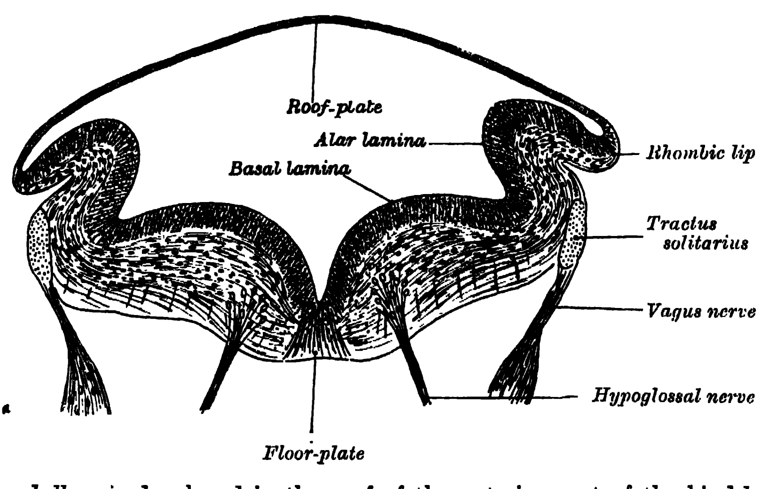
Fig. 152.—Transverse section of medulla oblongata of human embryo. × 32. (From Kollmann's 'Entwickelungsgeschichte.')



Neuroblasts accumulate in the mantle layer: those in the basal lamina correspond with the cells in the anterior horn of the spinal cord, and, like them, give origin to motor nerve-fibres; in the medulla they are, however, arranged in groups or nuclei, instead of forming a continuous column. From the alar lamina and its rhombic lip, neuroblasts migrate into the basal lamina, and become aggregated to form the olivary nuclei, while many send their axis-cylinders through the floor-plate to the opposite side of the medulla, and thus constitute the rudiment of the raphe of the medulla. By means of this thickening of the ventral portion of the medulla the motor nuclei are buried deeply in the interior, and, in the adult, are found close to the floor of the fourth ventricle. This is still further accentuated: (*a*) by the development of the anterior pyramids, which are formed about the fourth month by the downward growth of the motor fibres from the cerebral cortex; and (*b*) by the fibres which pass to and from the cerebellum.

The *pons Varolii* is developed from the ventro-lateral wall of the metencephalon by a process similar to that which has been described for the medulla.

Fig. 153.—Transverse section of medulla oblongata of human embryo. (After His.)

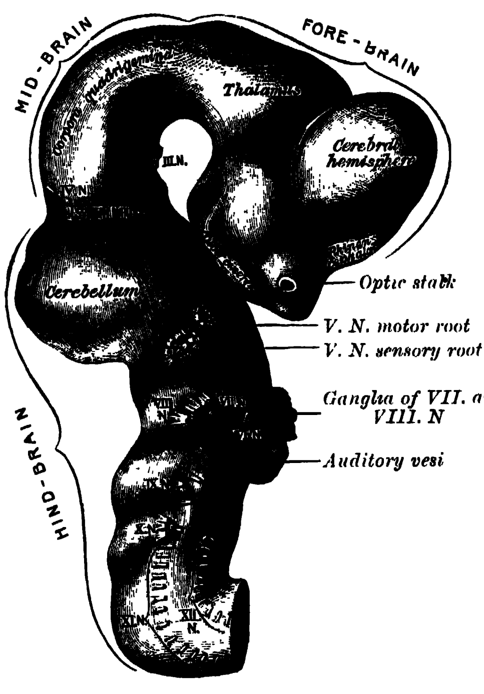


The *cerebellum* is developed in the roof of the anterior part of the hind-brain (figs. 154, 157). The alar laminæ of this region become thickened to form two lateral plates which soon fuse in the middle line and produce a thick lamina which roofs in the upper part of the cavity of the hind-brain vesicle; this constitutes the rudiment of the cerebellum, the outer surface of which is at first smooth and convex. During the second month a pair of fissures, the *floccular fissures*, appear, one on

either side, in the postero-lateral part of the lamina and become continuous with a third fissure, the *post-nodular*, which is developed across the central part of the lamina. By this means a narrow area is mapped off; the central part of this area becomes the nodule, its lateral extremities the flocculi, and the intermediate portions the inferior medullary velum. Three additional furrows are soon developed. One, the *fissura prima* of Elliot-Smith, appears as a transverse groove on the anterior part of the upper surface and extends into the hemispheres; it indicates the preclival fissure of the adult cerebellum. The portion of the cerebellum in front of it is differentiated into the lingula, the lobus centralis, and the lobus culminis. The other two furrows mark off the future pyramid and are named the *supra-pyramidal* and *pre-pyramidal fissures*. The supra-pyramidal is the *fissura secunda* of Elliot-Smith, and forms the post-pyramidal fissure of the adult cerebellum.

During the fourth and fifth months the following fissures appear in the lateral hemispheres: (1) the *post-lunate*, between the posterior crescentic and postero-superior lobes; the union of the two post-lunate fissures across the middle line forms the post-clival fissure which constitutes the posterior boundary of the lobus clivi; (2) the *para-pyramidal*, which blends with the post-pyramidal and separates the lobus tuberis from the lobus pyramidis; (3) the *post-tonsillar*, between the biventral lobe and the amygdala or tonsil; this becomes continuous with the pre-pyramidal, and with it forms the posterior limit of the lobus uvulæ; (4) the *great horizontal fissure*; although an important land-mark in the adult cerebellum, this fissure does not appear until about the end of the fifth month, and from a developmental point of view is therefore of secondary interest. Some observers maintain that the folium cacuminis, which connects the postero-superior lobes across the middle line, is not developed until after birth, while others assert that it is present at the sixth month of fœtal life. On the ventricular surface of the cerebellar lamina a transverse furrow, the *incisura fastigii*, appears, and deepens to form the tent-like recess of the roof of the fourth ventricle. The rudiment of the cerebellum at first projects in a dorsal direction; but, by the backward growth of the cerebrum, it is folded downwards and somewhat flattened, and the thin roof-plate of the fourth ventricle, originally continuous with the posterior border of the cerebellum, is projected inwards towards the cavity of the ventricle.

Fig. 154.—Exterior of brain of human embryo of four and a half weeks. (From model by His.)



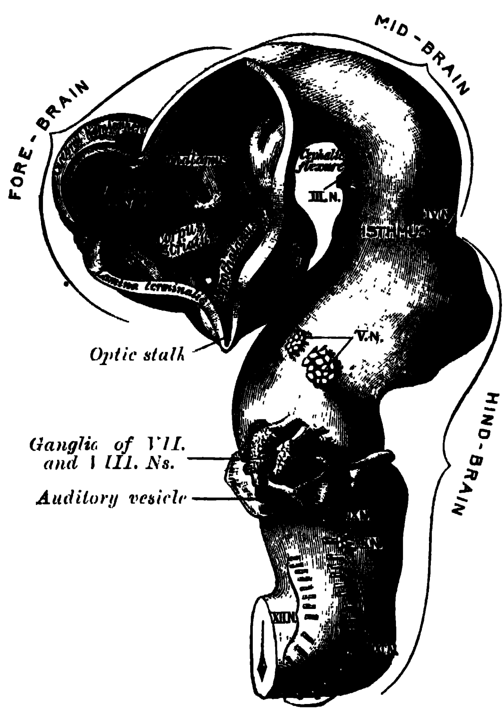
The mid-brain or mesencephalon.—The mid-brain (figs. 154 to 157) exists for a time as a thin-walled cavity of some size, and is separated from the isthmus rhombencephali behind, and from the fore-brain in front, by slight constrictions. Its cavity becomes relatively reduced in diameter, and forms the Sylvian aqueduct of the adult brain. Its basal laminæ increase in thickness to form the crura cerebri, which are at first of small size, but rapidly enlarge after the fourth month. The neuroblasts of these laminæ are grouped in relation to the sides and floor of the Sylvian aqueduct, and constitute the nuclei of the third and fourth nerves, and of the descending root of the fifth nerve. By a similar thickening process its alar laminæ are developed into the

corpora quadrigemina. The dorsal part of the wall for a time undergoes expansion, and presents an interior median furrow and a corresponding surface ridge; these, however, disappear, and the latter is replaced by a groove. Subsequently two oblique furrows extend inwards and backwards, and the thickened lamina is thus subdivided into the quadrigeminal bodies.

The fore-brain.—A transverse section of the early fore-brain shows the same parts as are displayed in similar sections of the spinal cord and medulla oblongata, viz.: a pair of thick lateral walls connected by thin floor and roof plates. Moreover, each lateral wall exhibits a division into a dorsal or alar and a ventral or basal lamina separated internally by a furrow termed the *sulcus of Monro.* This sulcus ends anteriorly at the inner extremity of the optic stalk, and in the adult brain is retained as a slight groove extending backwards from the foramen of Monro to the Sylvian aqueduct.

At a very early period—in some animals before the closure of the cranial part of the neural tube—two lateral diverticula, the *optic vesicles*, appear, one on either side of the fore-brain; for a time they communicate with the cavity of the fore-brain by relatively wide openings. The peripheral parts of the vesicles expand while the proximal parts are reduced to tubular stalks, the *optic stalks*. The optic vesicle gives rise to the retina and the epithelium on the back of the ciliary body and iris; the optic stalk is invaded by nerve-fibres to form the optic nerve. The fore-brain then grows forwards, and from the alar laminæ of this front portion the cerebral hemispheres originate as diverticula which rapidly expand to form two large pouches, one on either side. The cavities of these diverticula are the rudiments of the lateral ventricles; they communicate with the mesial part of the fore-brain cavity by relatively wide openings, which ultimately form the foramen of Monro in the adult brain. The mesial portion of the wall of the fore-brain vesicle consists of a thin lamina, the *lamina terminalis* (figs. 155, 157), which stretches from the foramen of Monro to the recess at the base of the optic stalk. The anterior part of the fore-brain, including the rudiments of the cerebral hemispheres, is named the *telencephalon*, and its posterior portion is termed the *diencephalon*; both of these contribute to the formation of the third ventricle.

Fig. 155.—Brain of human embryo of four and a half weeks, showing interior of fore-brain. (From model by His.)



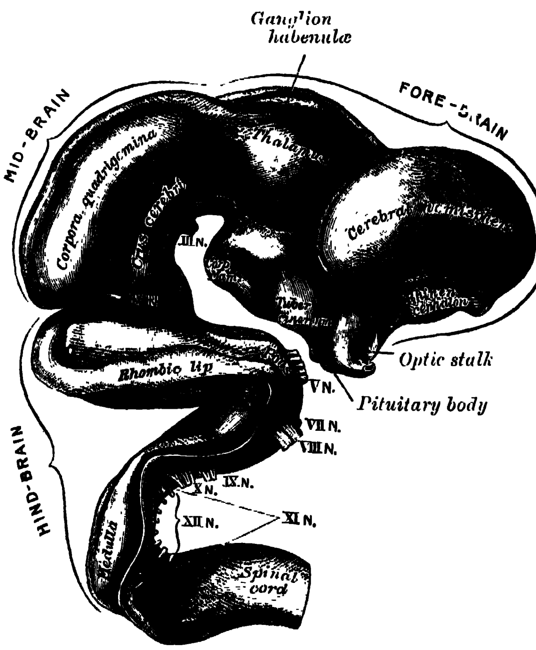
The *diencephalon.*—From the alar lamina of the diencephalon the thalamus, metathalamus, and epithalamus are developed. The *thalamus* (figs. 157, 158) arises as a thickening which involves the anterior two-thirds of the alar lamina. The two thalami are visible, for a time, on the surface of the brain, but are subsequently hidden by the cerebral hemispheres which grow backwards over them. The thalami extend inwards and gradually narrow the cavity between them into a slit-like aperture which forms the greater part of the third ventricle; their mesial surfaces ultimately adhere, in part, to each other, and the *middle* or *grey commissure* of the ventricle is developed across the point of contact. The *metathalamus* comprises the geniculate bodies which originate as slight outward bulgings of the alar lamina. In the adult the external geniculate body appears as an eminence on the

outer part of the posterior end of the thalamus, while the internal is situated on the lateral aspect of the mesencephalon.

The *epithalamus* includes the pineal body, the posterior commissure, and the trigonum habenulæ. The *pineal body* arises as an upward evagination of the roof-plate immediately in front of the mid-brain; this evagination becomes solid with the exception of its proximal part, which persists as the *recessus pinealis.* In lizards the pineal evagination is elongated into a stalk, and its peripheral extremity is expanded into a vesicle, in which a rudimentary lens and retina are formed; the stalk becomes solid and nerve-fibres make their appearance in it, so that in these animals the pineal body forms a rudimentary eye. The *posterior commissure* is formed by the ingrowth of fibres into the depression behind and below the pineal evagination, and the trigonum habenulæ is developed in front of the pineal recess.

From the basal laminæ of the diencephalon the *pars mamillaria hypothalami* is developed; this comprises the corpora mamillaria and the posterior part of the tuber cinereum. The corpora mamillaria arise as a median thickening, which becomes divided into two by a mesial furrow during the third month.

FIG. 156.—Exterior of brain of human embryo of five weeks. (From model by His.)



The roof-plate of the diencephalon, in front of the pineal body, remains thin and epithelial in character, and is subsequently invaginated by the choroid plexuses of the third ventricle.

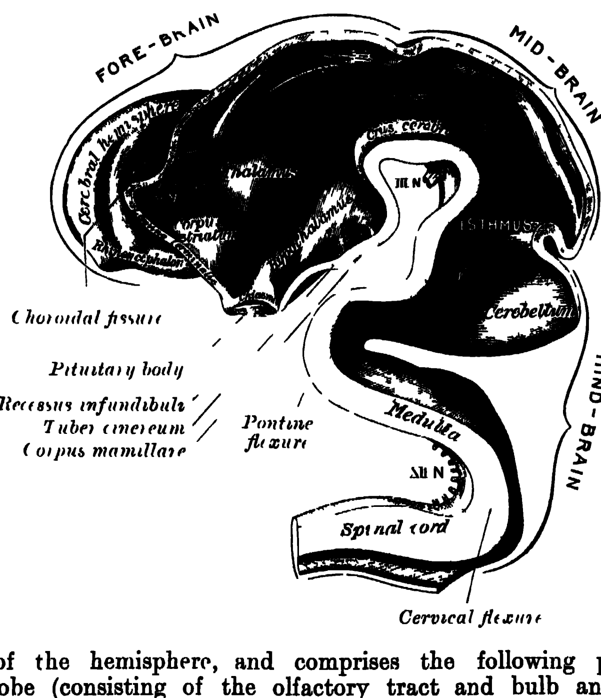
The *telencephalon.*—This consists of a median portion and two lateral diverticula, one on either side. The median portion forms the anterior part of the cavity of the third ventricle, and is closed below and in front by the lamina terminalis. The lateral diverticula consist of outward pouchings of the alar laminæ; the cavities represent the lateral ventricles, and their walls become thickened to form the nervous matter of the cerebral hemispheres. The roof-plate of the telencephalon remains thin, and is continuous in front with the lamina terminalis and behind with the roof-plate of the diencephalon. In the basal laminæ and floor-plate the *pars optica hypothalami* is developed; this comprises the anterior part of the tuber cinereum, the infundibulum and posterior lobe of the pituitary body, and the optic commissure. The anterior part of the tuber cinereum is derived from the posterior part of the floor of the telencephalon. The infundibulum and posterior lobe of the pituitary body arise as a downward diverticulum from the floor. The most

dependent part of the diverticulum becomes solid and forms the posterior lobe of the pituitary body; the anterior lobe of this body is developed from a diverticulum of the ectodermal lining of the stomatodæum (page 155). The optic commissure is developed by the meeting and partial decussation of the optic nerves, which subsequently grow backwards as the optic tracts and terminate in the diencephalon.

The *cerebral hemispheres*.—As already stated, these arise as diverticula of the alar laminæ of the telencephalon (figs. 154 to 157); they increase rapidly in size and ultimately overlap the parts which are developed from the mid- and hind-brains. This great expansion of the hemispheres is a characteristic feature of the brains of mammals, and attains its maximum development in the brain of man. Elliot-Smith divides each cerebral hemisphere into three fundamental parts, viz.: the rhinencephalon, the corpus striatum, and the neopallium.

The *rhinencephalon* (figs. 154, 156) represents the oldest part of the telencephalon, and forms almost the whole of the hemisphere in fishes, amphibians, and reptiles. In man it is feebly developed in comparison with

FIG. 157.—Interior of brain of human embryo of five weeks. (From model by HIS.)



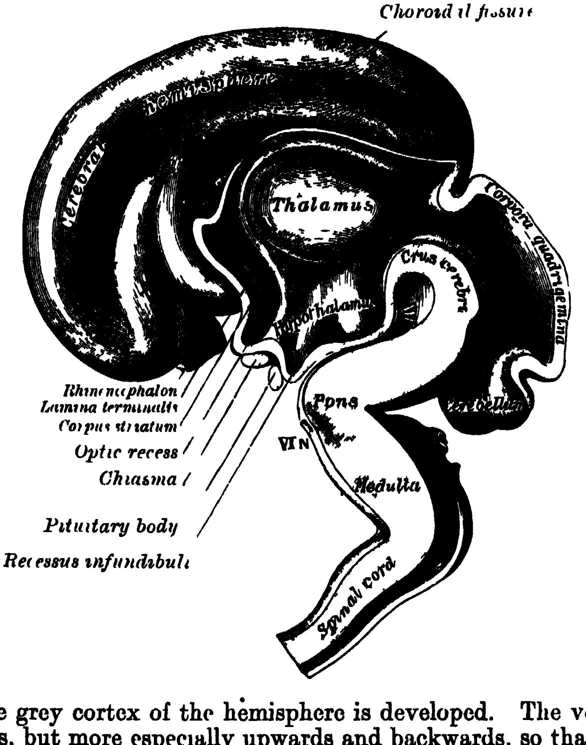
the rest of the hemisphere, and comprises the following parts, viz.: the olfactory lobe (consisting of the olfactory tract and bulb and the trigonum olfactorium), the locus perforatus anticus, the septum pellucidum, the subcallosal, supracallosal, and dentate gyri, the fornix, the hippocampus, and the uncus, the last is the representative of the large pyriform lobe of the lower animals. The olfactory lobe appears as a longitudinal ridge, with a corresponding internal furrow, on the under surface of the hemisphere close to the lamina terminalis. This ridge becomes divided by a groove into an anterior and a posterior part. The anterior grows forwards as a hollow stalk the lumen of which is continuous with the anterior part of the ventricular cavity. The stalk becomes solid and forms the rudiment of the olfactory bulb and tract; a strand of gelatinous tissue in the interior of the bulb indicates the position of the original cavity. From the posterior part the locus perforatus anticus and gyrus subcallosus are developed. The position and connections of the remaining portions of the rhinencephalon are described with the anatomy of the brain.

The *corpus striatum* (figs. 155, 157) appears in the fourth week as a triangular thickening of the wall of the telencephalon between the optic recess and the foramen

of Monro. It increases in size, and by the second month is seen as a swelling in the floor of the future lateral ventricle; this swelling reaches as far as the posterior end of the primitive hemisphere, and as a consequence when this part of the hemisphere grows backwards and downwards to form the temporal lobe, the posterior part of the corpus striatum is carried into the roof of the descending horn, where it is seen as the tail of the caudate nucleus in the adult brain. During the fourth and fifth months the corpus striatum becomes incompletely subdivided by the fibres of the internal capsule into two masses, an inner, the caudate nucleus, and an outer, the lenticular nucleus. In front, the corpus striatum is continuous with the grey matter of the locus perforatus anticus; externally it is confluent for a time with that portion of the wall of the vesicle which is developed into the island of Reil, but the continuity is subsequently interrupted by the fibres of the external capsule.

The *neopallium* forms the remaining, and by far the greater, part of the cerebral hemisphere. It consists, at an early stage, of a relatively large, more or less hemispherical cavity—the primitive lateral ventricle—enclosed by a thin wall

Fig. 158.—Median section of brain of human embryo of three months. (From model by His.)

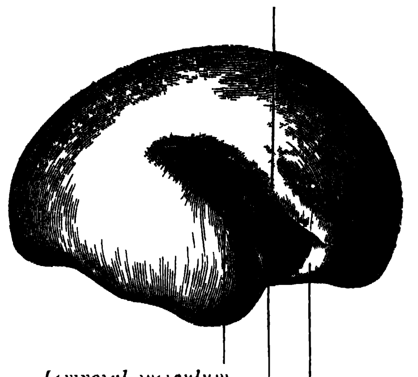


from which the grey cortex of the hemisphere is developed. The vesicle expands in all directions, but more especially upwards and backwards, so that by the third month the hemispheres cover the diencephalon, by the sixth they overlap the mid-brain, and by the eighth the hind-brain.

The hemispheres are separated by a deep cleft, the forerunner of the great longitudinal fissure, and this cleft is occupied by a septum of mesodermal tissue which constitutes the primitive falx cerebri. Coincidently with the expansion of the vesicle, its cavity is drawn out into three prolongations which represent the horns of the future lateral ventricle; the posterior extremity of the vesicle is carried downwards and forwards and forms the descending horn, the posterior horn being produced somewhat later, in association with the backward growth of the occipital lobe of the hemisphere. The roof-plate of the fore-brain remains thin and of an epithelial character, it is invaginated into the lateral ventricle along the mesial wall of the hemisphere. This invagination constitutes the choroidal fissure, and extends from the foramen of Monro to the posterior end of the vesicle. Mesodermal tissue, continuous with

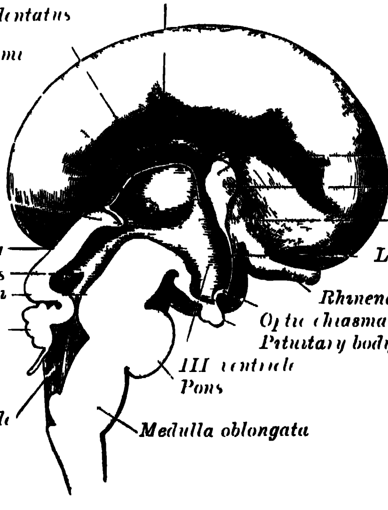
that of the septum in the fissure between the hemispheres, and carrying blood-vessels with it, spreads between the two layers of the invaginated fold and forms the rudiment of the velum interpositum, the margins of the velum become highly vascular and form the choroidal plexuses which for some months completely fill the ventricular cavities. By the downward and forward growth of the posterior end of the vesicle to form the temporal lobe the choroidal fissure finally reaches from the foramen of Monro to the extremity of the descending horn of the ventricle. The portion of the cerebral wall immediately above the choroidal fissure forms what is termed the *hippocampal formation*, and in the adult is represented by the supra-callosal gyrus, the hippocampus, and the gyrus dentatus.

FIG. 159. — Outer surface of cerebral hemisphere of human embryo of about five months.



The outer surface of the hemisphere is at first smooth, but later it exhibits a number of elevations or convolutions, separated from each other by furrows or fissures. The fissures, most of which make their appearance during the sixth or seventh months of fœtal life are divided into (*a*) *complete*, which result from foldings of the entire thickness of the cerebral wall, and thus produce corresponding eminences in the ventricular cavity, and (*b*) *incomplete*, affecting only the superficial part of the wall and therefore leaving no impressions in the ventricle. The complete fissures are the hippocampal or dentate, the collateral and the anterior part of the calcarine, and these give rise respectively to the following eminences in the ventricle, viz. the hippocampus major, the eminentia collateralis, and the calcar avis or hippocampus minor. The Sylvian fissure is sometimes described as a complete fissure but, strictly speaking, this is not correct. It first appears as a depression, the *Sylvian*

FIG. 160.—Median section of brain of human embryo of four months. (Marchand.)



fossa, on the outer surface of the hemisphere (fig. 159), this fossa corresponds with the position of the corpus striatum, and its floor is moulded to form the island of Reil. The intimate connection which exists between the cortex of the island

and the subjacent corpus striatum prevents this part of the hemisphere wall from expanding at the same rate as the portions which surround it. The neighbouring parts of the hemisphere therefore gradually grow over and cover in the island, and constitute the temporal, fronto-parietal, frontal, and orbital opercula of the adult brain. By the end of the first year after birth the island is completely submerged by the approximation of the opercula. The fissures separating the opposed margins of the opercula constitute the composite fissure of Sylvius.

The **commissures** (fig. 160).—The development of the middle (page 122) and posterior (page 123) commissures has already been referred to. The great commissures of the hemispheres, viz.: the corpus callosum, the fornix, and anterior commissure, arise from the lamina terminalis. About the fourth month a small thickening appears in this lamina, immediately in front of the foramen of Monro. The lower part of this thickening is soon constricted off, and fibres appear in it to form the anterior commissure. The upper part continues to grow with the hemispheres, and is invaded by two sets of fibres. Transverse fibres, extending between the hemispheres, pass into its dorsal part, which is now differentiated as the corpus callosum. Into the ventral part longitudinal fibres from the hippocampus pass to the lamina terminalis, and through that structure to the corpora mamillaria; these fibres constitute the fornix. A small portion of the original thickening, lying antero-inferiorly between the corpus callosum and fornix, is not invaded by the commissural fibres; it remains thin, and later a cavity forms in its interior. The cavity is the so-called fifth ventricle, and its bounding walls the septum pellucidum.

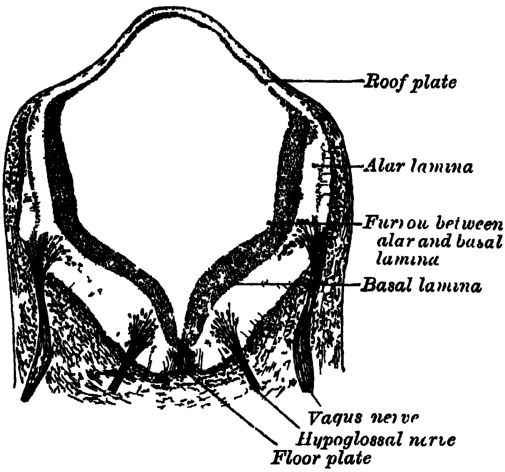
A summary of the parts derived from the brain vesicles is given in the following table:—

Hind-brain or rhombencephalon	1. Myelencephalon	Medulla oblongata Lower part of fourth ventricle.
	2. Metencephalon	Pons Varolii Cerebellum Upper part of fourth ventricle.
	3. Isthmus rhombencephali	Valve of Vieussens Superior peduncles of cerebellum.
Mid-brain or mesencephalon .		Crura cerebri Corpora quadrigemina Aqueduct of Sylvius.
Fore-brain	1. Diencephalon	Thalamus Metathalamus Epithalamus Pars mamillaria hypothalami Posterior part of third ventricle.
	2. Telencephalon	Anterior part of third ventricle Pars optica hypothalami Cerebral hemispheres Lateral ventricles Foramen of Monro.

The Cranial Nerves.—With the exception of the olfactory and optic nerves, which will be specially considered, the cranial nerves are developed in a similar manner to the spinal nerves (see page 118). The sensory or afferent nerves are derived from the cells of the ganglion rudiments of the neural crest. The central processes of these cells grow into the brain and form the roots of the nerves, while the peripheral processes extend outwards and constitute their fibres of distribution. It has been seen, in considering the development of the medulla oblongata (page 119), that the *tractus solitarius* (fig. 162), derived from the fibres which grow inwards from the ganglion rudiments of the glosso-pharyngeal and vagus

nerves, is the homologue of the *oval bundle* in the cord which had its origin in the posterior nerve-roots. The motor or efferent nerves arise as outgrowths of the neuroblasts situated in the basal laminæ of the mid- and hind-brain. While, however, the anterior spinal nerve-roots arise in one series from the basal lamina, the cranial motor nerves are grouped into two sets, according as they spring from the mesial or lateral parts of the basal lamina. To the former set belong the third, fourth, sixth, and twelfth nerves; to the latter, the eleventh and the motor fibres of the fifth, seventh, ninth, and tenth nerves (figs. 161, 162).

FIG. 161.—Transverse section of medulla oblongata of human embryo. × 32. (From Kollmann's 'Entwickelungsgeschichte.')

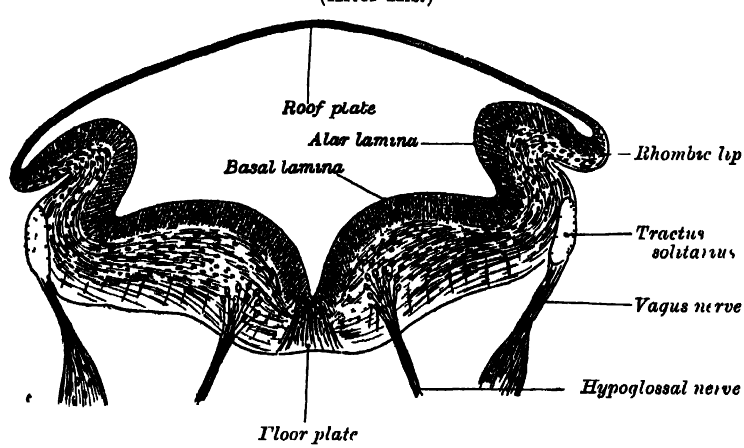


The Nose.—The development of the nose has already been considered (pages 110, 111).

The *olfactory nerves* are developed from the cells of the ectoderm which lines the olfactory pits; these cells undergo proliferation and give rise to what are termed the *olfactory cells* of the nose. The axons of the olfactory cells grow into the overlying olfactory bulb and form the olfactory nerves.

The Eye.—The development of the eyes commences by the protrusion of a pair of diverticula from the lateral aspects of the fore-brain. These diverticula are known as the *optic vesicles*, they project towards the sides of the head, and the peripheral part of each expands to form a hollow bulb, while the proximal part remains narrow and constitutes the *optic stalk* (figs. 163, 164). The ectoderm of the surface of the embryo in the area overlying the bulb becomes thickened, invaginated, and finally severed from the ectodermal covering of the

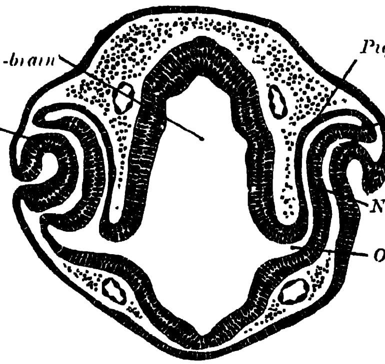
FIG. 162.—Transverse section of medulla oblongata of human embryo. (After His.)



head as a vesicle of cells, the *lens vesicle*, which constitutes the rudiment of the crystalline lens. The outer wall of the bulb is indented by the lens rudiment and invaginated until it comes into contact with the inner wall; the bulb is thus converted into a cup, the *optic cup*, consisting of two strata of cells (fig. 164). These two strata are continuous with each other at the cup margin, which ultimately overlaps the front of the lens and reaches as far forward as

the future aperture of the pupil. The invagination is not limited to the outer wall of the bulb, but involves also its postero-inferior surface and extends in the form of a groove for some distance along the optic stalk, so that, for a time, a gap or fissure, the *choroidal fissure*, exists in the lower part of the cup (fig. 165). Through the groove and fissure the mesoderm extends into the optic stalk and cup, and in this mesoderm a blood-vessel is developed; when the groove and fissure are closed this vessel forms the central artery of the retina. Some-

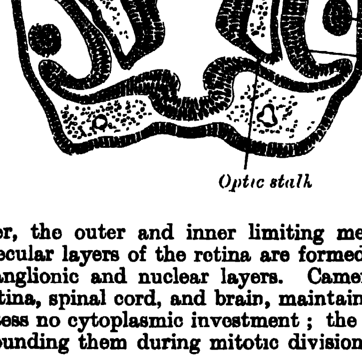
FIG. 163.—Transverse section of head of chick embryo of forty-eight hours' incubation. (From Duval's 'Atlas d'Embryologie.')



times the choroidal fissure remains patent, giving rise to the condition known as *coloboma*.

The retina is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells which assume a columnar shape, acquire pigment, and form the pigmented layer of the retina. The cells of the inner stratum proliferate and form a layer of considerable thickness from which the nervous elements and the sustentacular fibres of the retina, together with a portion of the vitreous body, are developed. In that portion of the cup which overlaps the lens the inner stratum is not differentiated into nervous elements, but forms a layer of columnar cells which is applied to the pigmented layer, and these two strata form the *pars ciliaris* and *pars iridica retinæ*.

FIG. 164.—Transverse section of head of chick embryo of fifty-two hours' incubation. (From Duval's 'Atlas d'Embryologie.')



The cells of the inner or retinal layer of the optic cup become differentiated into spongioblasts and germinal cells, and the latter by their subdivisions give rise to neuroblasts. As in the spinal cord, the spongioblasts ramify to form a myelospongium, from which the sustentacular fibres of Müller, the outer and inner limiting membranes, together with the ground-work of the molecular layers of the retina are formed. The neuroblasts become arranged to form the ganglionic and nuclear layers. Cameron,* after careful study of the neuroblasts in the retina, spinal cord, and brain, maintains that they consist of nuclei only, and that they possess no cytoplasmic investment; the 'clear protoplasm, which has been described as surrounding them during mitotic division, being merely the

* Development of the Retina in Amphibia, *Journal of Anatomy and Physiology*, vol. xxxix, 1905.

achromatic nuclear substance set free owing to the disappearance of the nuclear membrane.' He further maintains that the nuclei of the nuclear layers undergo subsequent multiplication by *direct* division. The layer of rods and cones is first developed in the central part of the optic cup, and from there gradually extends towards the cup-margin.

FIG. 165.—Optic cup and choroidal fissure seen from below, from a human embryo of about four weeks. (Kollmann.)

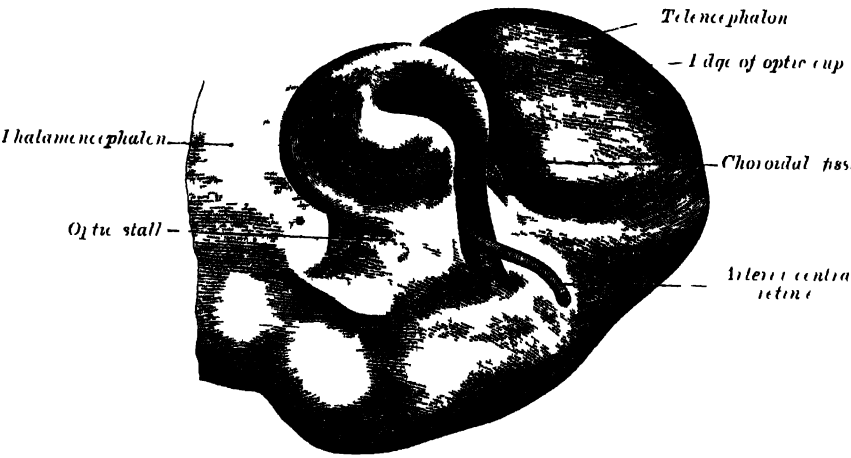


FIG. 166.—Horizontal section through the eye of an eighteen days embryo rabbit. × 30. (Kölliker.)

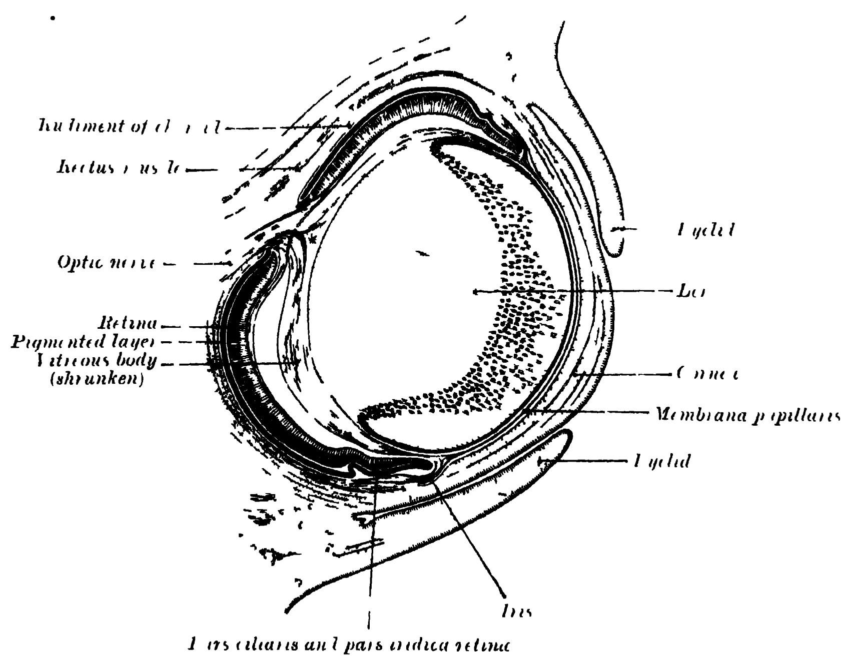


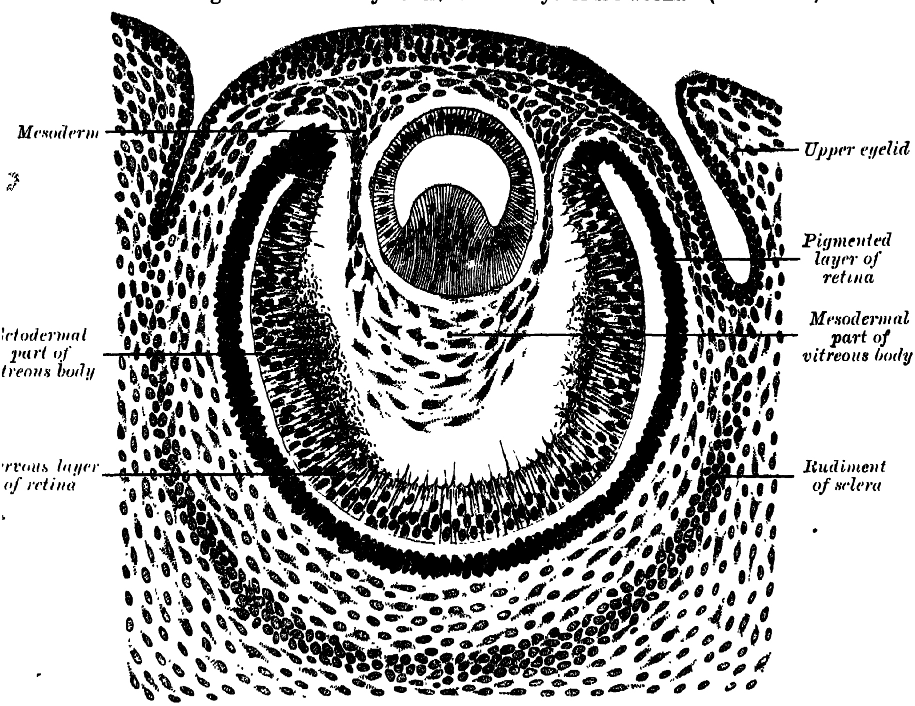
The rods and cones first appear as clear globules, which, after being protruded through the inner limiting membrane, rapidly increase in size—a process which would seem to depend on their power of digesting and absorbing the pigment from the cells of the pigmented layer.

The optic stalk is converted into the optic nerve by the obliteration of its cavity and the growth of nerve-fibres into it. Most of these fibres are centripetal,

and grow into the optic stalk from the nerve-cells of the retina, but a few extend in the opposite direction and are derived from nerve-cells in the brain.

The crystalline lens is developed from the lens vesicle, which recedes within the margin of the cup, and becomes separated from the overlying ectoderm by mesoderm. The cells forming the posterior wall of the vesicle lengthen and are converted into the lens-fibres, which grow forward and fill up the cavity of the vesicle. The cells

FIG. 167.—Sagittal section of eye of human embryo of six weeks. (Kollmann.)



forming the anterior wall retain their cellular character, and form the epithelium on the anterior surface of the adult lens. By the second month the lens is invested by a vascular mesodermal capsule, the *tunica vasculosa lentis*, the blood-vessels of which are chiefly derived from the central artery of the retina; the part of

FIG. 168.—Section through the head of a human embryo, about twelve days old, in the region of the hind-brain. (Kollmann.)

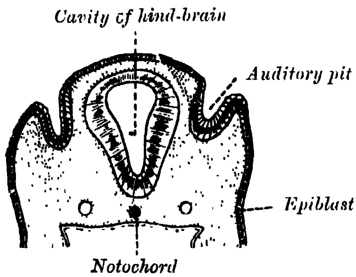


FIG. 169.—Section through hind-brain and auditory vesicles of an embryo more advanced than that of fig. 168. (After His.)

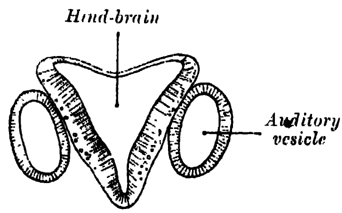

this capsule which covers the front of the lens is named the *membrana pupillaris*. By the sixth month all the vessels of the capsule are atrophied except one, the *arteria hyaloidea*, which disappears during the ninth month; the position of this artery is indicated in the adult by the canalis hyaloideus, which reaches from the

optic disc to the posterior surface of the lens. With the loss of its blood-vessels the tunica vasculosa lentis disappears, but sometimes the membrana pupillaris persists at birth, giving rise to the condition termed *congenital atresia of the pupil.*

The vitreous body is developed between the lens and the optic cup. Primarily it consists of a series of slender protoplasmic processes which project from the

FIG. 170.—Left auditory vesicle of a human embryo of four weeks, seen from the outer surface. (W. His, jun.)

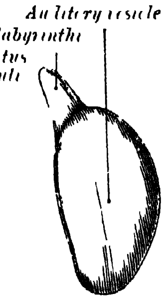

FIG. 171.—Left auditory vesicle of a human embryo of five weeks, seen from the outer surface. (W. His, jun.)

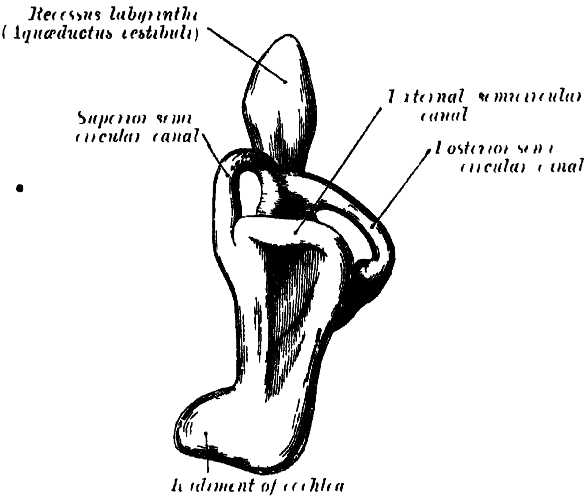
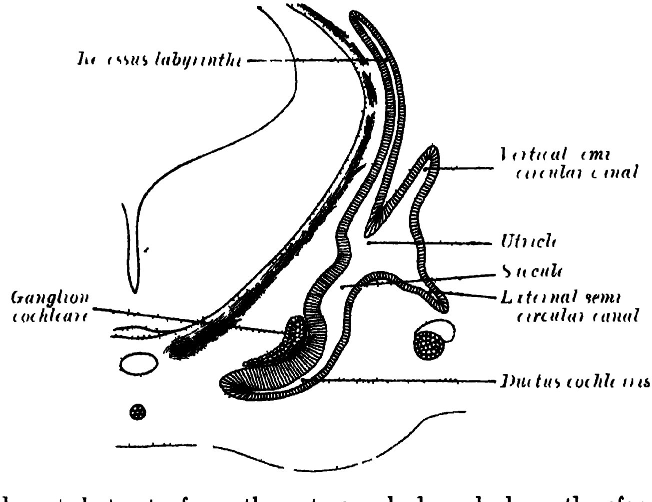


cells of the inner layer of the cup, and unite to form a delicate reticular tissue (fig. 167). At first these processes spring from the whole of the inner layer of the cup, but later their origins are limited to the ciliary region, where by a process of condensation they appear to form the zonule of Zinn. When the mesoderm extends into the cup through the choroidal fissure it becomes intimately united with this reticular

FIG. 172.—Transverse section through head of fœtal sheep, in the region of the labyrinth. × 30. (After Boettcher.)



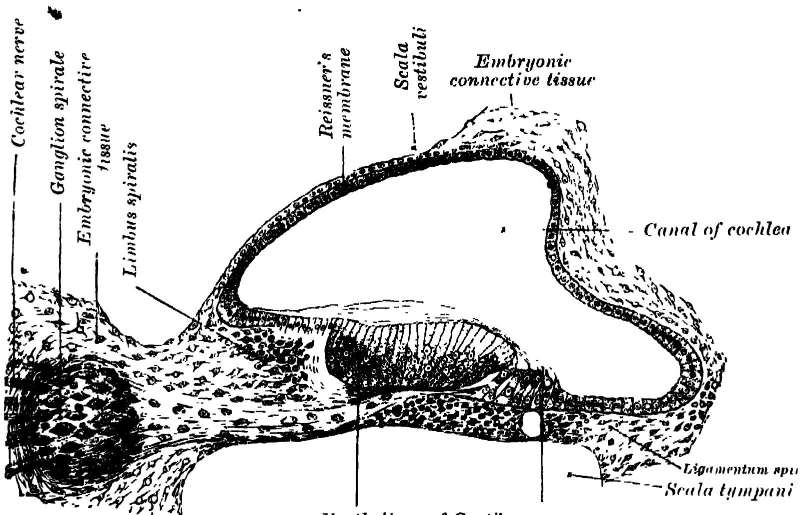
tissue, and contributes to form the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm.

The anterior chamber of the eye appears as a cleft in the mesoderm separating the lens from the overlying ectoderm. The layer of mesoderm in front of the cleft forms the substantia propria of the cornea, that behind the cleft the stroma of the iris and the membrana pupillaris.

The sclerotic and choroid coats of the eyeball are derived from the mesoderm surrounding the optic cup.

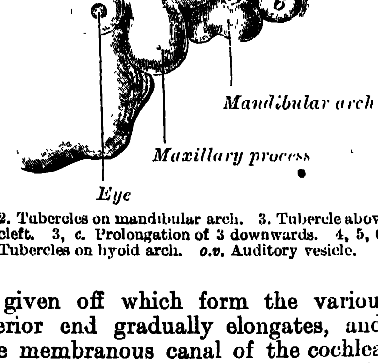
The eyelids are formed as small cutaneous folds (fig. 166), which at the end of the third month come together and unite in front of the globe and cornea. This union is broken up and the eyelids separate before the end of fœtal life.

Fig. 173.—Transverse section of the canal of the cochlea of a fœtal cat. (After Boettcher and Ayres.)



The lachrymal sac and nasal duct result from a thickening of the ectoderm in the groove between the lateral nasal and maxillary processes. This thickening becomes hollowed out into a channel, and the lips of the groove meet over it, and convert it into a duct, which eventually opens into the nasal fossa. The epithelium of the cornea and conjunctiva, and that which lines the ducts and alveoli of the lachrymal gland, are of ectodermal origin, as are also the eyelashes and the lining cells of the glands which open on the lid-margins.

Fig. 174.—Tubercles from which the different parts of the pinna are developed. (His.)

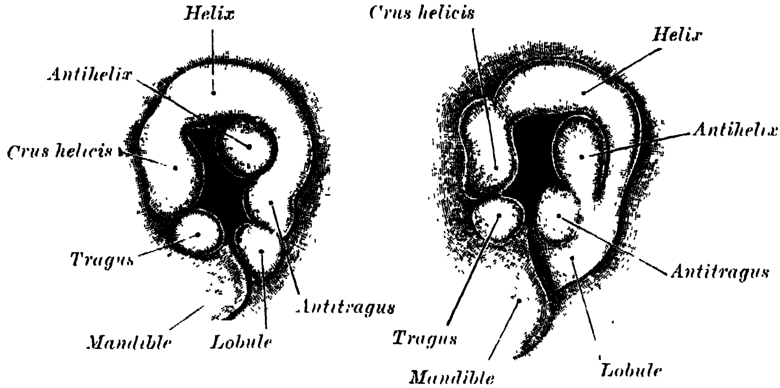


1, 2. Tubercles on mandibular arch. 3. Tubercle above cleft. 3, c. Prolongation of 3 downwards. 4, 5, 6. Tubercles on hyoid arch. *o.v.* Auditory vesicle.

The Ear.—The first rudiment of the internal ear appears shortly after that of the eye, in the form of a thickening of the surface ectoderm over the region of the hind-brain. The thickening is followed by an involution of the ectoderm to form the *auditory pit* (fig. 168), which deepens and forms a flask-shaped cavity. The mouth of the flask is then closed, and thus a shut sac, the *auditory vesicle,* is formed (fig. 169); from it the epithelial lining of the labyrinth is formed. The vesicle becomes pear-shaped; and the neck of the flask, or *recessus labyrinthi,* prolonged upwards, forms the ductus endolymphaticus. From the vesicle certain diverticula are given off which form the various parts of the labyrinth. One from the anterior end gradually elongates, and, forming a tube coiled on itself, becomes the membranous canal of the cochlea, the vestibular extremity of which is subsequently constricted to form the canalis reuniens. Three others appear as disc-like evaginations on the surface

of the vesicle; the central parts of the walls of the discs coalesce and disappear, while the peripheral portions persist to form the membranous semicircular canals, of which the external canal is the last to be developed (figs. 171, 172). The central part of the vesicle represents the membranous vestibule, and is subdivided by a constriction into a smaller anterior part, the saccule, and a larger posterior part, the utricle. This subdivision involves the proximal part of the ductus endolymphaticus, with the result that the utricle and saccule ultimately communicate with each other by means of a Y-shaped canal. The

FIG. 175.—Left ears of human embryos estimated at thirty-five and thirty-eight days respectively. (After His.)

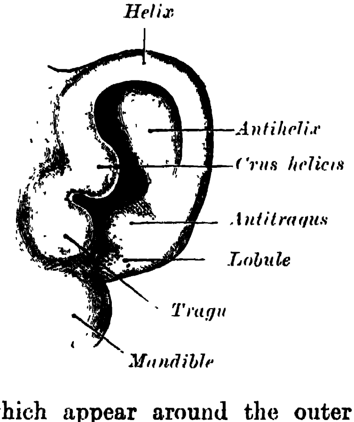


saccule opens into the membranous canal of the cochlea through the canalis reuniens and the membranous semicircular canals communicate with the utricle.

The auditory vesicle is imbedded in a mass of mesodermal tissue, which rapidly undergoes chondrification and ossification to form the bony labyrinth.

The middle ear, Eustachian tube, and mastoid antrum are developed from the inner part of the first branchial (hyomandibular) cleft, and are closed externally by the membrana tympani, which originally consists of a layer of ectoderm externally. and a layer of entoderm internally; between these two layers the mesoderm extends to form the substantia propria of the membrane. With regard to the exact mode of development of the ossicles of the middle ear there is some difference of opinion. The view generally maintained is that the *incus* and *malleus* are developed from the proximal end of the mandibular (Meckel's) cartilage (fig. 138); that the base of the *stapes* is formed by the ossification of the mesoderm which fills in the foramen ovale, while its arch is developed around a small vessel, the stapedial artery, which subsequently undergoes atrophy. As already stated (footnote, page 108), Gadow regards all three ossicles as being derived from the hyomandibula.

FIG. 176.—Pinna in a more advanced stage of development than those represented in fig. 175.

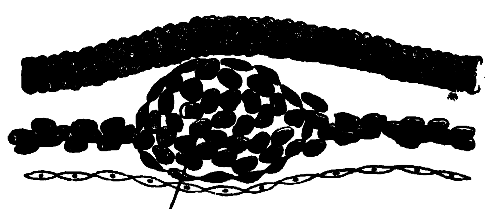


The external auditory meatus is formed from the outer part of the hyomandibular cleft, while the pinna is developed by the gradual differentiation of six tubercles which appear around the outer margin of the cleft. Two tubercles appear on the posterior edge of the mandibular arch; these represent the rudiments of the tragus and crus helicis. Three are found on the hyoid arch, and indicate, from below upwards, the lobule, antitragus, and antihelix. One arises above the cleft, and grows downwards behind the antitragus and antihelix; from it and its downward prolongation the upper and posterior parts of the helix are developed (figs. 174, 175, 176).

DEVELOPMENT OF THE VASCULAR SYSTEM

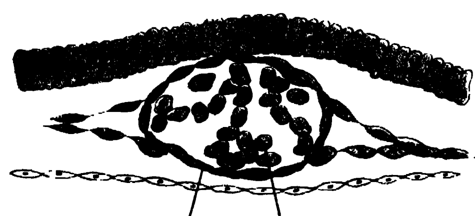
There are three distinct stages in the development of the circulatory system, each in accordance with the manner in which nourishment is provided for at different periods of the existence of the individual. In the first stage there is the *vitelline circulation*, during which nutriment is extracted from the *vitellus* or contents of the yolk-sac. In the second stage there is the *placental circulation*, during which nutriment is obtained by means of the placenta from the blood of the mother. In the third stage, commencing after birth, there is the *complete circulation of the adult*, during which nutrition is provided for by the organs of the individual.

FIG. 177.—Section through vascular area to show commencing development of blood-vessel. (Semi-diagrammatic.)



Blood-vessels first make their appearance in the mesodermal wall of the yolk-sac, i.e. outside the body of the embryo. Here the cells become arranged into solid strands or cords which join to form a close-meshed network. The peripheral cells of these strands become flattened and joined to each other by their edges to form the walls of the primitive blood-vessels. Fluid collects within the strands and converts them into tubes, and the more centrally situated cells of the cell-cords are thus pushed to the sides of the vessels and appear as masses of loosely arranged cells which project towards the lumen of the tube. These masses are termed *blood islands* (fig. 177); their cells acquire colouring matter (hæmoglobin), and are then detached to form the blood-corpuscles (fig. 178).* The earliest blood-corpuscles are all nucleated: they are also capable of subdivision and of executing amœboid movements, and in these respects resemble colourless blood-corpuscles. Soon, however, true colourless blood-corpuscles make their appearance, and, according to Beard,† are first derived from the rudiments of the thyroid gland.

FIG. 178.—Later stage.



Coincidently with the development of the blood-vessels in the vascular area, the first rudiment of the heart appears as a pair of tubular vessels which are developed in the splanchnopleure of the pericardial area. These are named the *primitive aortæ*, and a direct continuity is soon established between them and the vessels of the vascular area. Each receives anteriorly a vein—the vitelline vein—from the yolk-sac, and is prolonged backwards on the lateral aspect of the notochord under the name of the dorsal aorta. The dorsal aortæ end at first on the yolk-sac; but with the development of the allantois they are continued backwards through the body-stalk as the umbilical arteries to the villi of the chorion.

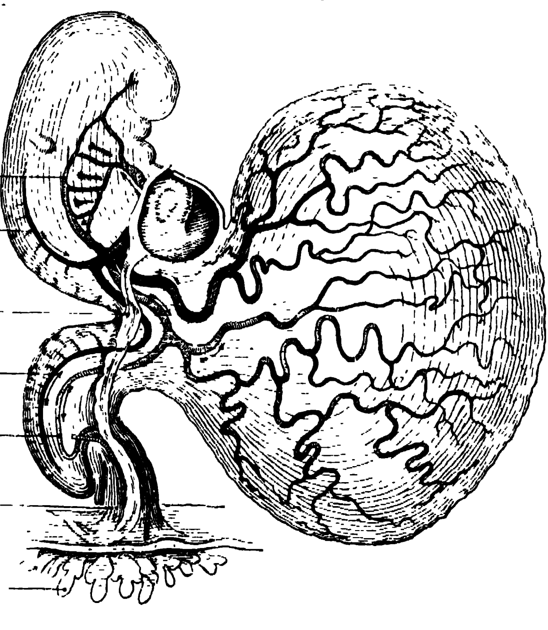
By the forward growth and flexure of the head the pericardial area and the anterior portions of the primitive aortæ are folded backwards on the ventral

* Some observers incline to the view that the endothelium of the vessels is of entodermal origin. The blood-corpuscles are developed from these endothelial cells, and are therefore also entodermal, the sequence of the development of the different structures being: first the heart, then the blood-vessels, and lastly the blood-corpuscles. (Consult Dr. E. Mehnert's *Biomechanik*, Jena, 1898.)

† *Anatomischer Anzeiger*, December 1900.

aspect of the fore-gut, and the original relation of the somatopleure and splanchnopleure layers of the pericardial area is reversed, the latter being placed on the dorsal aspect of the former. Each primitive aorta now consists of a ventral and a dorsal part connected anteriorly by an arch. These three parts are named respectively the anterior ventral aorta, the dorsal aorta, and the first cephalic arch. The first cephalic arches pass through the mandibular arches, and behind them five additional pairs subsequently develop, so that in all six pairs of aortic arches are formed. The vitelline veins which enter the embryo through the anterior wall of the umbilical orifice are now continuous with the posterior ends of the anterior ventral aortæ. With the formation of the tail-fold the posterior parts of the primitive aortæ are carried forward in a ventral direction to form the posterior ventral aortæ and primary caudal arches.* In the pericardial region the two primitive aortæ grow together, and fuse to form a single tubular heart (fig. 180), the posterior end of which receives the two vitelline veins, while from its anterior end the two anterior ventral aortæ emerge.† By the rhythmical contraction of the tubular heart the blood is forced through the aortæ and blood-

FIG. 179.—Human embryo of about fourteen days old with yolk-sac. (After His.) (From Kollmann's 'Entwickelungsgeschichte.')



vessels of the vascular area, from which it is returned to the heart by the vitelline veins. This constitutes the vitelline circulation (fig. 179), and by means of it nutriment is absorbed from the vitellus.

The vitelline veins at first open separately into the posterior end of the tubular heart, but after a time their terminal portions fuse, and the two vessels communicate with the heart through a common orifice. The vitelline veins ultimately drain the blood from the alimentary canal, and are modified to form the portal vein. This is caused by the growth of the liver, which interrupts their direct continuity with the heart; and the blood returned by them circulates through the liver before reaching the heart.

With the atrophy of the yolk-sac the vitelline circulation diminishes and ultimately ceases, while an increasing amount of blood is carried through the umbilical arteries to the villi of the chorion. Subsequently, as the non-placental chorionic villi atrophy, their vessels disappear; and then the umbilical arteries convey the whole of their contents to the placenta, whence it is returned to the heart by the umbilical veins. In this manner the placental circulation is

* Young and Robinson, *Journal of Anatomy and Physiology*, vol. xxxii.

† In most fishes and in the amphibia the heart originates as a single median tube.

established, and by means of it nutritive materials are absorbed from, and waste products given up to, the maternal blood.

The umbilical veins, like the vitelline, become interrupted by the liver, and the blood returned by them passes through this organ before reaching the heart. Ultimately the right umbilical vein shrivels up and disappears, as will be explained later (pages 145, 146).

Fig. 180.—Diagram to illustrate the simple tubular condition of the heart. (Drawn from Ecker-Ziegler model.)

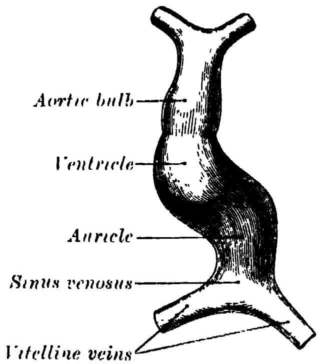


Fig. 181.—Heart further advanced than in fig. 180. (Drawn from Ecker-Ziegler model.)

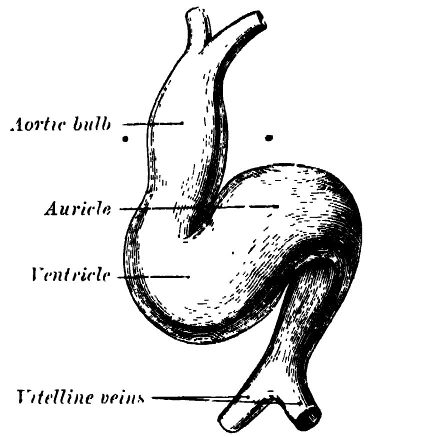
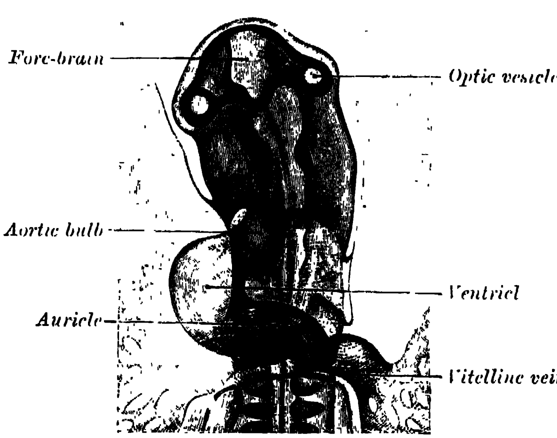


During the occurrence of these changes great alterations take place in the primitive heart and blood-vessels, and now require description.

Further development of the heart.—The simple tubular heart, already described, becomes elongated and bent on itself so as to form an S-shaped loop, the anterior part bending to the right and the posterior part to the left. The intermediate portion arches transversely from right to left, and then turns sharply forward into the anterior part of the loop. Slight constrictions make

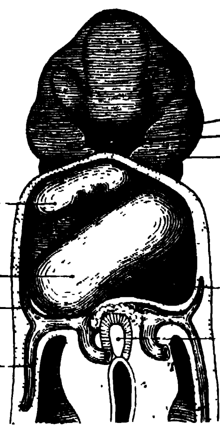
Fig. 182.—Head of chick embryo of about thirty-eight hours' incubation, viewed from the ventral surface. × 26. (From Duval's 'Atlas d'Embryologie.')



their appearance in the tube and divide it from behind forwards into four parts, viz.: (1) the *sinus venosus*; (2) the *primitive auricle*; (3) the *primitive ventricle*; (4) the *aortic bulb*, which consists of two portions, a proximal muscular portion known as the *bulbus cordis*, and a distal portion, the *primitive aortic stem* (figs. 180 to 182). The constriction between the auricle and ventricle constitutes the *auricular canal*, and indicates the site of the future auriculo-ventricular valves.

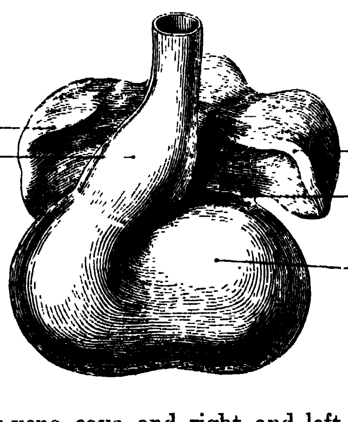
The sinus venosus is at first situated in the septum transversum (a layer of mesoderm in which the liver and the central tendon of the Diaphragm are developed) behind the common auricle, and is formed by the union of the vitelline veins. The veins or ducts of Cuvier from the body of the embryo and the umbilical veins from the placenta subsequently open into it (fig. 185). The sinus is at first placed transversely, and opens by a median aperture into the common auricle. Soon, however, it assumes an oblique position, and becomes crescentic in

FIG. 183.—Heart of human embryo of about fifteen days. (Reconstruction by His.)



form; its right half or horn increases more rapidly than the left, while the opening into the auricle now communicates with the right portion of the auricular cavity. The right horn ultimately becomes incorporated with and forms a part of the right auricle, the line of union between it and the auricle proper being indicated in the interior of the adult auricle by a vertical crest, the *crista terminalis* of His. The left horn, which ultimately receives only the left duct of Cuvier, persists as the coronary sinus (fig. 192). The vitelline and umbilical veins are soon replaced by a single vessel, the inferior vena cava, and

FIG. 184.—Heart showing expansion of auricles.
(Drawn from Ecker-Zeigler model.)

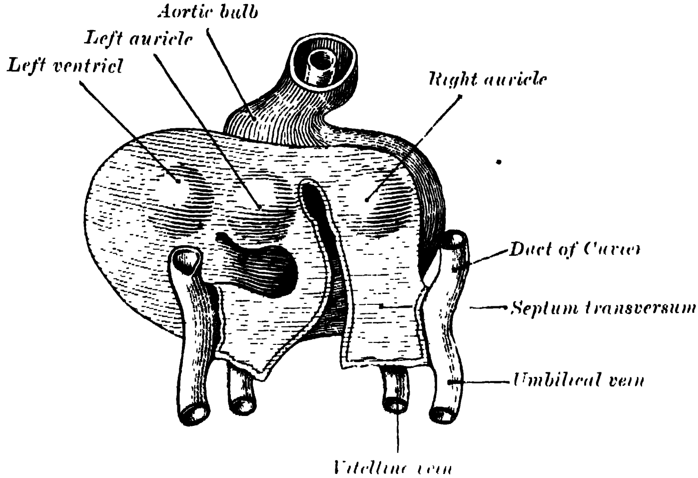


the three veins (inferior vena cava and right and left Cuvierian ducts) open into the dorsal aspect of the auricle by a common slit-like aperture (fig. 189). The upper part of this aperture represents the opening of the permanent superior vena cava, the lower that of the inferior vena cava, and the intermediate part the orifice of the coronary sinus. The slit-like aperture lies obliquely, and is guarded by two valves, the *right* and *left venous valves*, which unite with each other above the opening and are continuous with a fold named the *septum spurium*. The left venous valve practically disappears, while the right is

subsequently divided to form the Eustachian and Thebesian valves. At the lower extremity of the slit is a triangular thickening, the *spina vestibuli* of His, which partly closes the aperture between the two auricles, and, according to His, takes a part in the formation of both the interauricular and interventricular septa.

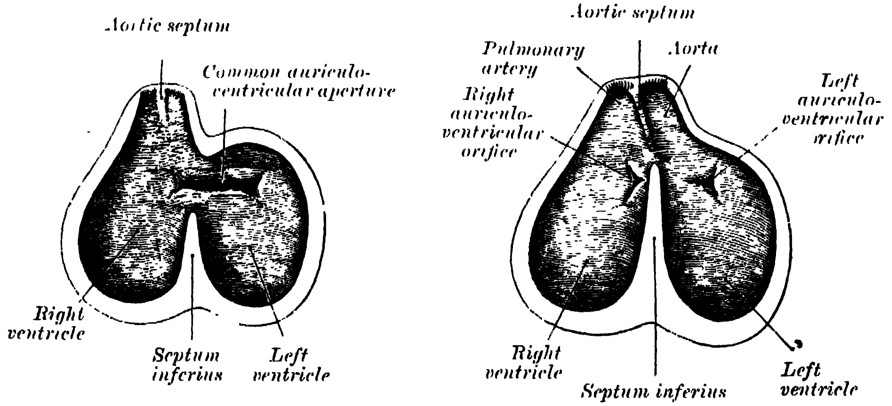
The auricular canal is at first a short straight tube connecting the auricular with the ventricular portion of the heart, but its growth is relatively slow, and it

FIG. 185.—Heart of human embryo, 4·2 mm. long, seen from behind. (His.)



becomes overlapped by the auricles and ventricles so that its position on the surface of the heart is indicated only by an annular constriction (fig. 184). Its lumen is reduced to a transverse slit, and two thickenings appear, one on its dorsal and another on its ventral wall. These thickenings, or *endocardial cushions* (fig. 189) as they are termed, project into the canal, and, meeting in the middle line, unite to form the *septum intermedium* which divides the canal into two channels, the future right and left auriculo-ventricular orifices.

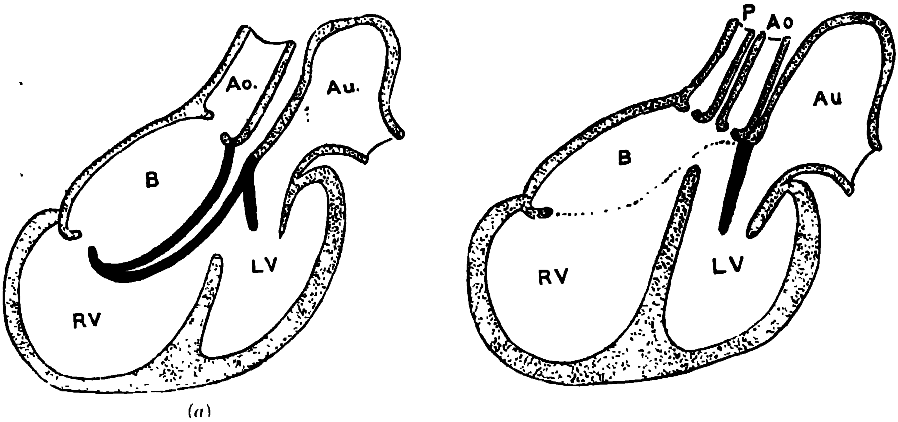
FIG. 186.—Diagrams to show the development of the septum of the aortic bulb and of the ventricles. (Born.)



The primitive auricular cavity becomes subdivided into right and left auricles by an incomplete septum, the *septum primum* (fig. 189), which grows downwards into the auricular cavity. For a time the two auricles communicate with each other by an opening, the ostium primum of Born, below the free margin of the septum. This opening is, however, closed by the union of the septum primum with the septum intermedium, and the communication between the auricles

is re-established through an opening which is developed in the upper part of the septum primum; this opening is known as the foramen ovale (ostium secundum of Born) and persists until birth. A second septum, the *septum secundum*, semilunar in shape, grows downwards from the upper wall of the auricle to the right of the primary septum and foramen ovale. Shortly after birth it fuses with the primary septum, and by this means the foramen ovale is closed, but sometimes the fusion is incomplete and the upper part of the foramen remains patent. The annulus ovalis denotes the free margin of the septum secundum.

FIG. 187.—Diagrams to illustrate the transformation of the bulbus cordis. (Keith.)

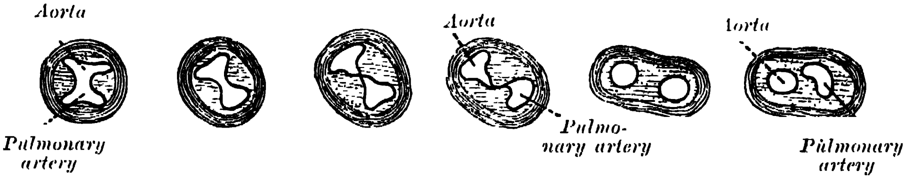


Ao, Primitive aortic stem. *Au*, auricle. *B*, Bulbus cordis. *RV*, Right ventricle. *LV*, Left ventricle. *P*, Pulmonary artery.

The primitive ventricle becomes divided by a septum, the *septum inferius* or *ventricular septum* (figs. 186, 189), which grows upwards from the lower part of the ventricle, its position being indicated on the surface of the heart by a furrow. Its dorsal part grows more rapidly than its ventral portion, and fuses with the dorsal part of the septum intermedium. For a time an interventricular foramen exists above its ventral portion, but this foramen is ultimately closed by the fusion of the aortic septum with the ventricular septum.

As already stated, the aortic bulb consists of a proximal muscular portion, the bulbus cordis, and a distal portion, the primitive aortic stem. When the heart

FIG. 188.—Transverse sections through the aortic bulb to show the growth of the aortic septum. The lowest section is on the left, the highest on the right of the figure. (After His.)



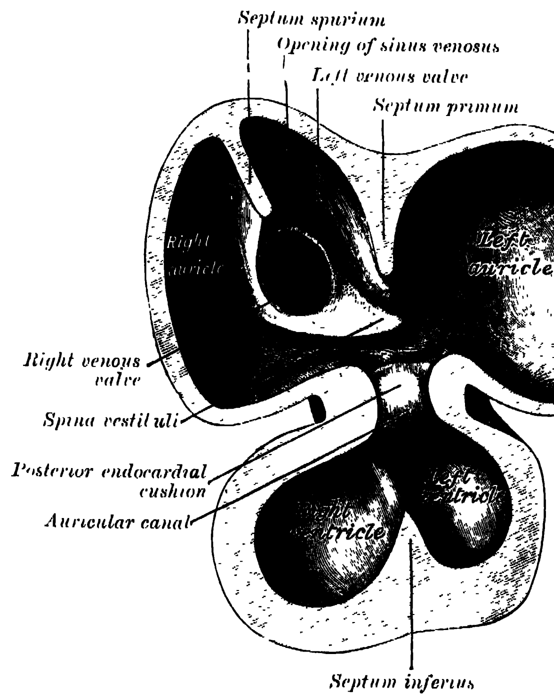
assumes its S-shaped form the bulbus cordis lies ventral to and in front of the primitive ventricle. The adjacent walls of the bulbus cordis and ventricle approximate, fuse, and finally disappear, and the bulbus cordis now communicates freely with the right ventricle, while the junction of the bulbus with the primitive aortic stem is brought directly ventral to and applied to the auricular canal. By the upgrowth of the ventricular septum the bulbus cordis is in great measure separated from the left ventricle, but remains an integral part of the right ventricle, of which it forms the infundibulum (fig. 187).

The primitive aortic stem is divided by the *aortic septum* (fig. 186). This makes its appearance as two ridge-like thickenings which project into the lumen

of the tube; these increase in size, and ultimately meet and fuse to form the septum, and thus the primitive aortic stem is divided into the pulmonary artery and the aorta. The aortic septum takes a spiral course towards the proximal end of the stem, so that the two vessels lie side by side above, but near the heart the pulmonary artery is in front of the aorta (fig. 188). The septum grows down into the ventricle as an oblique partition, which ultimately blends with the ventricular septum in such a way as to bring the bulbus cordis into communication with the pulmonary artery, and through the latter with the sixth pair of aortic arches; while the left ventricle is brought into continuity with the aorta, which communicates with the remaining aortic arches.

The valves of the heart.—The auriculo-ventricular valves are developed in relation to the auricular canal. By the upward expansion of the bases of the ventricles the canal becomes invaginated into the ventricular cavities. The invaginated margin forms the rudiments of the lateral cusps of the auriculo-ventricular valves; the mesial or septal cusps of the valves are developed as downward prolongations of the septum intermedium. The aortic and pulmonary valves are

FIG. 189.—Interior of dorsal half of heart from a human embryo 10 mm. long. (His.)



formed from four endocardial thickenings—an anterior, a posterior, and two lateral—which appear at the proximal end of the primitive aortic stem. As the aortic septum grows downwards it divides each of the lateral thickenings into two, thus giving rise to six thickenings—the rudiments of the semilunar valves—three at the aortic and three at the pulmonary orifice.

Further Development of the Arteries.—It has been seen (page 136) that each primitive aorta consists of a ventral and a dorsal part which are continuous through the first aortic arch. The dorsal aortæ at first run backwards separately on either side of the notochord, but about the third week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single trunk, the descending aorta. The first aortic arches pass through the mandibular arches, and behind them five additional pairs are developed within the visceral arches; so that, in all, six pairs of aortic arches are formed (fig. 191). The first and second arches pass between the ventral and dorsal aortæ, while the others arise at first by a common trunk from the aortic bulb, but terminate separately in the dorsal aortæ. As the neck elongates, the ventral

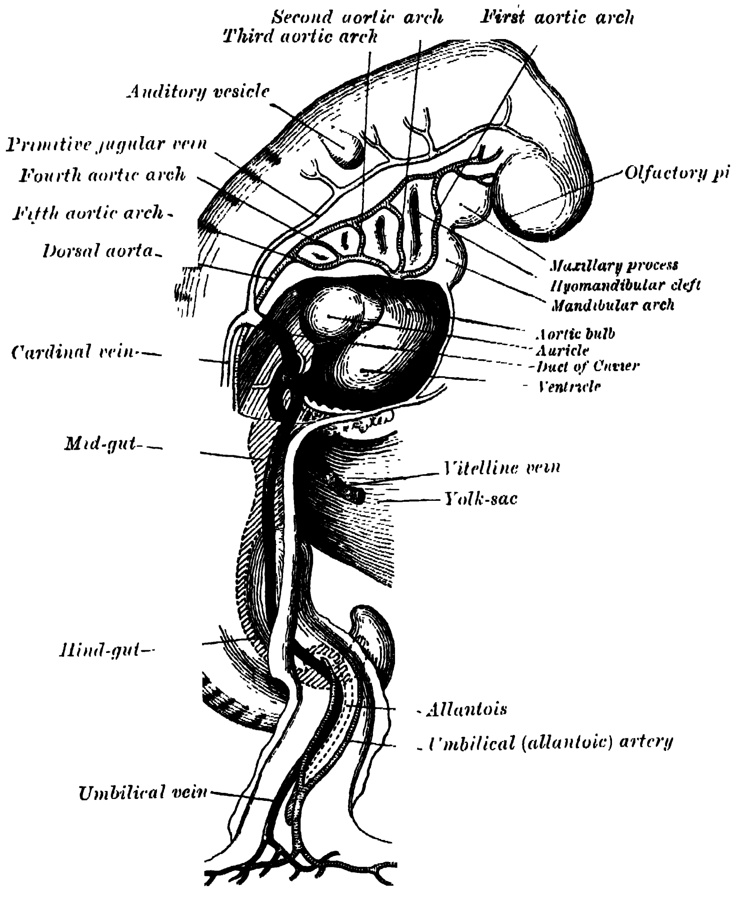
aortæ are drawn out, and the third and fourth arches arise directly from these vessels.

In fishes these arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of them remain as permanent structures, while others disappear or become obliterated (fig. 191).

The anterior ventral aortæ.—These persist on both sides. The right forms (*a*) the innominate artery, (*b*) the right common and external carotid arteries. The left gives rise to (*a*) the short portion of the aortic arch, which reaches from the origin of the innominate artery to that of the left common carotid artery; (*b*) the left common and external carotid trunks.

The aortic arches.—The first and second disappear; the third constitutes the commencement of the internal carotid artery, and is therefore named the *carotid*

FIG. 190.—Profile view of a human embryo estimated at twenty or twenty-one days old. (After His.)



arch. The fourth right arch forms the right subclavian as far as the origin of its internal mammary branch; while the fourth left arch constitutes the arch of the aorta between the origin of the left carotid artery and the termination of the ductus arteriosus. The fifth arch disappears on both sides. The sixth right arch disappears; the sixth left arch gives off the pulmonary arteries and forms the ductus arteriosus; this duct remains pervious during the whole of fœtal life, but a few days after birth becomes obliterated. His found that in the early embryo the right and left arches each gives a branch to the lungs, but that later both pulmonary arteries take origin from the left arch.

The dorsal aortæ.—In front of the third aortic arches the dorsal aortæ persist and form the forward continuation of the internal carotid arteries. Behind the

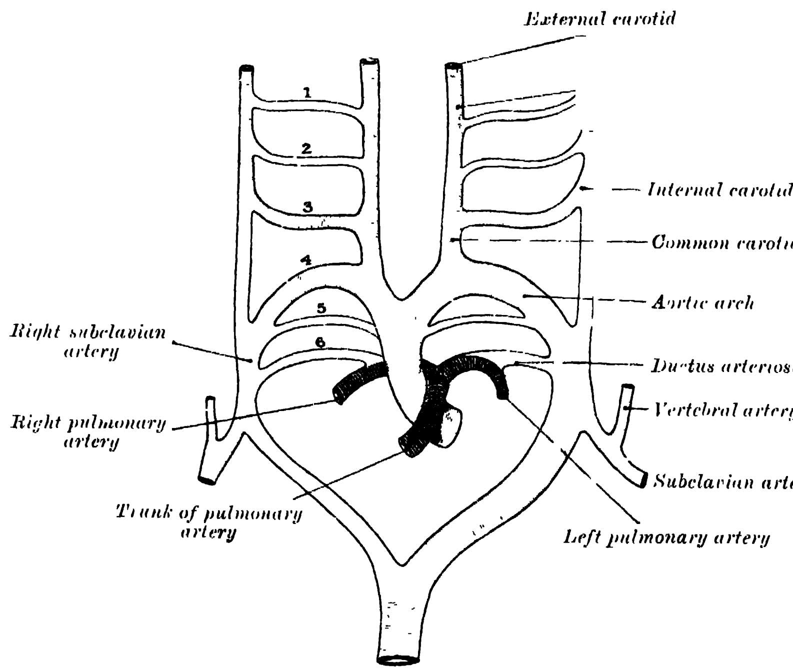
third arch the right dorsal aorta disappears as far as the point where the two dorsal aortæ fuse to form the descending aorta. The part of the left dorsal aorta which intervenes between the third and fourth arches disappears, while the remainder persists to form the descending part of the ărch of the aorta. A constriction, the *aortic isthmus*, is sometimes seen in the aorta between the origin of the left subclavian and the attachment of the ductus arteriosus.

Sometimes the right subclavian artery arises from the aortic arch beyond the origin of the left subclavian and passes upwards and to the right behind the trachea and œsophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth right arch.

In birds the fourth right arch forms the arch of the aorta; in reptiles the fourth arch on both sides persists and gives rise to the double aortic arch in these animals.

The heart originally lies on the ventral aspect of the pharynx, immediately behind the stomatodæum. With the elongation of the neck and development of the lungs it recedes within the thorax, and, as a consequence, the anterior

FIG. 191.—Scheme of the aortic arches and their destination. (Modified from Kollmann.)



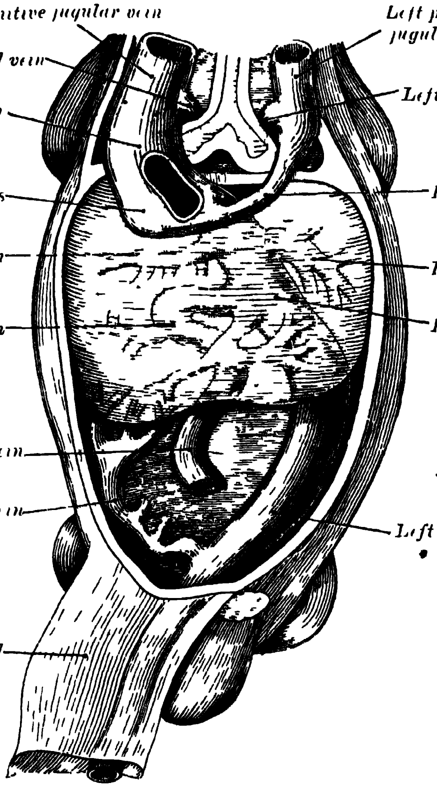
ventral aortæ are drawn out and the original position of the fourth and fifth arches is greatly modified. Thus, on the right side the fourth recedes to the root of the neck, while on the left side it is withdrawn within the thorax. The recurrent laryngeal nerves originally pass to their distribution under the sixth pair of arches, and are therefore pulled backwards with the descent of these structures, so that in the adult the left hooks round the ductus arteriosus; owing to the disappearance of the fifth and the sixth right arches the right nerve hooks round that immediately above them, i.e. the commencement of the subclavian artery.

A series of segmental arteries arises from the primitive dorsal aortæ, those in the neck alternating with the cervical segments of the spine. The seventh segmental artery which lies between the sixth and seventh cervical segments is of special interest, since it forms the lower part of the vertebral artery and, when the forelimb bud appears, sends a branch to it (i.e. the subclavian artery); the upper part of the vertebral artery is formed by an inter-segmental anastomosis between the higher segmental arteries. From the seventh segmental arteries the entire left subclavian and the greater part of the right subclavian are formed.

The subclavian artery is prolonged into the limb under the names of the axillary and brachial arteries, and these together constitute the arterial stem for the upper arm. The direct continuation of this stem in the forearm forms the anterior interosseous artery; while the radial and ulnar vessels, which ultimately exceed this artery in size, are in reality lateral branches of the main stem.

The formation of the primary caudal arches has already been referred to (page 136), and the fusion of the dorsal aortæ to form the greater part of the systemic aorta has been pointed out (page 135). The middle sacral artery of the adult was formerly regarded as the direct continuation of the adult aorta, but Young and Robinson (*op. cit.*) maintain that it 'is a secondary branch, probably representing fused segmental arteries.' They have also pointed out that while the dorsal and ventral extremities of the primary caudal arches remain, their middle portions 'disappear and are replaced by "secondary" caudal arches

Fig. 192.—Human embryo with heart and anterior body wall removed to show the sinus venosus and its tributaries. (After His.) (From Kollmann's 'Entwickelungsgeschichte.')



which lie to the outer sides of the Wolffian ducts.' 'The vessels which are to be looked upon as the posterior continuations of the primitive aorta in the adult in man, rodents, &c., are the common iliac, internal iliac, and hypogastric arteries.'

The hypogastric arteries are continued into the umbilical cord as the umbilical arteries. After birth they become obliterated from the umbilicus as far as the origin of the superior vesical arteries.

The primary arterial stem for the lower limb is formed by the sciatic artery, which accompanies the great sciatic nerve along the posterior aspect of the thigh to the back of the knee, whence it is continued as the peroneal artery. This arrangement exists in reptiles and amphibians. The femoral artery arises later as a branch of the common iliac, and, passing down the front and inner side of the thigh to the bend of the knee, joins the sciatic artery. The femoral quickly enlarges, and, coincidently with this, the part of the sciatic immediately above the

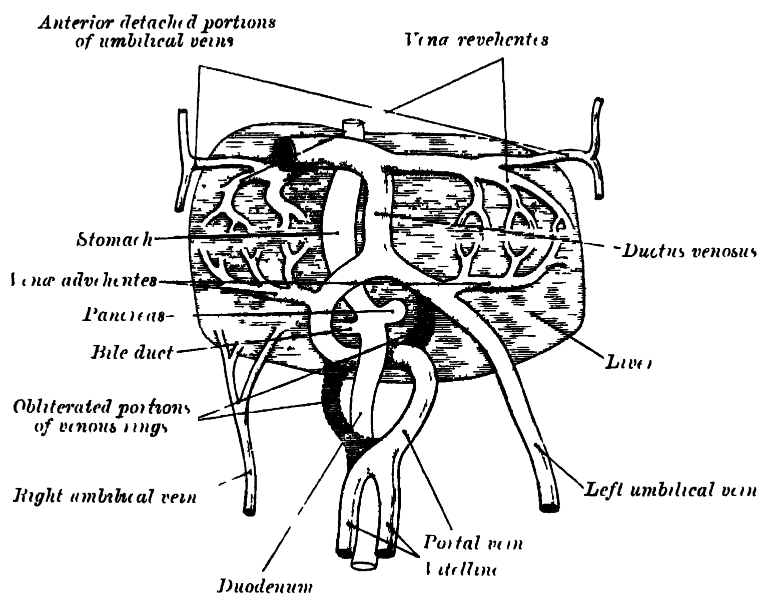
knee undergoes atrophy. The anterior and posterior tibial arteries are branches of the main arterial stem.

Further development of the Veins.—The formation of the great veins of the embryo may be best considered by dividing them into two groups, visceral and parietal.

The *visceral veins* are the two vitelline or omphalo-mesenteric veins bringing the blood from the yolk-sac, and the two umbilical or allantoic veins returning the blood from the placenta; these four veins open close together into the sinus venosus (fig. 194).

The vitelline veins run upwards at first in front, and subsequently on either side of the intestinal canal. They unite on the ventral aspect of the canal, and beyond this are connected to one another by two cross branches, the first on the dorsal, the second on the ventral aspect of the duodenal portion of the intestine which is thus encircled by two venous rings (fig. 193). The portions of the veins above the upper ring become invaded by the developing liver and broken up by it into a plexus of small capillary-like vessels termed *sinusoids* (Minot). The branches conveying the blood to this plexus are named

FIG. 193.—The liver and the veins in connection with it, of a human embryo, twenty-four or twenty-five days old, as seen from the ventral surface. (After His.)



the *venæ advehentes*, and become the branches of the portal vein; while the vessels draining the plexus into the sinus venosus are termed the *venæ revehentes*, and form the future hepatic veins (figs. 192 and 193). Ultimately the left vena revehens no longer communicates directly with the sinus venosus, but opens into the right vena revehens. The lower part of the *portal vein* is formed from the fused vitelline veins which receive the veins from the alimentary canal; its upper part is derived from the venous rings by the persistence of the left half of the lower and the right half of the upper ring, so that the vessel forms a spiral turn round the duodenum (fig. 193).

The two umbilical veins fuse early to form a single trunk in the body-stalk, but remain separate within the embryo and pass forwards to the sinus venosus in the side walls of the body. Like the vitelline veins, their direct connection with the sinus venosus becomes interrupted by the invasion of the liver, and thus at this stage the whole of the blood from the yolk-sac and placenta passes through the substance of the liver before it reaches the heart. The right umbilical vein shrivels and disappears; the left, on the other hand, becomes enlarged and opens into the upper venous ring of the vitelline veins.

Finally a direct branch is established between this ring and the right hepatic vein; this branch is named the *ductus venosus*, and, enlarging rapidly, it forms a wide channel through which most of the blood, returned from the placenta, is carried direct to the heart without passing through the liver. A small proportion of the blood from the placenta is, however, conveyed from the left umbilical vein to the liver through the left vena advehens. The left umbilical vein and the ductus venosus undergo atrophy and obliteration after birth, and form respectively the ligamentum teres and ligamentum venosum of the liver.

The parietal veins.—The first indication of a parietal system consists in the appearance of two short transverse veins (the *ducts of Cuvier*), which open, one on either side, into the sinus venosus. Each of these ducts receives an ascending and descending vein. The ascending veins return the blood from the parietes of the trunk and from the Wolffian bodies, and are called *cardinal* veins. The descending veins return the blood from the head, and are called *primitive jugular* veins (fig. 190). The blood from the lower limbs is collected by the right and left iliac veins, which, in the earlier stages of development, open into the corresponding right and left cardinal veins (fig. 190); later on, a transverse branch (the left common iliac vein) is developed between the lower parts of the two cardinal veins (fig. 196), and through this the blood is carried into the right cardinal vein. The portion of the left cardinal vein below the left renal vein atrophies and disappears up to the point of entrance of the left spermatic vein; the portion above the left renal vein persists as the superior and inferior azygos minor veins and the lower portion of the left superior intercostal vein. The right cardinal vein, which now receives the blood from both lower extremities, forms a large venous trunk along the posterior abdominal wall; up to the level of the renal veins it forms the lower part of the inferior vena cava. Above the level of the renal veins the right cardinal vein persists as the vena azygos major, and receives the right intercostal veins, while the azygos minor veins are brought into communication with it by the development of transverse branches in front of the vertebral column (figs. 196, 197).

FIG. 194.—Scheme of arrangement of parietal veins.

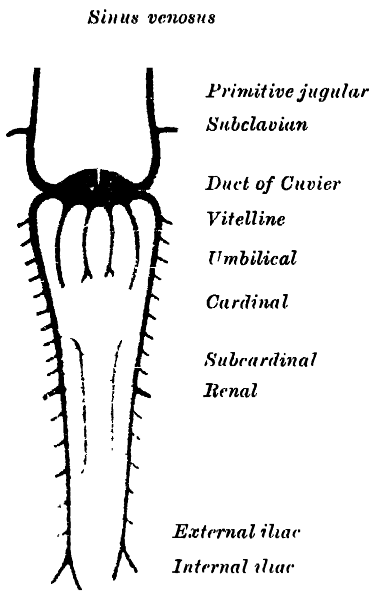


FIG. 195.—Scheme showing early stages of development of the inferior vena cava.

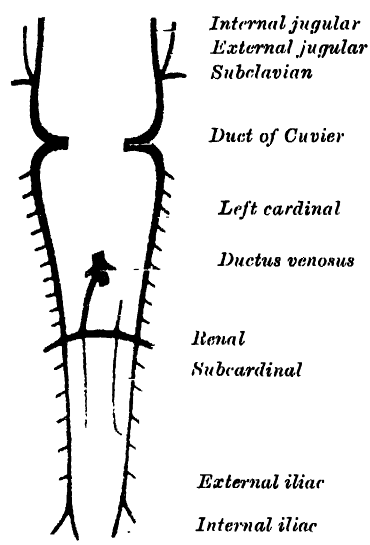
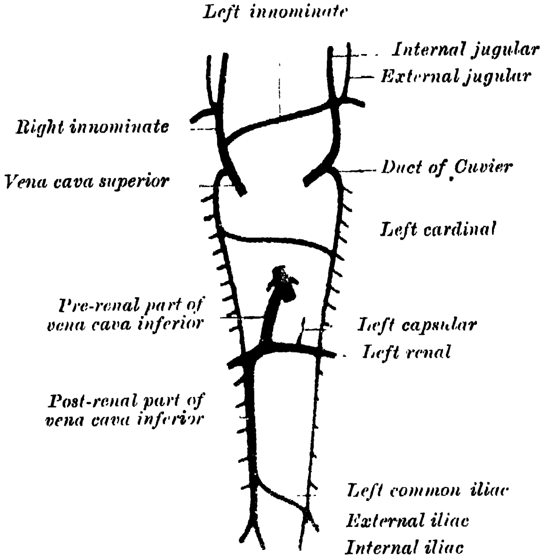


Inferior vena cava.—The development of the inferior vena cava is associated with the formation of two veins, the *subcardinal veins* (figs. 194 and 195). These lie parallel to, and on the ventral aspect of, the cardinal veins, and originate as longitudinal anastomosing channels which link up the tributaries from the mesentery to the cardinal veins; they communicate with the cardinal veins above and below, and also by a series of transverse branches. The two

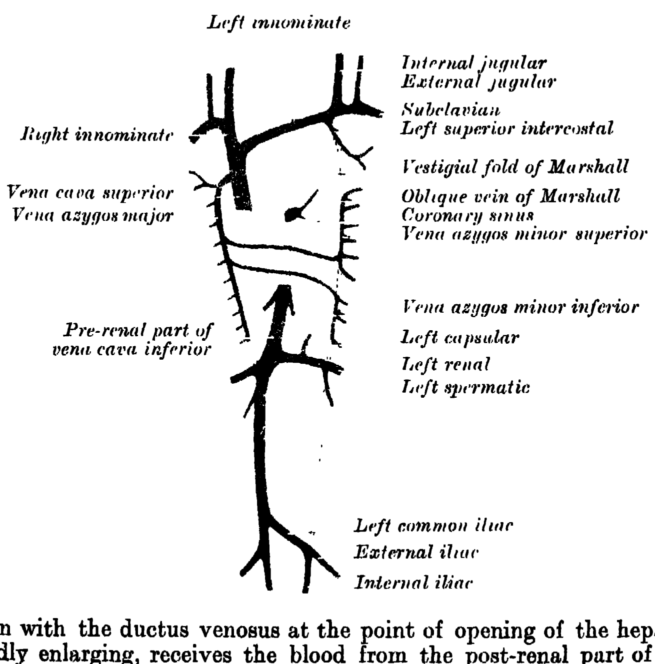
subcardinals are for a time connected with each other in front of the aorta by cross branches, but these disappear and are replaced by a single transverse channel at the level where the renal veins join the cardinals, and at the same level

FIG. 196.—Diagram showing development of main cross branches between jugulars and between cardinals.



a cross communication is established on either side between the cardinal and subcardinal (fig. 195). The portion of the right subcardinal behind this cross communication disappears, while that in front (i.e. the pre-renal part) forms a

FIG. 197.—Diagram showing completion of development of the parietal veins.



connection with the ductus venosus at the point of opening of the hepatic veins, and, rapidly enlarging, receives the blood from the post-renal part of the right cardinal through the cross communication referred to. In this manner a single

trunk, the *inferior vena cava* (fig. 197), is formed, and consists of the proximal part of the ductus venosus, the pre-renal part of the right subcardinal vein, the post-renal part of the right cardinal vein, and the cross branch which joins these two veins. The left subcardinal disappears, except the part immediately in front of the renal vein, which is retained as the left suprarenal vein. The spermatic (or ovarian) vein opens into the post-renal part of the corresponding cardinal vein. This portion of the right cardinal, as already explained, forms part of the inferior vena cava, so that the right spermatic opens directly into that vessel. The post-renal segment of the left cardinal disappears, with the exception of the portion between the spermatic and renal vein, which is retained as the proximal part of the left spermatic vein.

In consequence of the atrophy of the Wolffian bodies the cardinal veins diminish in size; the primitive jugular veins, on the other hand, become enlarged, owing to the rapid development of the head and brain. They are further augmented by receiving the veins (*subclavian*) from the upper extremities, and so come to form the chief veins of the Cuvierian ducts; these ducts gradually assume an almost vertical position in consequence of the descent of the heart into the thorax. The right and left Cuvierian ducts are originally of the same diameter, and are frequently termed the *right* and *left superior venæ cavæ*. By the development of a transverse branch (the *left innominate vein*) between the two primitive jugular veins, the blood is carried across from the left to the right primitive jugular (figs. 196, 197). The portion of the right primitive jugular vein between the left innominate and the vena azygos major forms the upper part of the superior vena cava of the adult; the lower part of this vessel (i.e. below the entrance of the vena azygos major) is formed by the right Cuvierian duct. Below the origin of the transverse branch the left primitive jugular vein and left Cuvierian duct atrophy, the former constituting the upper part of the left superior intercostal vein, while the latter is represented by the vestigial fold and oblique vein of Marshall (fig. 197). Both right and left superior venæ cavæ are present in some animals, and are occasionally found in the adult human being. The oblique vein of Marshall passes downwards across the back of the left auricle to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus.

The primitive jugular or anterior cardinal veins are situated on the ventral surface of the brain, on the mesial side of the cranial nerve-roots. A considerable portion of each of these veins disappears and is replaced by a vein which is developed on the lateral aspect of the cranial nerves from the fifth to the twelfth inclusive. This new vein (*vena capitis lateralis*) leaves the skull in company with the seventh nerve. The blood from the hind-brain is collected into a vein (the future lateral sinus) which passes through the foramen jugulare on the lateral aspect of the vagus nerve; here the two vessels join to form the internal jugular vein. On the dorsal aspect of the ear-capsule an anastomotic channel is opened up between the vena capitis lateralis and the lateral sinus; and, coincident with this, the portion of the former vein which extends from the fifth to the tenth cranial nerve becomes obliterated, and thus the whole of the blood from the brain is ultimately drained away by the lateral sinuses. The primitive jugular vein is therefore represented in the adult by the internal jugular, and not by the external jugular, as is usually stated.* The external jugular vein is a vessel of later formation, which at first drains the region behind the ear (posterior auricular) and enters the primitive jugular as a lateral tributary. A group of veins from the face and lingual region converge to form a common vein, the linguo-facial,† which also terminates in the primitive jugular. Later, cross communications develop between the external jugular and the linguo-facial, with the result that the posterior group of facial veins is transferred to the external jugular.

Peculiarities of the fœtal heart.—In early fœtal life the heart is placed directly under the head and is relatively of large size. Later it assumes its position in the thorax, but lies at first in the middle line; towards the end of pregnancy it gradually becomes oblique in direction. The auricular portion is at first larger than the ventricular part, and the two auricles communicate freely through the foramen

* Consult *Die Entwickelung des Blutgefäss-systems*, by Hochstetter, in Hertwig's *Entwickelungslehre*; and also an article by Mall in the *American Journal of Anatomy*, vol. iv., December 1904.

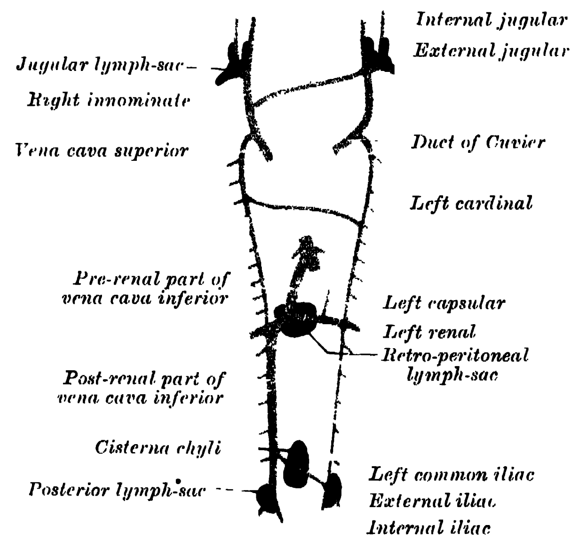
† Lewis, *American Journal of Anatomy*, vol. ix., No. 1, Feb. 1909.

ovale. In consequence of the communication between the pulmonary artery and the aorta, through the ductus arteriosus, the contents of the right ventricle are mainly carried into the latter vessel instead of to the lungs, and hence the wall of the right ventricle is as thick as that of the left. At the end of fœtal life, however, the left ventricle is thicker than the right, a difference which becomes more and more emphasised after birth.

The fœtal circulation and the changes which take place in the circulation after birth are described on pages 614 to 616.

The lymphatic vessels.—The lymphatic system begins as a series of sacs * at the points of junction of certain of the embryonic veins. These lymph-sacs are developed by the confluence of numerous venous radicles, which at first lose their connections with the venous system, but subsequently, on the formation of the sacs, regain them. The lymphatic system is therefore developmentally an offshoot of the venous system, and the lining walls of its vessels are always endothelial. As already stated in the chapter on Histology (page 61), it forms a closed system, and has not as was formerly supposed any direct communication with tissue clefts or spaces.

FIG. 198.—Scheme showing relative positions of primary lymph-sacs based on the description given by Florence Sabin.



In the human embryo the lymph-sacs from which the lymphatic vessels are derived are six in number: two paired, the jugular and the posterior lymph-sacs; and two unpaired, the retro-peritoneal and the cisterna chyli. In lower mammals an additional pair, subclavian, is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows: (1) jugular sac, at the junction of the subclavian vein with the primitive jugular; (2) posterior sac, at the junction of the iliac vein with the posterior cardinal; (3) retro-peritoneal, in the position of the cross branch between the renal veins; (4) cisterna chyli at the site of the cross branch between the two iliac veins (fig. 198). From the lymph-sacs the lymphatic vessels bud out along fixed lines corresponding more or less closely to the course of the embryonic blood-vessels. They all arise as endothelial outgrowths, which later become canalised. Both in the body wall and in the wall of the intestine,† the deeper plexuses are the first to be developed; by continued growth of these the vessels in the superficial layers are gradually formed. It is as yet undetermined whether the thoracic duct is formed from anastomosing outgrowths from the jugular sac and cisterna chyli or whether it is developed by the transformation

* Sabin. *American Journal of Anatomy*, vol. ix., No. 1, Feb. 1909. † Heuer. *Ibid.*

of some of the radicles of the azygos veins. At its connection with the cisterna chyli it is at first double, but the right vessel soon joins with the left.

All the lymph-sacs except the cisterna chyli are, at a later stage, divided up by slender connective tissue bridges and transformed into groups of lymphatic glands. The lower portion of the cisterna chyli is similarly converted, but its upper portion remains as the receptaculum chyli.

The Pericardium.—As already pointed out (page 87), the anterior portion of the embryonic area in front of the oral plate or bucco-pharyngeal membrane is named the pericardial area. Previous to the formation of the head-fold the mesoderm has divided into its somatic and splanchnic layers, and these two layers, together with the intervening cœlomic space, extend forwards on either side of the bucco-pharyngeal membrane into the pericardial area; the part of the cœlom contained within this area becomes the cavity of the pericardium. This is, at first, in the shape of a crescent, the lateral horns of which extend backwards on either side of the bucco-pharyngeal membrane and are continuous with the pleuro-peritoneal part of the cœlomic space. The primitive blood-vessels, which, in the pericardial region, fuse to form the primitive heart, are developed in the splanchnic mesoderm of the pericardial area. By the rapid elongation of the embryo, and the formation of the head-fold, the pericardial area and its contained blood-vessels are folded backwards to form the ventral wall of the fore-gut. By means of this process the surfaces of the pericardial area are reversed, its splanchnic layer being now situated on the dorsal aspect of its somatic layer, while its original anterior limit comes to form the front boundary of the umbilicus. The vitelline veins, bringing the blood from the yolk-sac, enter the embryo through the anterior wall of the umbilicus and pass upwards and forwards to open into the tubular heart, which is, for a time, suspended along its entire length, from the ventral aspect of the fore-gut, by a dorsal mesentery (dorsal mesocardium) (fig. 225). By the absorption of the middle part of this dorsal mesocardium behind the ascending aorta and pulmonary artery the great transverse sinus of the pericardium is formed.

In amphibians and birds the pericardium is developed by the fusion of the lateral halves of the cœlom in the middle line beneath the fore-gut, and therefore in these animals there exists, for a period, a ventral mesocardium; but Robinson has shown that the pericardial cavity in mammals is from the first a single cavity, and that there is never at any time a ventral mesocardium.

The mesoderm immediately in front of the umbilicus becomes thickened to form the septum transversum, above which are situated the lateral horns of the pericardial cavity. These assume the form of tubular passages on the sides of the fore-gut, and constitute the communications between the pericardial and pleuro-peritoneal parts of the cœlom (fig. 225). The lung buds grow out behind the ducts of Cuvier into these passages, and push their way outwards and forwards into the tissue of the septum transversum. The expansion of the pleural cavities therefore takes place in the septum, which by this means is differentiated into the central part of the Diaphragm and the posterior wall of the pericardium. The anterior limit of the septum transversum is indicated by the Cuvierian ducts (superior venæ cavæ), by the growth of which the passages between the pericardium and pleuræ are closed.

DEVELOPMENT OF THE ALIMENTARY AND RESPIRATORY SYSTEMS

The Alimentary Canal.—As already indicated (page 92), the primitive alimentary canal consists of three parts, viz.: (1) the *fore-gut*, within the cephalic flexure, and dorsal to the heart; (2) the *mid-gut*, opening freely into the yolk-sac; and (3) the *hind-gut*, within the caudal flexure (figs. 199, 200). At first the fore-gut and hind-gut end blindly. The anterior end of the fore-gut is separated from the stomatodæum by the pharyngeal septum (fig. 201); the hind-gut terminates posteriorly in the cloaca, which is closed externally by the cloacal membrane.

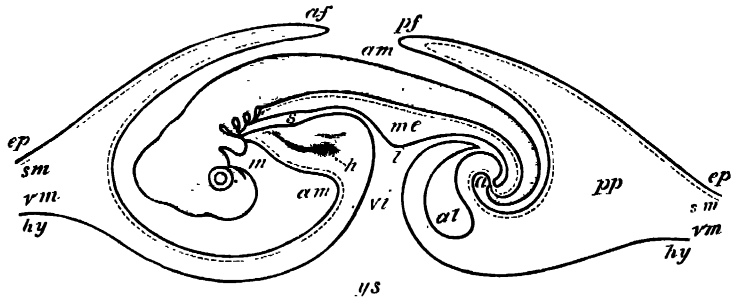
The pharynx, œsophagus, stomach, and greater part of the duodenum are developed from the fore-gut,* while the liver and pancreas are formed as diverticula

* The level of the opening of the common bile-duct is usually regarded as the junction of the fore-gut with the mid-gut.

from the duodenum; the descending, iliac, and pelvic parts of the colon, the rectum, and the tubular stalk of the allantois are developed from the hind-gut; the mid-gut gives origin to the remainder of the alimentary tube.

The mouth.—The mouth is developed partly from the stomatodæum, and partly from the floor of the anterior portion of the fore-gut. By the growth

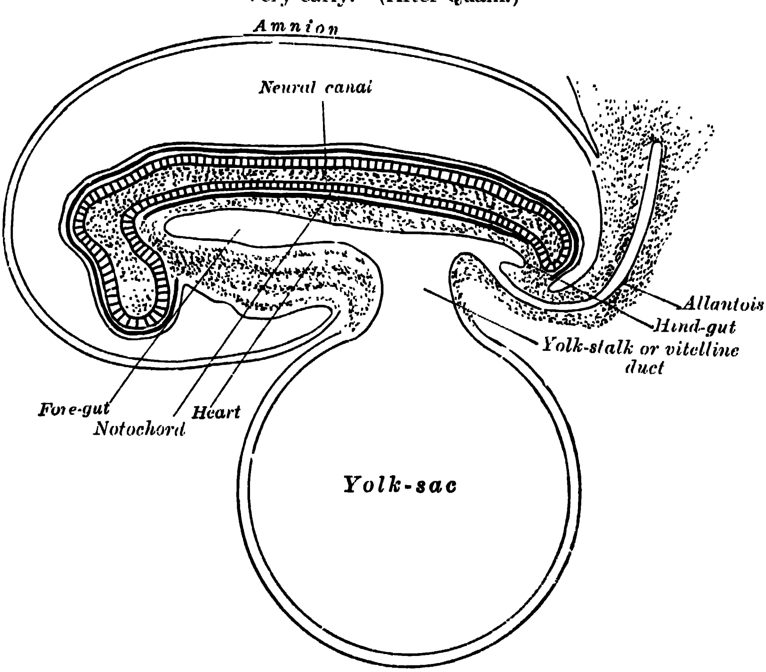
FIG. 199.—Diagrammatic outline of a sagittal section of the chick on the fourth day. (From Quain's 'Anatomy,' Allen Thomson.)



a. future anus, still closed; *af.* cephalic fold; *al.* the allantoic vesicle; *am.* cavity of true amnion; *ep.* ectoderm; *h.* heart; *hy.* entoderm; *i.* intestine; *m.* the mouth; *me.* the mesentery; *pf.* caudal fold; *pp.* space between inner and outer folds of amnion; *s.* fore-gut; *sm.* somatic mesoderm; *vi.* vitelline duct; *vm.* splanchnic mesoderm; *ys.* yolk-sac.

of the head end of the embryo, and the formation of the cephalic flexure, the pericardial area and the oral plate or bucco-pharyngeal area come to lie on the ventral surface of the embryo. With the further expansion of the brain, and the bulging forwards of the pericardium, the oral plate is depressed

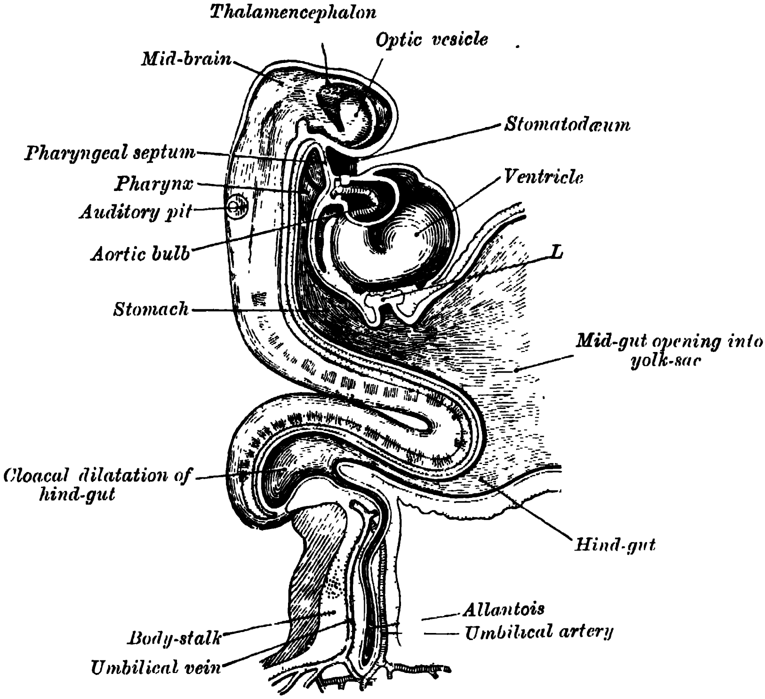
FIG. 200.—Diagram of a sagittal section of a mammalian embryo. Very early. (After Quain.)



between these two prominences. This depression constitutes the *stomatodæum* (fig. 201). It is lined by ectoderm, and is separated from the anterior end of the fore-gut by the oral plate, which is now named the *pharyngeal septum* (fig. 201). This septum is devoid of mesoderm, being formed by the apposition of the stomatodæal ectoderm with the fore-gut entoderm; at the end of a fortnight it

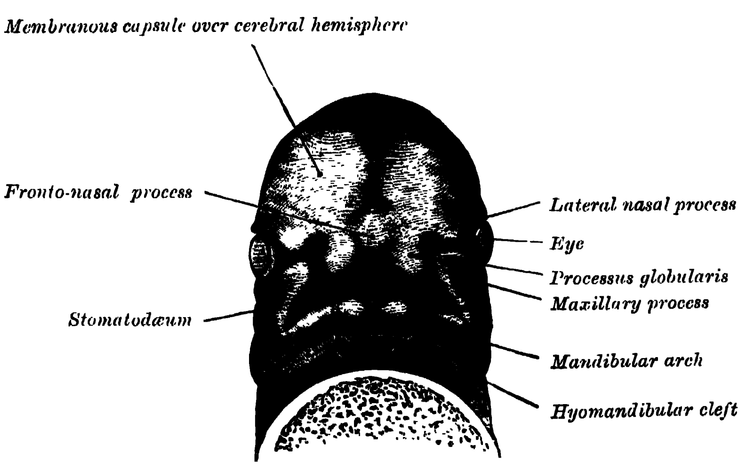
disappears, and thus a communication is established between the mouth and the future pharynx. No trace of the pharyngeal septum is found in the adult; and the communication just mentioned must not be confused with the isthmus faucium,

Fig. 201.—Human embryo about fifteen days old. Brain and heart represented from right side. Alimentary canal and yolk-sac in mesial section. (After His.)



since, as His has shown, the anterior pillars of the fauces are developed from the second visceral arches.

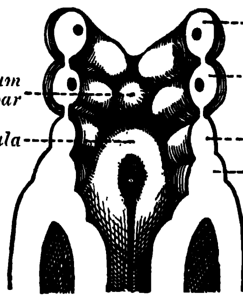
Fig. 202.—Under surface of the head of a human embryo about twenty-nine days old. (After His.)



The visceral arches extend in a ventral direction between the stomatodæum and the pericardium; and with the completion of the mandibular arch and the formation of the maxillary processes, the mouth assumes the appearance of a

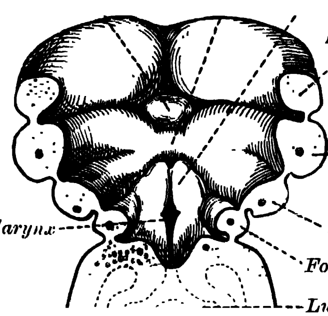
pentagonal orifice. The orifice is bounded in front by the fronto-nasal process which covers the fore-brain and contains the anterior part of the coalesced trabeculæ cranii, behind by the mandibular arch, and laterally by the maxillary processes (fig. 202). With the inward growth and fusion of the palatal processes (figs. 142, 143), the upper portion of the stomatodæum is shut off to form the nasal cavities, while from its lower or buccal portion the roof and anterior part of the mouth, together with the teeth, are developed.

FIG. 203.—The floor of the pharynx of a human embryo about fifteen days old. × 50. (From His.)



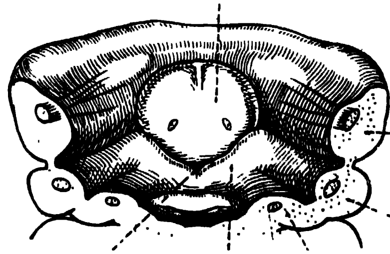
The **salivary glands** arise as diverticula from the epithelial lining of the mouth, and their rudiments appear in the following order, viz.: the parotid during the fourth week, the submaxillary in the sixth week, and the sublingual during the ninth week (Hammar).

FIG. 204.—The floor of the pharynx of a human embryo about twenty-three days old. × 30. (From His.)



The tongue (figs. 203 to 205).—The tongue is developed in the floor of the pharynx. The rudiment of the anterior or buccal portion appears during the third week as a rounded elevation, immediately behind the ventral ends of the

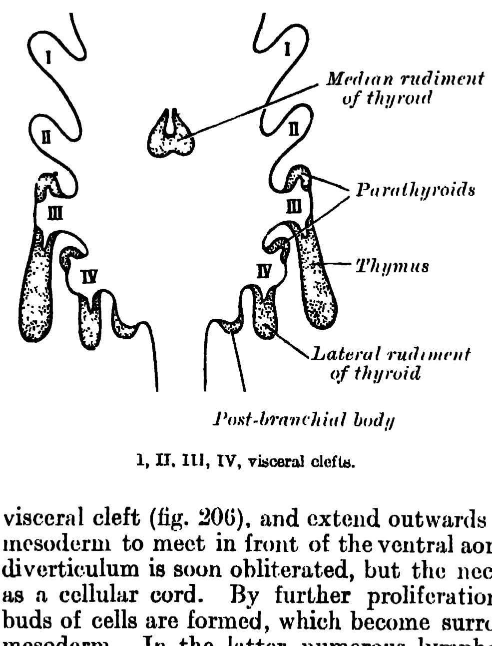
FIG. 205.—Floor of mouth of an embryo slightly older than that shown in fig. 204. × 16. (From His.)



mandibular arches. This elevation is named the ***tuberculum impar*** (figs. 203 and 204); it extends forwards on the oral surface of the mandibular arch, and increases markedly in size by the development of a pair of lateral tongue-elevations,

which raise themselves from the inner surfaces of the mandibular arches, and, blending with the tuberculum impar, form the tip and greater portion of the buccal part of the tongue. These lateral growths correspond with similar structures which were described by E. Kallius in the development of the tongue of the lizard. From the ventral ends of the fourth arch there arises a second and larger elevation, in the centre of which is a median groove or furrow. This elevation is named the *furcula* (fig. 203), and is at first separated from the tuberculum impar by a depression, but later by a ridge formed by the forward growth and fusion of the ventral ends of the second and third arches. The posterior or pharyngeal part of the tongue is developed from this ridge, which extends forwards in the form of a V, so as to embrace between its two limbs the tuberculum impar (figs. 204 and 205). At the apex of the V a pit-like invagination occurs, to form the middle thyroid rudiment, and this depression is represented in the adult by the *foramen cæcum* of the tongue. In the adult the union of the anterior and posterior parts of the tongue is marked by a V-shaped depression (sulcus terminalis), the apex of which is at the foramen cæcum, while the two limbs run outwards and forwards, parallel to, but a little behind, the circumvallate papillæ. The prominent anterior part of the furcula forms the epiglottis; the furrow behind it is the entrance to the larynx; and the anterior parts of its lateral margins constitute the aryteno-epiglottidean folds.

FIG. 206.—Scheme showing development of branchial epithelial bodies. (Modified from Kohn.)



I, II, III, IV, visceral clefts.

The **tonsils** are developed from the lower parts of the second visceral clefts, immediately behind the anterior pillars of the fauces. The entoderm which lines these clefts grows in the form of a number of solid buds into the surrounding mesoderm. These buds become hollowed out by the degeneration and casting off of their central cells, and by this means the tonsillar crypts are formed. Lymphoid cells accumulate around the crypts, and become grouped to form the lymphoid follicles; the latter, however, are not well defined until after birth.

The **thymus gland** appears in the form of two flask-shaped entodermal diverticula, which arise, one on either side, from the third visceral cleft (fig. 206), and extend outwards and backwards into the surrounding mesoderm to meet in front of the ventral aortæ. The pharyngeal opening of each diverticulum is soon obliterated, but the neck of the flask persists for some time as a cellular cord. By further proliferation of the cells which line the flask, buds of cells are formed, which become surrounded and isolated by the invading mesoderm. In the latter, numerous lymphoid cells make their appearance, and are aggregated to form lymphoid follicles. These lymphoid cells are probably derivatives of the entodermal cells which lined the original diverticulum and its subdivisions.

The **thyroid body** is developed from a median and two lateral diverticula (fig. 206). The median diverticulum appears about the fourth week, immediately behind the tuberculum impar of the tongue, between the mandibular and hyoid arches. It grows downwards and backwards as a tubular duct, which bifurcates and subsequently subdivides into a series of cellular cords, from which the isthmus and part of the lateral lobes of the thyroid body are developed. The lateral diverticula arise from the inner aspects of the fourth visceral clefts; they grow backwards and fuse with the median portion to form the remainder of the lateral lobes. The connections of the lateral diverticula with the pharynx disappear early. That of the median rudiment is termed the *thyro-glossal duct*; its continuity is subsequently interrupted by the development of the body of the hyoid bone, and it

undergoes degeneration, its upper end being represented by the foramen cæcum of the tongue, and its lower by the pyramidal lobe of the thyroid body.

The *parathyroid bodies* are developed as outgrowths from the inner aspects of the third and fourth visceral clefts (fig. 206).

A pair of diverticula arise behind the fifth arch and form what are termed the *postbranchial bodies* (fig. 206); these degenerate and disappear at an early stage.

The **pituitary body, or hypophysis cerebri.**—This consists of a large anterior, and a small posterior, lobe: the former is derived from the ectoderm of the stomatodæum, the latter from the floor of the fore-brain. About the fourth week there appears a pouch-like diverticulum of the ectodermal lining of the roof of the stomatodæum. This, the pituitary involution or *pouch of Rathke* (fig. 207), is the rudiment of the anterior lobe of the pituitary body; it extends upwards in front of the cephalic end of the notochord and the remnant of the pharyngeal septum, and comes into contact with the under surface of the fore-brain. It is then constricted off to form a closed vesicle, but remains for a time connected to the ectoderm of the stomatodæum by a solid cord of cells. The vesicle sends out hollow processes into the surrounding mesoderm, and is gradually converted into a mass of small, tortuous tubules lined with columnar or cubical cells. The upwardly directed pituitary involution becomes applied to the antero-lateral aspect of a downwardly directed diverticulum from the base of the fore-brain (page 123). This diverticulum constitutes the future infundibulum in the floor of the third ventricle, while its lower extremity becomes modified to form the posterior lobe of the pituitary body. In some of the lower animals the posterior lobe contains nerve-cells and nerve-fibres, but in man and the higher vertebrates these are replaced by connective tissue. A canal (*cranio-pharyngeal canal*) is sometimes found extending from the pituitary fossa to the under surface of the skull, and marks the original position of Rathke's pouch.

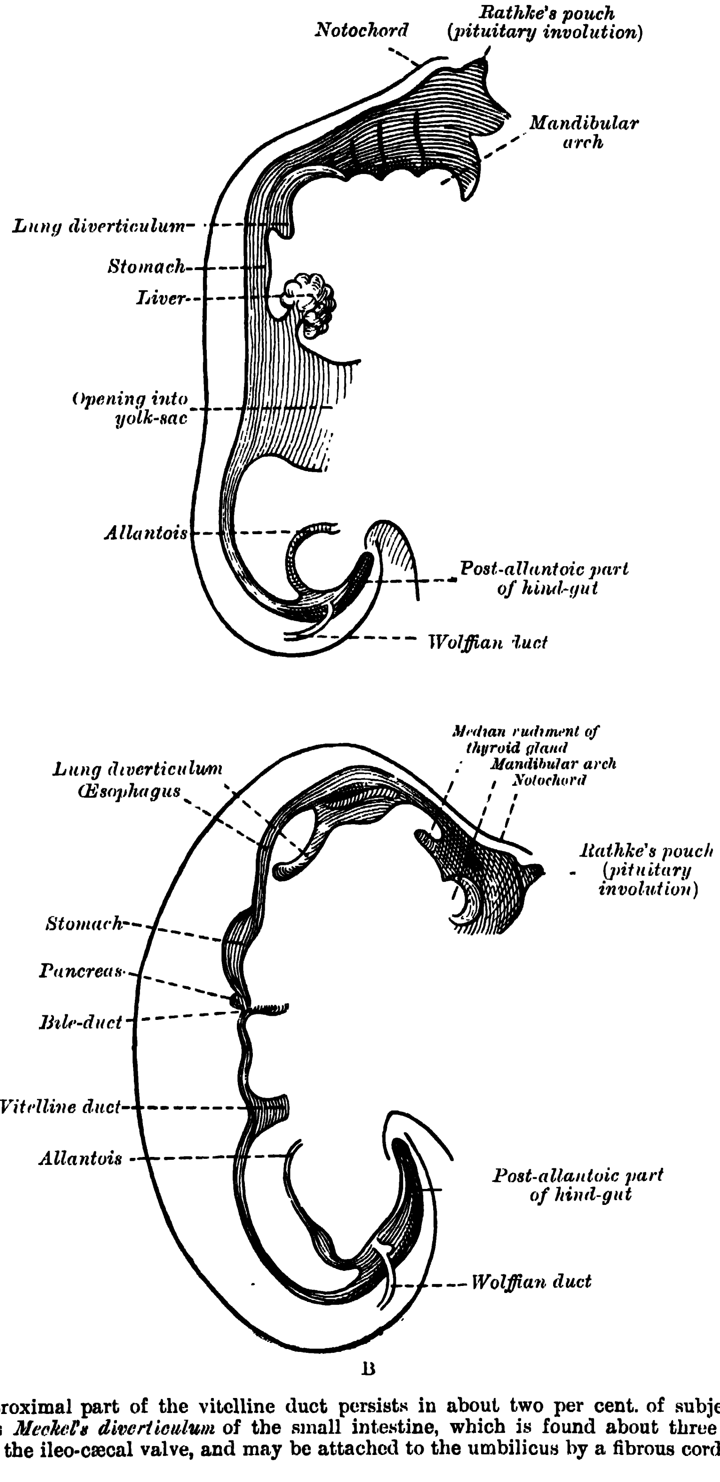
The further development of the alimentary canal.—The upper part of the fore-gut becomes dilated to form the pharynx (fig. 208), in relation to which the branchial arches are developed (fig. 136) (see page 107); the succeeding part remains tubular, and with the descent of the stomach is elongated to form the œsophagus. About the fourth week a fusiform dilatation, the future stomach,

makes its appearance, and beyond this the mid-gut opens freely into the yolk-sac (figs. 208 and 209). The opening is at first wide, but is gradually narrowed into a tubular stalk, the *yolk-stalk* or *vitelline duct.** At this stage, therefore, the

FIG. 208.—Sketches in profile of two stages in the development of the human alimentary canal. (His.) Fig. A × 30. Fig. B × 20.

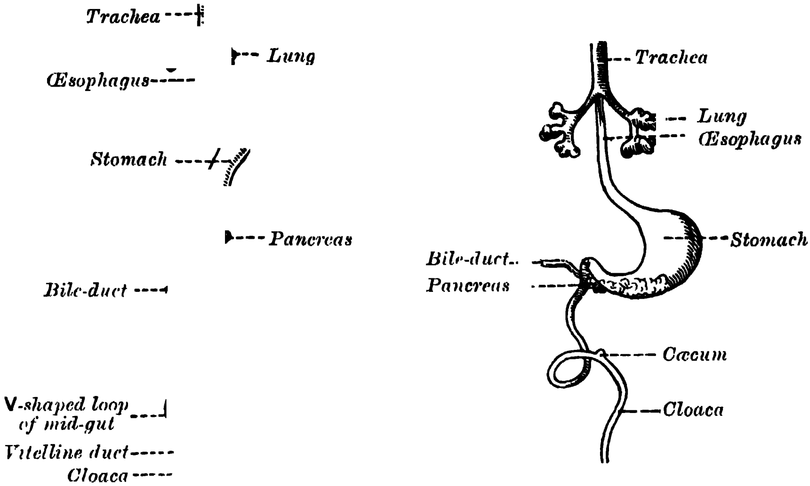


B

* The proximal part of the vitelline duct persists in about two per cent. of subjects and constitutes *Meckel's diverticulum* of the small intestine, which is found about three or four feet above the ileo-cæcal valve, and may be attached to the umbilicus by a fibrous cord.

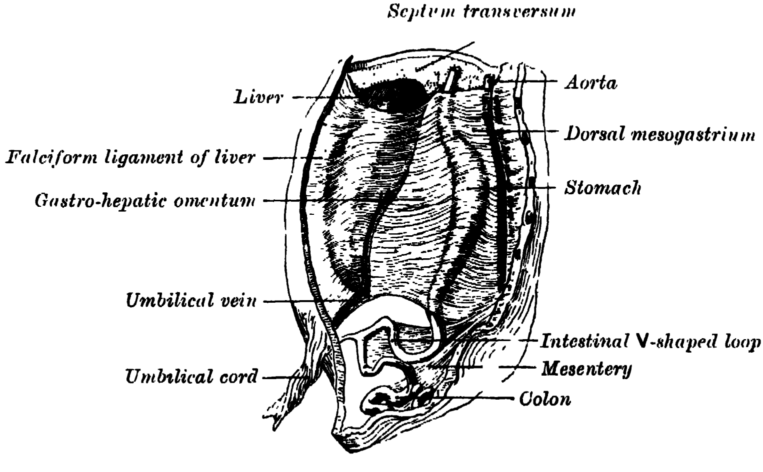
alimentary canal forms a nearly straight tube in front of the notochord and primitive aortæ (fig. 200). From the stomach to the rectum it is attached to the notochord by a band of mesoderm; from which the common mesentery of the gut is subsequently developed. The stomach has an additional attachment, viz. : to the

FIG. 209.—Front view of two successive stages in the development of the alimentary canal. (His.)



ventral abdominal wall as far as the umbilicus by the septum transversum. The cephalic portion of the septum takes part in the formation of the Diaphragm (see page 167), while the caudal portion into which the liver grows forms the *ventral mesogastrium* (fig. 210). The stomach undergoes a further dilatation, and its two curvatures can be recognised (figs. 208, B, and 210), the greater directed

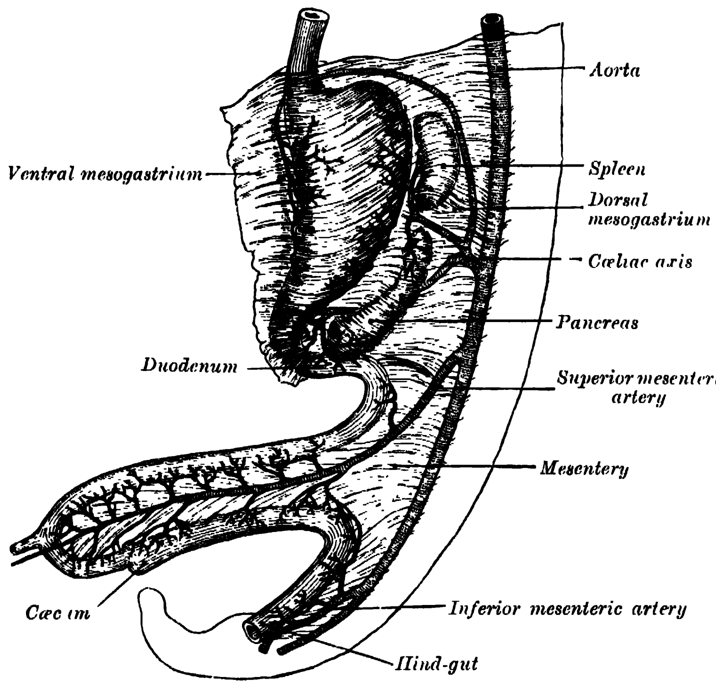
FIG. 210.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)



towards the vertebral column and the lesser towards the anterior wall of the abdomen, while its two surfaces look to the right and left respectively. The mid-gut undergoes great elongation, and forms a V-shaped loop which projects downwards and forwards; from the bend or angle of the loop the vitelline duct passes to the umbilicus (fig. 211). For a time a part of the loop extends beyond

the abdominal cavity into the umbilical cord, but by the end of the third month it is withdrawn within the cavity. With the lengthening of the tube, the mesoderm, which attaches it to the future vertebral column and carries the blood-vessels for the supply of the gut, is thinned and drawn out to form the *posterior common mesentery.* The portion of this mesentery attached to the greater curvature of the stomach is named the *dorsal mesogastrium*, and the part which suspends the colon is termed the *mesocolon* (fig. 211). About the sixth week a lateral diverticulum makes its appearance a short distance behind the opening of the vitelline duct, and indicates the future cæcum and appendix. The part of the loop on the distal side of the cæcal diverticulum increases in diameter and forms the future ascending and transverse portions of the large intestine. Until the third month the cæcal diverticulum has a uniform calibre, but from this time onwards its most dependent part remains rudimentary and forms the vermiform appendix, while its upper part expands to form the cæcum. Changes also take place in the shape and position of the stomach. Its dorsal part or greater curvature, with the

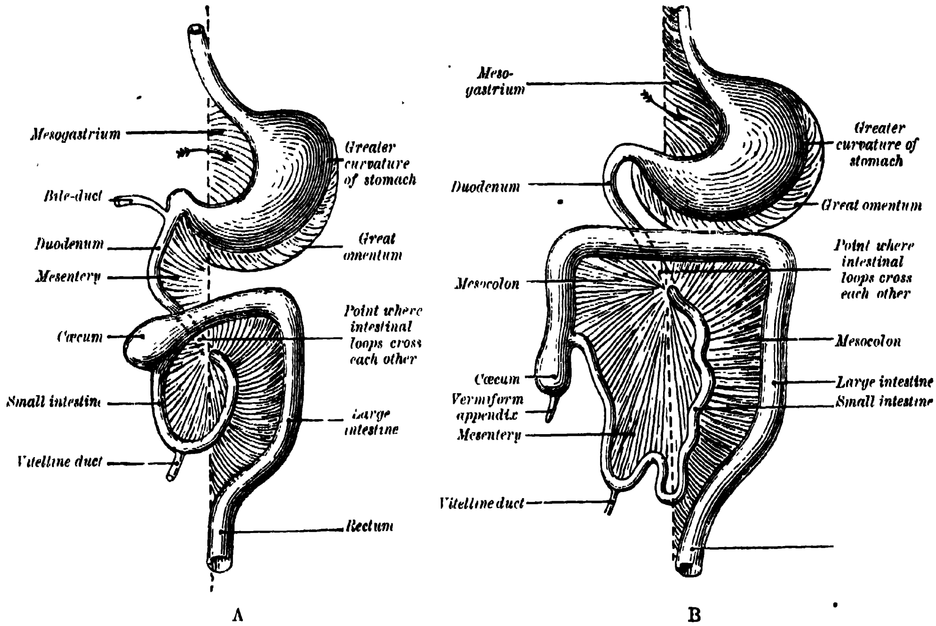
FIG. 211.—Abdominal part of alimentary canal and its attachment to the primitive or common mesentery. Human embryo of six weeks. (After Toldt.) (From Kollmann's 'Entwickelungsgeschichte.')



dorsal mesogastrium attached, grows much more rapidly than its ventral part or lesser curvature to which the ventral mesogastrium is attached. Further, the greater curvature is carried downwards and to the left, so that the right surface of the stomach is now directed backwards and the left surface forwards—a change in position which explains why the left vagus nerve is found on the front of the stomach and the right vagus on the back of it. The dorsal mesogastrium being attached to the greater curvature must necessarily follow its movements, and hence it becomes greatly elongated and drawn outwards from the vertebral column, and, as in the case of the stomach, the right surfaces of both the dorsal and ventral mesogastria are now directed backwards, and the left forwards. In this way a pouch, the *bursa omentalis*, is formed behind the stomach ; this pouch is the future lesser sac of the peritoneum, and it increases in size as the alimentary tube undergoes further development ; the entrance to the pouch constitutes the future *foramen of Winslow* (figs. 212, 215). The duodenum is developed from that part of the tube which immediately succeeds the stomach ; it undergoes little elongation, being more or less fixed in position by the liver and pancreas, which arise as diverticula

from it. The duodenum is at first suspended by a mesentery, and projects forwards in the form of a loop. The loop and its mesentery are subsequently displaced by the transverse colon, so that the right surface of the duodenal

Fig. 212.—Diagrams to illustrate two stages in the development of the human alimentary canal and its mesentery. The arrow indicates the entrance to the bursa omentalis.

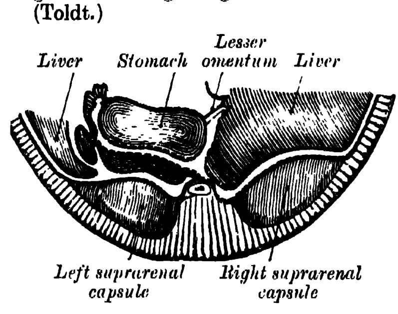


mesentery is directed backwards, and, adhering to the parietal peritoneum, is lost. The remainder of the alimentary canal becomes greatly elongated, and as a consequence the tube is coiled on itself, and this elongation demands a corresponding increase in the width of the intestinal attachment of the mesentery, which becomes folded.

At this stage the small and large intestines are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.*

The gut is now rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cæcum is placed immediately below the liver; about the sixth month the cæcum descends into the right iliac fossa, and the large intestine forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (figs. 212, 217). Sometimes the downward progress of the cæcum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

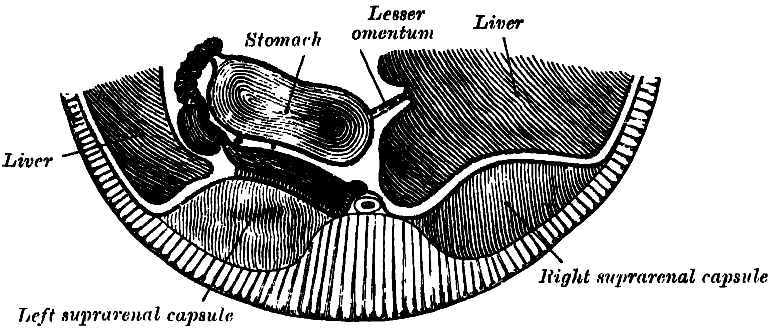
Fig. 213.—Schematic and enlarged cross section through the body of a human embryo in the region of the mesogastrium. Beginning of third month. (Toldt.)



* Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesial plane, where it is continued into the jejunum; the arteries to the small intestine (rami intestini tenuis) also arise from the right instead of the left side of the superior mesenteric artery.

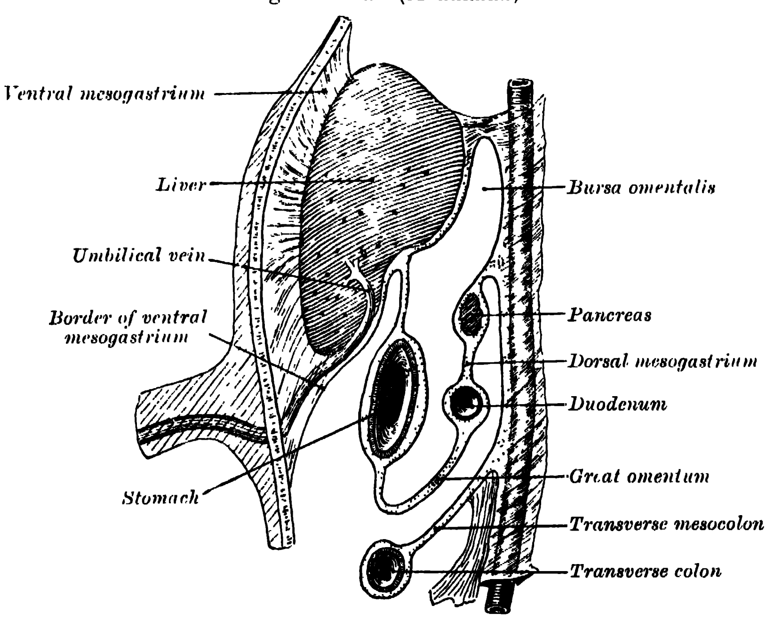
Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the stomach, grows downwards to form the great omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the

FIG. 214.—Section through same region as in fig. 213, at end of third month. (Toldt.)



posterior layer of the great omentum, but ultimately the two blend, and hence the great omentum appears as if attached to the transverse colon (fig. 216). The mesenteries of the ascending and descending parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

FIG. 215.—Schematic figure of the bursa omentalis, &c. Human embryo of eight weeks. (Kollmann.)

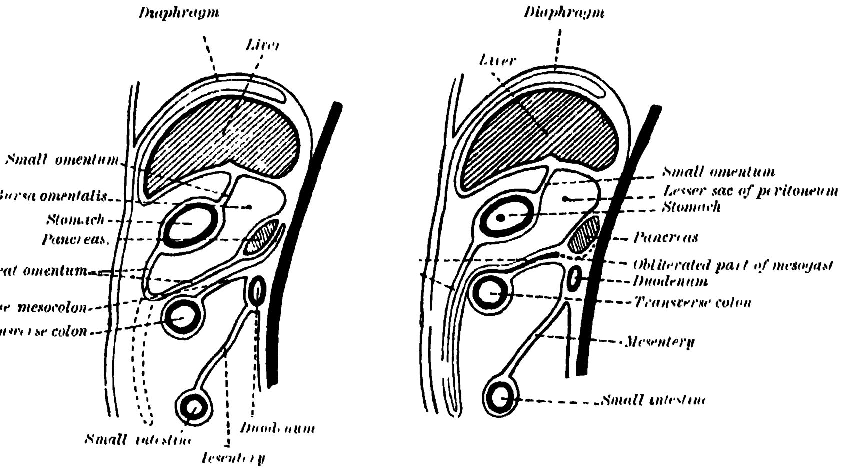


The small omentum is formed, as indicated above, by a thinning of the mesoderm or *ventral mesogastrium*, which attaches the stomach and duodenum to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoderm is divided into two parts, viz.: the small omentum between the stomach and liver, and the falciform and coronary ligaments between the liver and the abdominal wall and Diaphragm (fig. 210).

The **rectum and anal canal.**—The hind-gut is at first prolonged backwards into the body-stalk as the tube of the allantois; but, with the growth and

flexure of the tail-end of the embryo, the body-stalk, with its contained allantoic tube, is carried forwards to the ventral aspect of the body, and consequently a

FIG. 216.—Diagrams to illustrate the development of the great omentum and transverse mesocolon.



bend is formed at the junction of the hind-gut and allantois. This bend becomes dilated into a pouch, which constitutes the *entodermal cloaca*; into its dorsal part the hind-gut opens, and from its ventral part the allantois passes forwards. At a later stage the Wolffian and Müllerian ducts open into its ventral portion. The cloaca is, for a time, shut off from the exterior by a membrane, the *cloacal membrane*, formed by the apposition of the ectoderm and entoderm, and reaching, at first, as far forwards as the future umbilicus. Behind the umbilicus, however, the mesoderm subsequently extends inwards to form the lower part of the abdominal wall and symphysis pubis. By the growth of the surrounding tissues the cloacal membrane comes to lie at the bottom of a depression, which is lined by ectoderm and named the *ectodermal cloaca* (fig. 218).

FIG. 217.—Final disposition of the intestines and their vascular relations. (Jonnesco.)

A. Aorta. H. Hepatic artery. M, Col. Branches of superior mesenteric artery. m, m', Branches of inferior mesenteric artery. S. Splenic artery.

The entodermal cloaca is divided into a dorsal and a ventral part by means of a partition consisting of two lateral mesodermal folds which grow inwards and unite with each other in the middle line. The dorsal part forms the rectum, and the anterior part the urogenital sinus and bladder. By the rupture of the cloacal membrane the entodermal cloaca opens on the exterior, thus giving rise to a condition which exists permanently in the reptile, bird, and monotreme. Into this cloacal channel in these animals the urine, the fæces, and the products of the genital organs are discharged. The communication of the rectum with the cloaca is obliterated by the inward growth of two eminences, which make their appearance one on either side of the cloaca. These join in the middle line to form the perineal septum, and also fuse with the hinder edge of the septum which separates the urogenital sinus and bladder from the rectum. The anal canal is not developed from the cloacal opening of the hind-gut, but is formed by an invagination of the ectoderm behind the perineal septum. This invagination is termed the *proctodæum* (fig. 223), and it meets with the ventral aspect of the hind-gut and forms with it the *anal membrane*. By the absorption of this membrane the anal canal becomes continuous with

the rectum (fig. 224). A small part of the hind-gut projects backwards beyond the anal membrane; it is named the *post-anal gut*, and usually becomes obliterated and disappears.*

F. Wood-Jones † gives a different account from the above as to the manner in which the rectum is separated from the cloaca. He maintains that the growth of the hind-gut keeps pace with that of the hind-end of the embryo, and 'buds backwards past its cloacal orifice, past its old termination in the allantois, and forms the portion of the hind-gut distal to the allantois'; this portion he terms the

FIG. 218.—Tail end of human embryo from fifteen to eighteen days old. (From model by Keibel.)

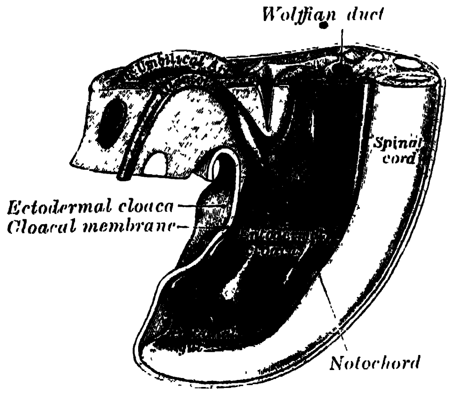


FIG. 219.—Cloaca and appendages of human embryo from twenty-five to twenty-seven days old. (From model by Keibel.)

post-allantoic gut (figs. 221, 222). 'The cloacal opening of the hind-gut is now normally lost; originally a small opening in the embryo of 12 somites (which is about 2 mm. in total length), the rapid growth of the hind-gut, the post-allantoic gut, and of the allantois itself, together with the lateral infolding of the wall described by Keibel, serve to close the opening of the hind-gut into the cloaca' (fig. 223). This view, which affords a satisfactory explanation of the varieties of imperforate rectum and anus which are sometimes found, leads to the conclusion

* Consult, in this connection, the following article: 'A Contribution to the Morphology of the Human Urino-genital Tract,' by D. Berry Hart, M.D., F.R.C.P.E. *Journal of Anatomy and Physiology*, April 1901, vol. xxxv.

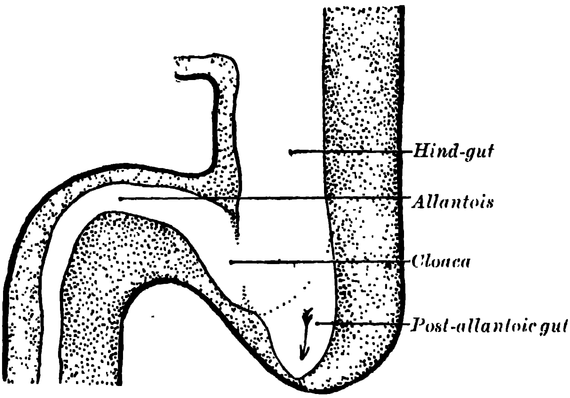

FIG. 222.—Diagram to illustrate the further development of the post-allantoic gut. The hind-gut still opens into the cloaca. The opening of the Müllerian ducts is also seen. (After Wood-Jones.)

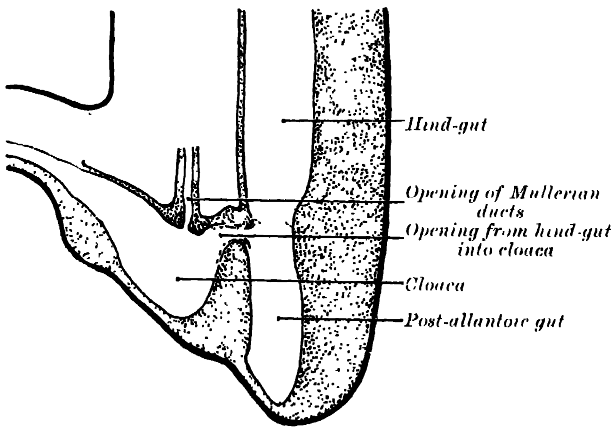

FIG. 223.—Diagram to illustrate the separation of the hind-gut from the cloaca. The hind-gut has now lost its cloacal opening. The post-allantoic gut is about to meet the proctodæal depression. (After Wood-Jones.)

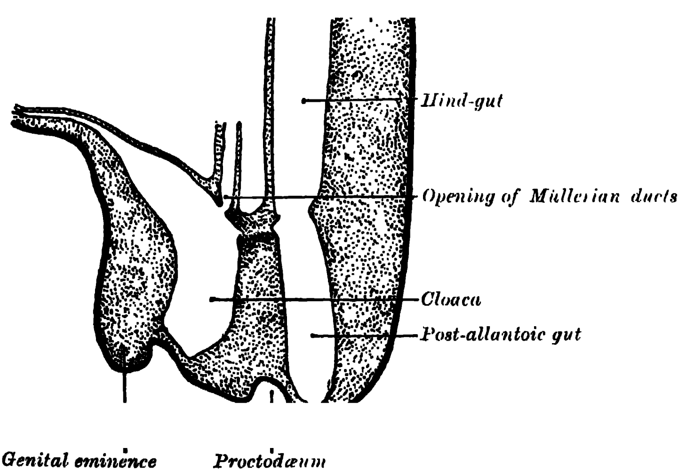
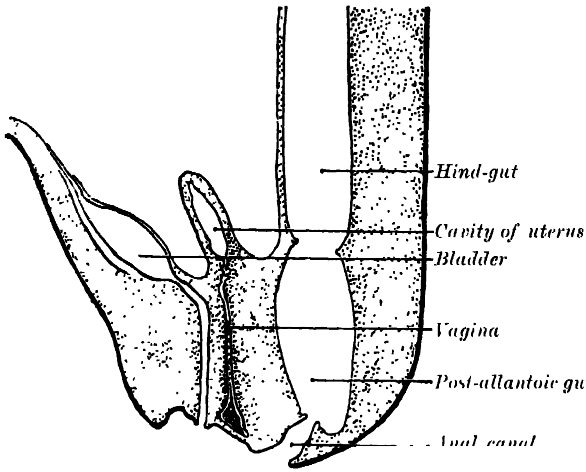


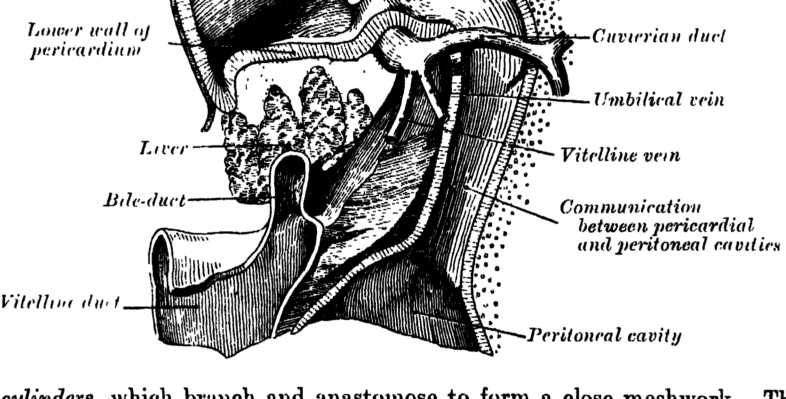
that the cloaca does not contribute to the formation of the rectum, and that the septa which have been described as fusing in the middle line to form the perinæum are non-existent.

Fig. 224.—Diagram to illustrate the formation of the vagina, bladder, and urethra. The Müllerian ducts have lost their opening into the urogenital sinus, and the new solid vagina has grown down and later becomes canalised. (After Wood-Jones.)



The **liver** arises in the form of a diverticulum or hollow outgrowth from the ventral surface of that portion of the gut which afterwards becomes the second part of the duodenum (figs. 208, 225). This diverticulum is lined by entoderm, and grows upwards and forwards into the septum transversum, and there gives off two solid buds of cells which represent the right and the left lobes of the liver. The solid buds of cells grow into columns or cylinders, termed the

Fig. 225.—Liver with the septum transversum. Human embryo 3 mm. long. (After model and figure by His.)



hepatic cylinders, which branch and anastomose to form a close meshwork. This network invades the vitelline and umbilical veins, and breaks up these vessels into a series of capillary-like vessels termed *sinusoids* (Minot), which ramify in the

meshes of the cellular network and ultimately form the venous capillaries of the liver. By the continued growth and ramification of the hepatic cylinders the mass of the liver is gradually formed. The original diverticulum from the duodenum forms the common bile-duct, and from this the cystic duct and gall-bladder arise as a hollow evagination.

As the liver undergoes enlargement, both it and the ventral mesogastrium of the fore-gut are gradually differentiated from the septum transversum; and from the under surface of the latter the liver projects downwards into the abdominal cavity. By the growth of the liver the ventral mesogastrium is divided into two

FIG. 226.—Pancreatic buds from a human embryo 7·5 mm. long. (Kollmann.)

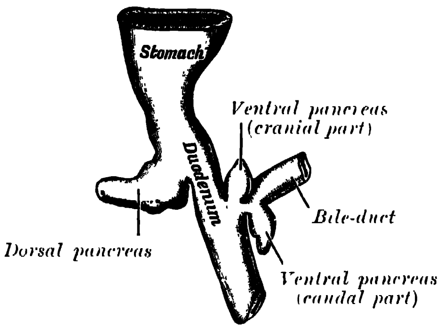


FIG. 227.—Pancreas of a human embryo of five weeks. (Kollmann.)

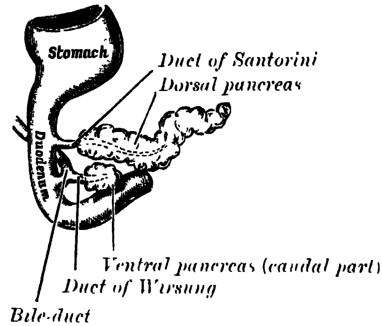
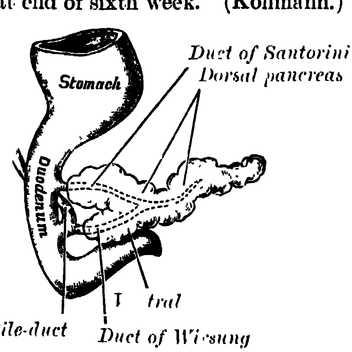


parts, of which the anterior forms the falciform and coronary ligaments, and the posterior the gastro-hepatic omentum. About the third month the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right. From this period the relative development of the liver is less active, more especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right; but up to the end of fœtal life the liver remains relatively larger than in the adult.

The **pancreas** (figs. 226 to 228).—The pancreas is developed in two parts, a dorsal and a ventral. The former arises as a diverticulum from the dorsal aspect of the duodenum a short distance above the hepatic diverticulum, and, growing upwards and backwards into the dorsal mesogastrium, forms the body and tail of the pancreas. The ventral part appears in the form of two diverticula, cranial and caudal, from the primitive bile-duct; the caudal enlarges to form the head of the pancreas, while the cranial atrophies and disappears. The duct of the dorsal part (duct of Santorini) therefore opens into the duodenum, while that of the ventral part (duct of Wirsung) terminates with the common bile-duct. During the sixth week, in consequence of the rotation of the duodenum, the two parts of the pancreas meet and fuse, and a communication is established between their ducts. After this has occurred the terminal part of the duct of Santorini, i.e. the part between the duodenum and the point of meeting of the two ducts, undergoes little or no enlargement, while the duct of Wirsung increases in size and forms the main duct of the gland. The opening of the duct of Santorini into the duodenum is sometimes obliterated, and even when it remains patent it is probable that the whole of the pancreatic secretion is conveyed through the duct of Wirsung.

FIG. 228.—Pancreas of human embryo at end of sixth week. (Kollmann.)



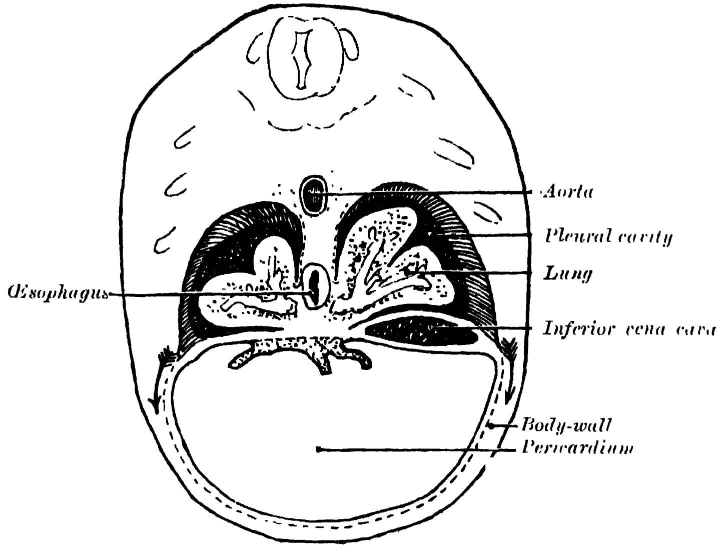
At first the pancreas is directed upwards and backwards between the two layers of the dorsal mesogastrium which give to it a complete peritoneal investment, and its surfaces look to the right and left. With the change in the position of the stomach the dorsal mesogastrium is drawn downwards and to the left, and

the right side of the pancreas is directed backwards and the left forwards. The right surface becomes applied to the posterior abdominal wall, and the peritoneum which covered it undergoes absorption ; and thus, in the adult, the gland appears to lie behind the peritoneal cavity.

The **spleen** (fig. 211).—Although the spleen belongs to the group of ductless glands, its development may be conveniently referred to here. It appears in the second month as a localised thickening of the mesoderm in the dorsal mesogastrium above the tail of the pancreas. It grows towards the left side of the dorsal mesogastrium, and thus comes into contact with the right surface of the stomach. With the change in position of this viscus the spleen is carried to the left, and comes to lie behind the cardiac part of the stomach and in contact with the left kidney. The part of the dorsal mesogastrium which intervened between the spleen and the greater curvature of the stomach forms the gastro-splenic omentum.

The Respiratory Organs.—Towards the end of the third week a deep longitudinal furrow (figs. 203 and 204) appears in the ventral wall of the fore-gut, commencing at the level of the fourth visceral arch and reaching backwards nearly as far as the stomach. It is bounded in front by an elevation termed the

FIG. 229.—Diagram of transverse section through rabbit embryo. (After Keith.)



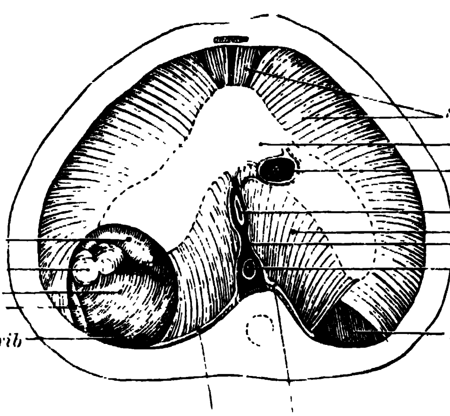
furcula (page 154) and laterally by two ridges. By the union of the posterior parts of the two ridges the groove is converted into a tube-like diverticulum, which is lined by entoderm and grows backwards on the ventral aspect of the œsophagus ; from the entoderm the epithelial lining of the entire respiratory tract is developed. The upper end of this diverticulum is expanded to form the larynx ; the furcula is the future epiglottis, and the upper parts of the lateral ridges constitute the aryteno-epiglottidean folds. The thyroid cartilage is developed from the cartilages of the fourth and fifth visceral arches, while that of the sixth visceral arch appears to be modified to form the cricoid and arytenoid cartilages and the cartilages of the trachea.

The lower end of the tube-like diverticulum bifurcates into a larger right and a smaller left bud, the *right* and *left lung buds*, the stalks of which form the right and left bronchi. The right divides into three and the left into two parts ; these subdivisions are the early indications of the corresponding lobes of the lungs (fig. 208). The buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the infundibula of the lung. After the sixth month the air-sacs begin to make their appearance on the infundibula in the form of minute pouches. The pulmonary arteries are derived from the sixth aortic arches.

The **Diaphragm** and **pleuræ** (figs. 229 and 230).—The following description is based on that given by Keith.* The *central tendon* of the Diaphragm is derived from the septum transversum; each half of its muscular portion is developed in two parts, viz.: (*a*) a *sterno-costal* portion, derived from the ventral longitudinal musculature of the embryonic neck; and (*b*) a *spinal* or *vertebral* portion, arising from the bodies of the vertebræ and arcuate ligaments, and derived from the cervical part of the Transversalis. The pleuro-peritoneal opening is closed by the approximation of the sterno-costal and vertebral parts; and the spino-costal fibrous hiatus, best seen on the left half of the adult Diaphragm, marks its position after closure. Sometimes the opening remains patent, and may allow of the formation of a congenital diaphragmatic hernia.

The formation or separation of the Diaphragm—for at first it forms part of the wall of the body-cavity—results from the development of the pleural cavities

FIG. 230.—The thoracic aspect of the Diaphragm of a newly born child in which the communication between the peritoneum and pleura has not been closed on the left side; the position of the opening is marked on the right side by the spino-costal hiatus. (After Keith.)



and lungs. The lung buds appear in the cervical region of the embryo, and they, together with the parts of the cœlom in which they are contained, undergo a rapid development, growing forwards and outwards into the tissue of the dorsal part of the septum transversum and of the body-wall; within that tissue the pleural cavities are excavated. The pleural cavities also develop within the body-wall towards the ventral median line, thus separating the pericardium from the lateral thoracic wall (see arrows in fig. 229). In this manner the pleural cavities are excavated within the body-wall, dorsal to and on each side of the pericardium. The formation of the pleural cavities separates an inner layer from the ventro-lateral aspect of the body-wall to form the sterno-costal part of the Diaphragm, and also an inner layer from the dorsal aspect of the body-wall to form the vertebral part of the Diaphragm.

DEVELOPMENT OF THE URINARY AND GENERATIVE ORGANS

The urinary and generative organs are developed from the intermediate cell-mass which is situated between the primitive segments and the lateral plates of mesoderm. The permanent organs of the adult are preceded by a set of structures which are purely embryonic, and which with the exception of the ducts disappear almost entirely before the end of fœtal life. These embryonic structures are on either side: the pronephros, the mesonephros, the Wolffian and Müllerian ducts. The pronephros disappears very early; the structural elements of the mesonephros mostly degenerate, but in their place is developed the genital gland

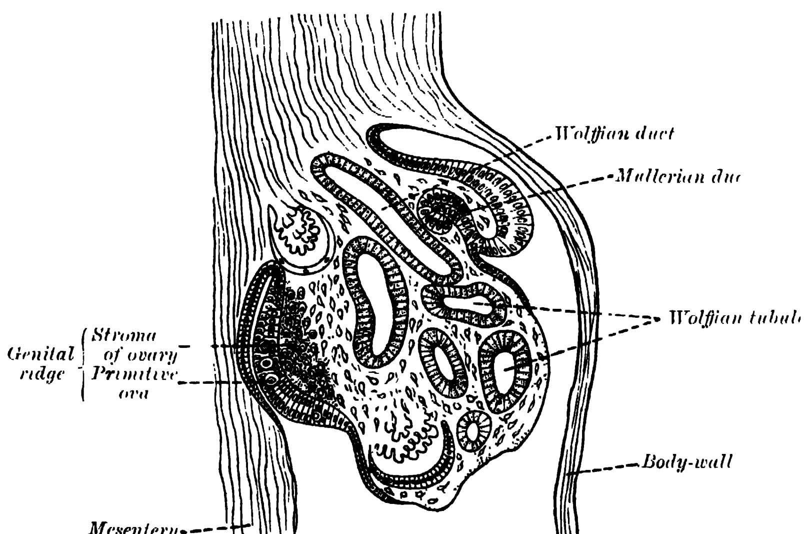
* *Human Embryology and Morphology*, by Arthur Keith, M.D., F.R.C.S., 2nd edition, 1904. Consult also an article on the development of the Diaphragm, by the same author, in vol. xxxix. of the *Journal of Anatomy and Physiology*.

in association with which the Wolffian duct remains as the duct of the male genital gland, the Müllerian as that of the female.

The Pronephros and Wolffian duct.—In the outer part of the intermediate cell-mass, immediately under the ectoderm, a longitudinal cord of cells makes its appearance. This cellular cord sinks into the subjacent mesoderm, and, acquiring a lumen, constitutes the *Wolffian duct*,* which passes backwards and opens into the ventral part of the cloaca.

In front of the duct there are developed a number of tubules which form the *pronephros* or *head-kidney*—an early embryonic structure in all vertebrates. This consists of a series of transverse tubules which open into a duct termed the *pronephric duct*; this duct is continuous posteriorly with the Wolffian duct. Each pronephric tubule communicates by means of a funnel-shaped ciliated opening with the cœlomic cavity, and in the course of each duct a glomerulus also is developed. The pronephros undergoes rapid atrophy and practically disappears. In the female the remains of it are probably represented by the hydatids of Morgagni at the fimbriated end of the Fallopian tube; in the male, by the stalked hydatid at the upper end of the testicle.

Fig. 231.—Section of the urogenital area of a chick embryo of the fourth day. (Waldeyer.)



The Mesonephros, Müllerian duct, and Genital gland.—On the inner side of the Wolffian duct a series of tubules, the *Wolffian tubules*, are developed. Each tubule opens externally into the duct, while its opposite end is invaginated by a tuft of capillary blood-vessels to form a glomerulus. These tubules increase in number, and collectively constitute the *mesonephros* or *Wolffian body* (figs. 231, 232). At the beginning of the second month this body forms an elongated spindle-shaped structure, which projects into the cœlomic cavity at the side of the dorsal mesentery, and reaches from the septum transversum in front to the fifth lumbar somite behind. The Wolffian body persists and forms the permanent kidney in fishes and amphibians, but in reptiles, birds, and mammals it is superseded by the *metanephros*, which forms the permanent kidney in these animals. The anterior tubules of the Wolffian body become attached to the sexual eminence or *genital ridge* from which the ovary in the female and the testicle in the male are developed. During the development of the permanent kidneys, the Wolffian bodies atrophy, and this process proceeds to a much greater extent in the female than in the male.

* The Wolffian duct is regarded by some embryologists as being of ectodermal origin, formed by a longitudinal invagination of the ectoderm which overlies the intermediate cell-mass.

In the male the Wolffian duct persists, and forms the tube of the epididymis, the vas deferens, and common ejaculatory duct, while the seminal vesicle arises as a lateral diverticulum from its hinder end. The anterior Wolffian tubules form the rete testis, vasa efferentia, and coni vasculosi of the testicle; while the posterior tubules are represented by the vasa aberrantia of the globus minor, and by the organ of Giraldès, which is sometimes found in front of the spermatic cord above the globus major (fig. 235, c).

Atrophied remains of the Wolffian duct. f. The terminal bulb or hydatid. h. The Fallopian tube, originally the duct of Muller. i. Hydatid attached to the extremity. l. The ovary

The **suprarenal bodies** are generally regarded as being developed from two sources. The medullary part of the organ is of ectodermal origin, and is derived from the tissues forming the sympathetic ganglia of the abdomen, while the cortical portion is of mesodermal origin, and appears to be derived from invaginations of that portion of the cœlomic epithelium which overlies the Wolffian body. The

* Berry Hart (*op. cit.*) has described the Wolffian ducts as ending at the site of the future hymen in bulbous enlargements, which he has named the *Wolffian bulbs*; and states that the hymen is formed by these bulbs, 'aided by a special involution from below of the cells lining the urogenital sinus.' He further believes that 'the lower third of the vagina is due to the coalescence of the upper portion of the urogenital sinus and the lower ends of the Wolffian ducts,' and that 'the epithelial lining of the vagina is derived from the Wolffian bulbs.' He also regards the colliculus seminalis of the male urethra as being formed from the lower part of the Wolffian ducts.

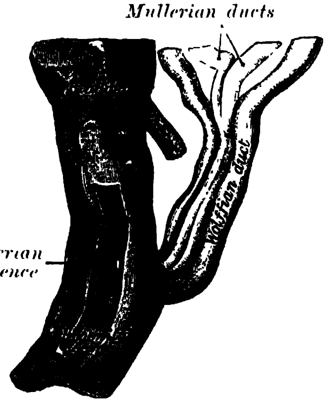
two parts are at first quite distinct, but become combined in the process of development. The suprarenal bodies are at first larger than the kidneys; about the tenth week they equal them in size, and from that time decrease relatively to the kidneys, though they remain, throughout fœtal life, proportionately much larger than in the adult.

The Müllerian ducts.—Shortly after the formation of the Wolffian ducts a second pair of ducts is developed; these are named the *Müllerian ducts.* Each arises on the outer aspect of the corresponding Wolffian body as a tubular invagination of the cells lining the cœlom (fig. 231). The orifice of the invagination remains patent, and undergoes enlargement and modification to form the abdominal ostium of the Fallopian tube. The ducts pass backwards on the outer aspects of the Wolffian bodies, but towards the posterior end of the embryo they cross to the inner side of the Wolffian ducts, and thus come to lie side by side between and behind the latter—the four ducts forming what is termed the *genital cord* (fig. 234).

Ultimately, the Müllerian ducts open into the ventral part of the cloaca between the orifices of the Wolffian ducts, and terminate on an elevation named the *Müllerian eminence* (fig. 234). Berry Hart describes them as ending blindly on this eminence.

In the male the Müllerian ducts atrophy, but traces of their anterior ends are represented by the sessile hydatids of the epididymis, while their terminal fused portions form the uterus masculinus or sinus pocularis in the floor of the prostatic portion of the urethra (fig. 235, C).

FIG. 234.—Urogenital sinus of female human embryo of eight and a half to nine weeks old.



In the female the Müllerian ducts persist and undergo further development. The portions which lie in the genital cord fuse to form the uterus and vagina; the parts in front of this cord remain separate, and each forms the corresponding Fallopian tube—the abdominal ostium of which is developed from the anterior extremity of the original tubular invagination from the cœlom (fig. 235, B). The fusion of the Müllerian ducts begins in the third month, and the septum formed by their fused mesial walls disappears from below upwards, and thus the cavities of the vagina and uterus are produced. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The development of the vagina in the manner just described would necessitate the growth of a septum between it and the urethra; but Wood-Jones (*op. cit.*) maintains that no such septum exists, and that 'the vagina is, for a great part of fœtal life, a solid rod, and not an open canal at all' (fig. 224). He says: 'Early in the history of the embryo the Müllerian ducts open into the urogenital sinus at its upper part (fig. 223); late in its history they open at the hind-end of the vagina, and for a considerable interval they have no opening at all—the old one being lost and the new one not yet formed. No septal division is employed in this change; but as the hind-gut, when its cloacal opening is lost, re-establishes communication with the exterior by a new downgrowth, so the Müllerian ducts, when their cloacal opening becomes obliterated, tunnel a new passage to the hind-end. The active agents in this strange growth are two epithelial masses that have been described by Berry Hart as the Wolffian bulbs, but to give this name to them is to give a definite idea as to their origin, and this seems to be by no means clear.'

Genital gland.—The first appearance of the genital gland is essentially the same in the two sexes, and consists in a thickening of the epithelial layer which lines the peritoneal or body cavity on the inner side of the Wolffian ridge. Beneath this thickened epithelium an increase in the mesoderm takes place, forming a distinct projection. This is termed the *genital ridge* (fig. 231), and from it the testis in the male and the ovary in the female are developed.

Fig. 235.—Diagrams to show the development of male and female generative organs from a common type. (Allen Thomson.)

C. Cowper's gland of one side. *cp.* Corpora cavernosa penis cut short. *e.* Caput epididymis. *g.* The gubernaculum. *i.* Lower part of the intestine. *m.* Müllerian duct, the upper part of which remains as the hydatid of Morgagni; the lower part, represented by a dotted line descending to the prostatic vesicle, constitutes the occasionally existing cornu and tube of the uterus masculinus. *pr.* The prostate gland. *s.* Scrotum. *sp.* Corpus spongiosum urethræ. *t.* Testicle in the place of its original formation. *t'*, together with the dotted lines above, indicates the direction in which the testicle and epididymis descend from the abdomen into the scrotum. *vd.* Vas deferens. *vh.* Vas aberrans. *vs.* The vesicula seminalis. *W.* Scattered remains of the Wolffian body, constituting the organ of Giraldès, or the paradidymis of Waldeyer.

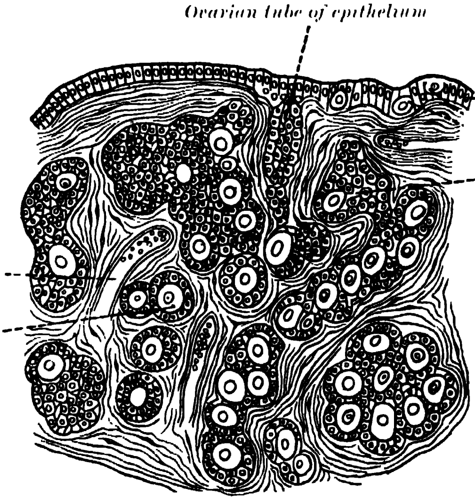
At first the Wolffian body and genital ridge are suspended by a common mesentery, but as the embryo grows the genital ridge gradually becomes pinched off from the Wolffian body, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the *mesorchium* or *mesovarium* (fig. 236). About the seventh week the distinction of sex in the genital ridge begins to be perceptible.

FIG. 236.—Transverse section of human embryo of eight and a half to nine weeks old. (From model by Keibel.)

The **ovary**, thus formed from the genital ridge, consists of a central part of connective tissue covered by a layer of epithelium, the *germinal epithelium.* Between the cells of the germinal epithelium a number of larger cells, the *primitive ova*, are found, and these are carried into the subjacent stroma by bud-like ingrowths of the germinal epithelium, the cells of which surround the primitive ova; in this manner the primitive Graafian follicles are formed. The rest of the germinal epithelium on the surface of the ovary forms the permanent epithelial covering of this organ (fig. 237). According to Beard the primitive ova are early set apart during the segmentation of the ovum and migrate into the germinal ridge.

Waldeyer taught, and for many years his views have been accepted, that the primitive germ-cells are derived from the 'germinal epithelium' covering the genital ridge. Beard,* on the other hand, maintains that in the skate they are not derived from this epithelium, but are probably formed during the later stages of cell-cleavage, before there is any trace of an embryo; and a similar view was advanced by Nussbaum as to their origin in amphibia. Beard says: 'At the close of segmentation many of the future germ-cells

FIG. 237.—Section of the ovary of a newly born child. (Waldeyer.)



lie in the segmentation cavity just beneath the site of the future embryo, and there is no doubt they subsequently wander into it.' The germ-cells, 'after they enter the resting phase, are sharply marked off from the cells of the embryo by entire absence of mitoses

* *Journal of Anatomy and Physiology*, vol. xxxviii.

among them.' They can be further recognised by their irregular form and amœboid processes, and by the fact that their cytoplasm has no affinity for ordinary stains, but assumes a brownish tinge when treated by osmic acid. The path along which they travel into the embryo is a very definite one—viz. 'from the yolk-sac upwards between the splanchnopleure and gut in the hinder portion of the embryo.' This pathway, named by Beard the *germinal path*, 'leads them directly to the position which they ought finally to take up in the "germinal ridge" or nidus.' A considerable number apparently never reach their proper destination, since 'vagrant germ-cells are found in all sorts of places, but more particularly on the mesentery.' Some of these may possibly find their way into the germinal ridge; some probably undergo atrophy, while others may persist and become the seat of dermoid tumours.

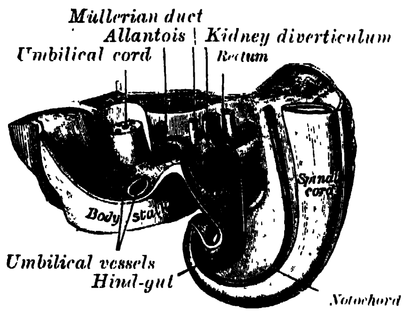
The **testis** is developed in a very similar way to the ovary. Like the ovary, in its earliest stages it consists of a central mass of connective tissue covered by germinal epithelium, among which larger cells, the *primitive sperm-cells*, are seen. These are carried into the subjacent stroma by tubes of germinal epithelium, which form the lining of the seminiferous tubules, while the primitive sperm-cells form the spermatogonia. The seminiferous tubules become connected with outgrowths from the Wolffian body, which, as before mentioned, form the rete testis and vasa efferentia.

Descent of the testes.—The testes, at an early period of fœtal life, are placed at the back part of the abdominal cavity, behind the peritoneum and a little below the kidneys; their anterior surfaces and sides are invested by peritoneum. About the third month of intra-uterine life a peculiar structure, the *gubernaculum testis*, makes its appearance. This is at first a slender band, extending from that part of the skin of the groin which afterwards forms the scrotum through the inguinal canal to the body and epididymis of the testis, and thence continued upwards in front of the kidney towards the Diaphragm. As development advances, the peritoneum covering the testis encloses it and forms a mesentery, the *mesorchium*, which encloses also the gubernaculum and forms two folds, one above the testis and the other below it. The one above the testis is the *plica vascularis*, and contains ultimately the spermatic vessels; the one below, the *plica gubernatrix*, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the processus vaginalis, which protrudes itself down the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, while the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. As the scrotum develops, the main portion of the lower end of the gubernaculum is carried with the skin to which it is attached to the bottom of this pouch; other bands are carried to the inner side of the thigh and to the perineum. The fold of peritoneum constituting the processus vaginalis projects itself downwards into the inguinal canal, and emerges at the external abdominal ring, pushing before it a part of the Internal oblique and the aponeurosis of the External oblique, which form respectively the Cremaster muscle and the external spermatic fascia. It forms a gradually elongating pouch or *cul-de-sac*, which eventually reaches the bottom of the scrotum, and behind this the testis is drawn by the growth of the body of the fœtus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testis, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal and eventually into the scrotum. It seems certain also that the gubernacular cord becomes shortened as development proceeds, and this assists in causing the testis to reach the bottom of the scrotum. By the eighth month the testis has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downwards to within a short distance of the testis. The process of peritoneum surrounding the testis is now entirely cut off from the general peritoneal cavity and constitutes the *tunica vaginalis*.*

* The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete.

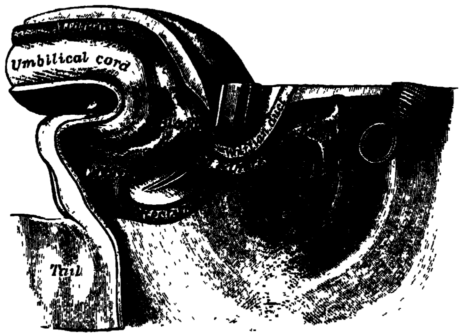
In the female there is also a gubernaculum, which effects a considerable change in the position of the ovary, though not so extensive a change as in that of the testis in the male. The gubernaculum in the female, as it lies on either side in contact with the fundus of the uterus, contracts adhesions to this organ, and thus the ovary is prevented from descending below this level. The upper part of the gubernaculum, i.e. the part between the ovary and the uterus, becomes ultimately the round ligament of the ovary, while the lower part, i.e. the part between the attachment of the cord to the uterus and its termination in the labium majus, ultimately forms the round ligament of the uterus. A pouch of peritoneum analogous to the processus vaginalis in the male accompanies it along the inguinal canal: it is called the *canal of Nuck*. In rare cases the gubernaculum may fail to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labium majus, extending down the canal of Nuck, and under these circumstances its position resembles that of the testis in the male.

Fig. 238.—Tail end of human embryo of twenty-five to twenty-nine days old. (From model by Keibel.)



The Metanephros or Permanent Kidney.—The rudiments of the permanent kidneys make their appearance about the end of the first or beginning of the second month. Each arises as a diverticulum from the hind-end of the Wolffian duct, close to where the latter opens into the cloaca (figs. 238, 239). This diverticulum grows upwards and forwards into the posterior part of the intermediate cell-mass, where its blind or anterior extremity becomes dilated and subsequently divides into several buds, which form the rudiments of the pelvis and calyces of the kidney. By further subdivision it gives rise to the collecting tubules of the kidney; whether the secretory tubules are developed from the renal diverticulum or from the surrounding mesoderm is not as yet determined. The mesoderm around the subdivisions of the diverticulum becomes condensed to form the connective tissue and vessels of the kidney. The diverticulum is elongated to form the ureter, the posterior extremity of which opens at first into the hind-end of the Wolffian duct; after the sixth week it separates from the Wolffian duct, and opens independently into the part of the cloaca which ultimately becomes the bladder (fig. 240). The manner in which this separation is brought about is not fully known.*

Fig. 239.—Tail end of human embryo of thirty-two to thirty-three days old. (From model by Keibel.)



The secretory tubules of the kidney become arranged into pyramidal masses

* The separation of the ureter from the Wolffian duct may be brought about by the absorption of the hinder end of the latter into the genito-urinary chamber, and by the growth of the wall of this chamber between the openings. Robinson (*Proceedings of the Anatomical Society of Great Britain and Ireland*, May 1903, page lxiii) states, regarding an embryo of about seven weeks, that 'from the posterior or lower opening of the Wolffian duct a grooved ridge, the *Wolffian ledge*, runs caudally on the wall of the genito-urinary chamber and gradually disappears at the junction of the Wolffian angle with the body of the chamber. The lateral margins of the groove are continuous anteriorly with the lateral margins of the Wolffian duct, and apparently fuse together to form the ventral wall of the lower part of the duct. . . . Obviously, if the lateral margins of the groove were to fuse from before backwards, the aperture of the Wolffian duct would be carried further backward in the chamber, and its distance from the opening of the ureter increased.'

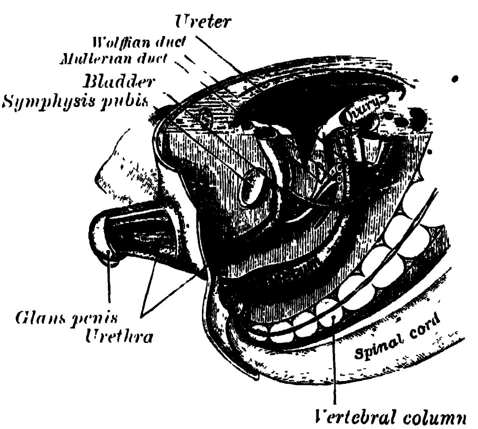
or lobules, and the lobulated condition of the kidneys exists for some time after birth, while traces of it may be found even in the adult. The kidney of the ox and many other animals remains lobulated throughout life.

The Urethra.—In the female the urethra is formed from the upper part of the urogenital sinus, viz. that part which lies above the openings of the Wolffian and Müllerian ducts. The portion of the sinus below these openings becomes gradually shortened, and is ultimately opened out to form the vestibule, and in this manner the urethra and vagina come to open separately on the surface. Wood-Jones regards the female urethra as 'the cloacal remnant in its simplest form,' and points out that it does not remain tubular throughout fœtal life, but is for a time 'obliterated more or less completely by the proliferation of the vaginal bulbs.' Developmentally considered, the male urethra consists of two parts: (1) the prostatic and membranous portions, which are derived from the urogenital sinus, and correspond to the whole of the female urethra; (2) the penile portion, which is formed by the fusion of the inner genital folds (see below).

The Prostate Gland originally consists of two separate portions, each of which arises as a series of diverticular buds from the epithelial lining of the urogenital sinus, between the third and fourth months. These buds become tubular, and form the glandular substance of the two lobes, which ultimately meet and fuse behind the urethra and also extend on to its ventral aspect. The third or middle lobe is formed as an extension of the lateral lobes between the common ejaculatory ducts and the bladder. *Skene's ducts* in the female urethra are regarded as the homologues of the prostatic glands.

The *glands of Cowper* in the male, and *of Bartholin* in the female, also arise as diverticula from the epithelial lining of the urogenital sinus.

FIG. 240.—Tail end of human embryo, from eight and a half to nine weeks old. (From model by Keibel.)



The Urinary Bladder.—The trigone of the bladder is formed from the upper part of the urogenital sinus (page 161); the remainder of the viscus is developed from the part of the cloaca which lies above the sinus (fig. 239). The bladder is at first tubular in shape, its canal being continuous with that of the allantois, but after the second month its cavity expands to form a sac, from the summit of which the tube of the allantois extends to the umbilicus; this tube undergoes obliteration to form the fibrous cord of the urachus. In some cases the allantoic canal remains patent, and urine may escape by it at the umbilicus. If the urethra be looked upon as the remnant of the cloaca, then the bladder, with the exception of the trigone, must be regarded as being developed by a dilatation of the proximal part of the allantois.

The External Organs of Generation (fig. 241), like the internal, pass during development through an indifferent stage in which there is no distinction of sex. It is therefore necessary to describe this stage, and then follow the development of the female and male organs respectively.

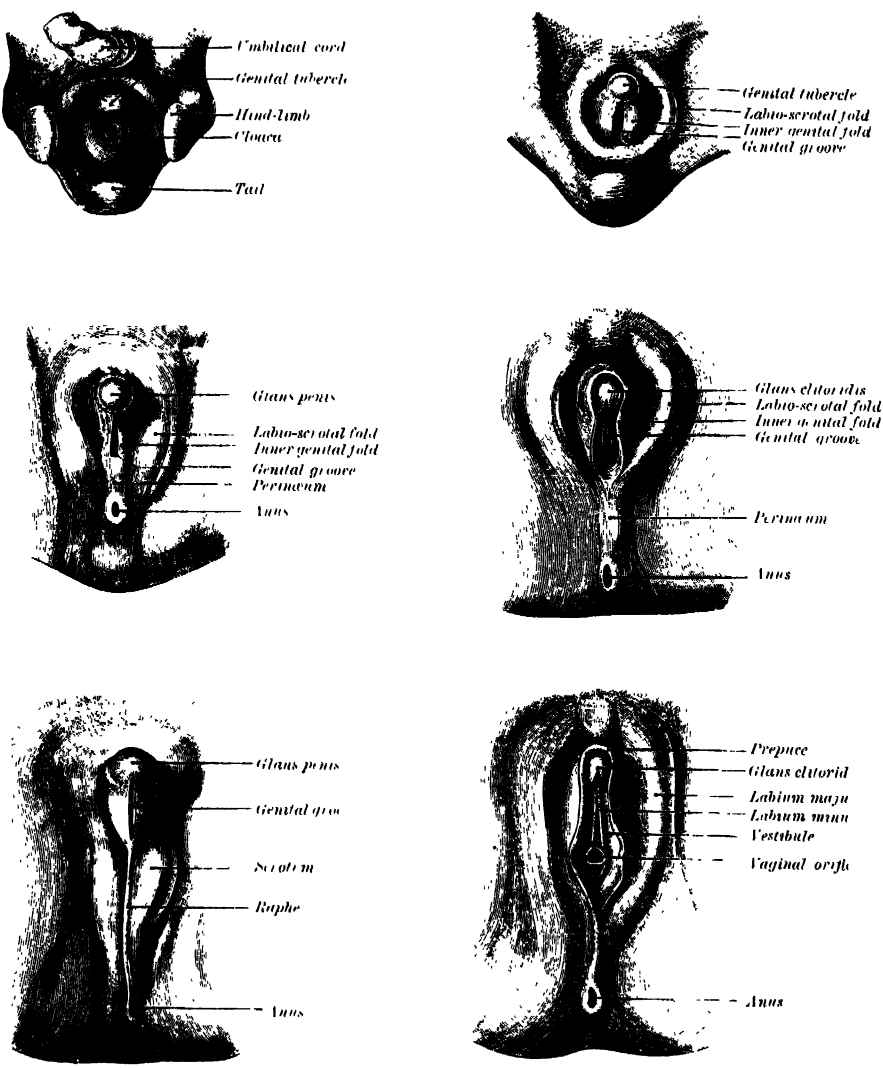
As already stated (page 161), the cloacal membrane, which is composed of ectoderm and entoderm, originally reaches from the umbilicus to the tail. The mesoderm around the cloacal chamber gradually extends between the layers of the membrane, stopping short, however, round the margins of the entodermal cloaca, so that the bilaminar cloacal membrane is limited to this part. About the fifth week a prominence, the *genital tubercle*, arises in front of the cloacal membrane, while at the sides the edges of the mesoderm are elevated to form the *labio-scrotal* or *outer genital folds*.

Along the under surface of the genital tubercle the ectoderm is thickened, and at the apex of the tubercle projects forwards as an epithelial horn. In this ectodermal

thickening a longitudinal groove, the genital groove, appears, and into its lips the mesoderm extends to form the *inner genital folds*. After the rupture of the cloacal membrane this groove becomes continuous with the urogenital sinus. With the formation of these parts the *indifferent stage* of the external genital organs is reached.

In the *female* this stage is largely retained; the lower part of the urogenital sinus persists as the vestibule, the genital tubercle forms the clitoris, the labio-scrotal folds the labia majora, and the inner genital folds the labia minora.

FIG. 241.—Stages in the development of the external sexual organs in the male and female. (Drawn from the Ecker-Ziegler models.)



In the *male* the changes are greater on account of the development of the penile portion of the urethra. The genital tubercle enlarges to form the corpora cavernosa and glans penis. The lips of the inner genital folds meet and fuse from behind forwards to form the penile urethra, the bulb, and the corpus spongiosum. The part of the urethral groove on the glans penis is closed independently, and the last part of the urethral tube to be completed is that at the junction of the glans and body of the penis. If the lips of the groove fail to close, the condition known as *hypospadias* results.

The labio-scrotal folds meet and unite in the middle line to form the scrotum, their line of union being indicated by the median raphe.

The *prepuce* is formed by the growth of a solid plate of ectoderm into the superficial part of the genital tubercle; on coronal section this plate presents the shape of a horseshoe. By the breaking down of its more centrally situated cells this plate is split into two lamellæ, and a cutaneous fold, the prepuce, is liberated and forms a hood over the glans. 'Adherent prepuce is not an adhesion really, but a hindered central desquamation' (Berry Hart, *op. cit.*).*

The homologies of the different parts of the sexual organs may be stated in tabular form as follows :—

INDIFFERENT STAGE	MALE	FEMALE
Genital ridge	Testis.	Ovary.
Wolffian body. .	Rete testis, vasa efferentia, coni vasculosi, organ of Giraldès.	Epoöphoron or organ of Rosenmüller. Paroöphoron.
Wolffian duct .	Canal of epididymis, vas deferens, common ejaculatory duct. Seminal vesicle.	Hydatid of Morgagni. (Duct of Gärtner.)
Müllerian ducts	Sessile hydatids of epididymes. Uterus masculinus.	Fallopian tubes, uterus, vagina.
Genital tubercle	Corpora cavernosa and glans penis.	Clitoris.
Urogenital sinus	Prostatic and membranous parts of urethra.	Urethra. Vestibule.
Inner genital folds.	Penile urethra, bulb and corpus spongiosum.	Labia minora.
Labio-scrotal folds	Scrotum.	Labia majora.

THE FORM OF THE EMBRYO AT DIFFERENT STAGES OF ITS GROWTH

First Week.—During the early part of this period the ovum is in the Fallopian tube. Having been fertilised in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus before the end of the first week. Peters† described a specimen, the age of which he reckoned as from three to four days. It was imbedded in the decidua on the posterior wall of the uterus and enveloped by a decidua capsularis, the central part of which, however, consisted merely of a layer of fibrin. The ovum was in the form of a sac, the outer wall of which consisted of a layer of trophoblast; inside this was a thin layer of mesoderm composed of round, oval, and spindle-shaped cells. Numerous villous processes—some consisting of trophoblast only, others possessing a core of mesoderm—projected from the surface

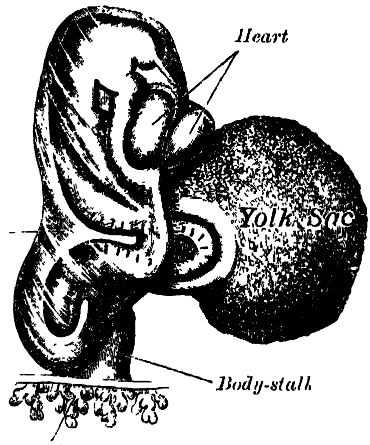
* Spicer (*Journal of Anatomy and Physiology*, vol. xliii. 1909) describes the prepuce as arising in the form of an annular hood of mesodermal tissue which proceeds forwards *within the substance of the surrounding epithelium*. 'The main portion of this hood springs from mesoblastic tissue considerably posterior to the cervix glandis, in the form of a crescentic swelling or collar, and this creeps forward, burrowing always in the epithelial layers, bridging over the groove of the cervix which is filled with epidermal cells, and finally overlaps the body of the glans. This hood is the prepuce.'

'The epidermis covering the glans thus becomes divided into two layers: an outer, which forms the superficial covering of the prepuce, and an inner, which remains as a more or less solid layer between the prepuce and the glans until after birth. From it is differentiated a basal layer of cubical or cylindrical epithelium to line the inner aspect of the prepuce, and another to cover the surface of the glans, while central desquamation ensues later and prepares the way for a movable prepuce.'

† *Die Einbettung des Menschlichen Eies.* 1899.

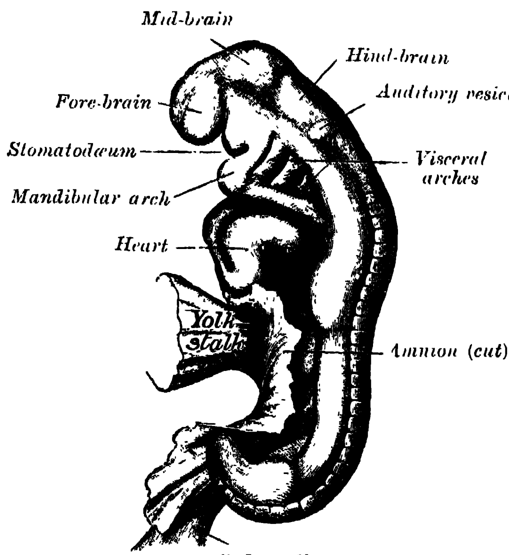
of the ovum into the surrounding decidua. Inside this sac the rudiment of the embryo was found in the form of a patch of ectoderm, covered by a small but completely closed amnion. It possessed a minute yolk-sac and was surrounded by mesoderm, which was connected by a band to that lining the trophoblast (fig. 123).*

FIG. 242.—Human embryo of about fifteen days old. (His.)



Second Week.—By the end of this week the ovum has increased considerably in size, and the majority of its villi are vascularised. The embryo has assumed a definite form, and its cephalic and caudal extremities are easily distinguished. The neural or medullary folds are partly united. The embryo is more completely separated from the yolk-sac, and the paraxial mesoderm is being divided into the primitive segments (fig. 242).

FIG. 243.—Human embryo between eighteen and twenty-one days old. (His.)



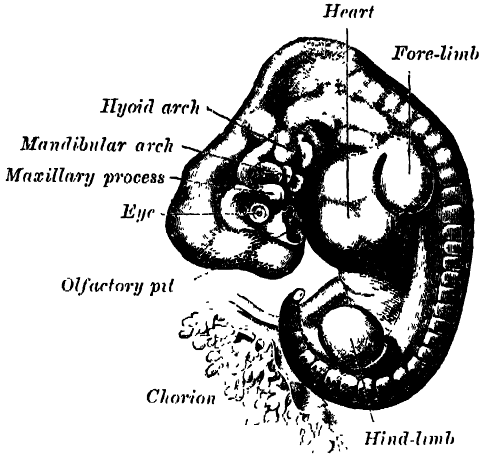
Third Week.—By the end of the third week the embryo is strongly curved, and the primitive segments number about thirty. The primary divisions of the brain are visible,

* Bryce and Teacher (*Early Development and Imbedding of the Human Ovum*, 1908) have described an ovum which they regard as thirteen to fourteen days old. In it the two vesicles, the amnion and yolk-sac, were present, but there was no trace of a layer of embryonic ectoderm. They are of opinion that the age of Peters' ovum has been understated, and estimate it as between $13\frac{1}{2}$ and $14\frac{1}{2}$ days.

and the ocular and auditory vesicles are formed. Four visceral clefts are present; the stomatodæum is well marked, and the bucco-pharyngeal membrane has disappeared. The rudiments of the limbs are seen as short buds, and the Wolffian bodies are visible (fig. 243).

Fourth Week.—The embryo is markedly curved on itself, and when viewed in profile is almost circular in outline. The cerebral hemispheres appear as hollow buds, and the elevations which form the rudiments of the pinna are visible. The limbs now appear as oval flattened projections (fig. 244).

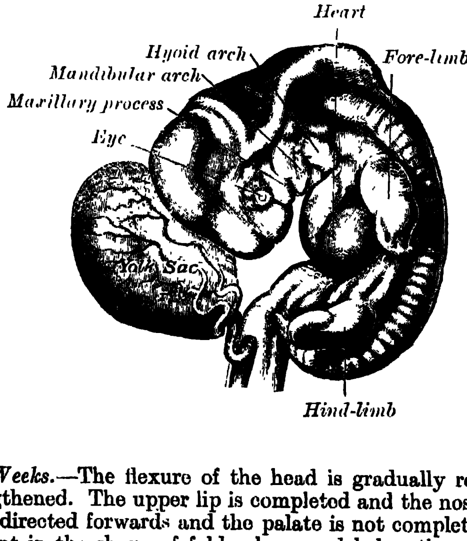
FIG. 244.—Human embryo, twenty-seven to thirty days old. (His.)



Fifth Week.—The embryo is less curved and the head is relatively of large size. Differentiation of the limbs into their segments occurs. The nose forms a short, flattened projection. The genital tubercle is evident (fig. 245).

Sixth Week.—The curvature of the embryo is further diminished. The visceral clefts—except the first—have disappeared, and the rudiments of the fingers and toes can be recognised (fig. 246).

FIG. 245.—Human embryo, thirty-one to thirty-four days old. (His.)



Seventh and Eighth Weeks.—The flexure of the head is gradually reduced and the neck is somewhat lengthened. The upper lip is completed and the nose is more prominent. The nostrils are directed forwards and the palate is not completely developed. The eyelids are present in the shape of folds above and below the eye, and the different parts of the pinna are distinguishable. By the end of the second month the fœtus measures from 28 to 30 mm. in length (fig. 247).

Third Month.—The head is extended and the neck is lengthened. The eyelids meet and fuse, remaining closed until the end of the seventh month. The limbs are well developed and nails appear on the digits. The external organs are so far differentiated that it is possible to distinguish the sex. By the end of this month the length of the fœtus is about 7 cm., but if the legs be included it is from 9 to 10 cm.

Fourth Month.—The loop of gut which projected into the umbilical cord is withdrawn within the fœtus. The hairs begin to make their appearance. There is a general increase in size so that by the end of the fourth month the fœtus is from 12 to 13 cm. in length, but if the legs be included it is from 16 to 20 cm.

Fifth Month.—It is during this month that the first movements of the fœtus are usually observed. The eruption of hair on the head commences, and the *vernix caseosa* begins to be deposited. By the end of this month the total length of the fœtus, including the legs, is from 25 to 27 cm.

FIG. 246.—Human embryo of about six weeks. (His.)

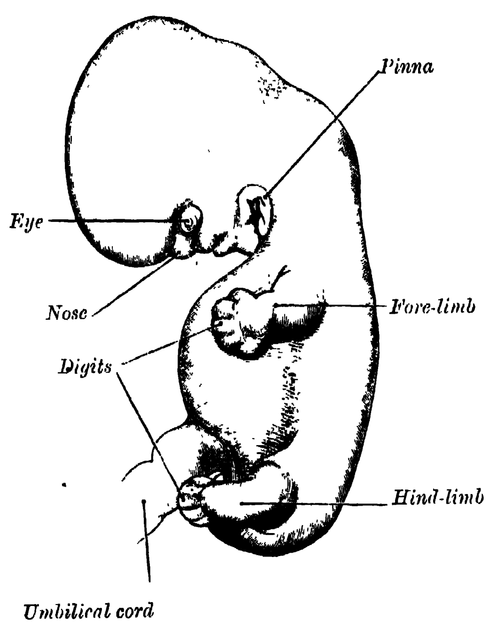


FIG. 247.—Human embryo about eight and a half weeks old. (His.)

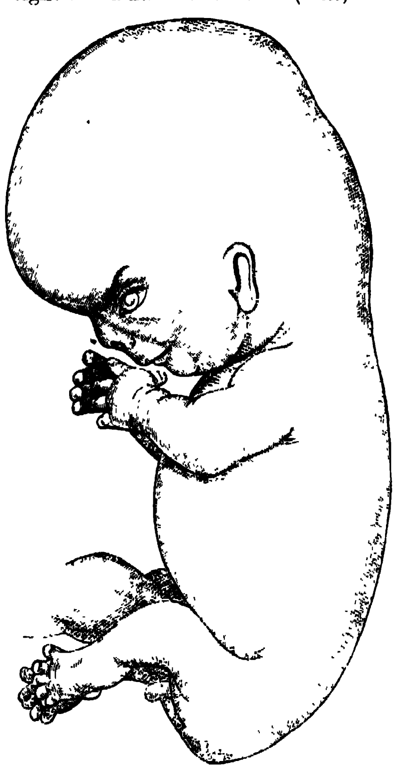


Sixth Month.—The body is covered by fine hairs (*lanugo*) and the deposit of vernix caseosa is considerable. The papillæ of the skin are developed and the free border of the nail projects from the corium of the dermis. Measured from vertex to heels, the total length of the fœtus at the end of this month is from 30 to 32 cm.

Seventh Month.—The pupillary membrane atrophies and the eyelids reopen. The testis passes into the vaginal process of the peritoneum. From vertex to heels the total length at the end of the seventh month is from 35 to 36 cm., i.e. about 14 in. The weight is a little over three pounds.

Eighth Month.—The skin assumes a pink colour and is now entirely coated with vernix caseosa, and the lanugo begins to disappear. Subcutaneous fat has been developed to a considerable extent, and the fœtus presents a plump appearance. The total length, i.e. from head to heels, at the end of the eighth month is about 40 cm. (16 in.), and the weight varies between 4½ and 5½ lbs.

Ninth Month.—The lanugo has largely disappeared from the trunk. The umbilicus is almost in the middle of the body and the testes are in the scrotum. At full time the fœtus weighs from 6½ to 8 lbs., and measures from head to heels about 50 cm. (20 in.).

OSTEOLOGY

THE general framework of the body is built up mainly of a series of bones, supplemented, however, in certain regions by pieces of cartilage; the bony part of the framework constitutes the *skeleton*.

In comparative anatomy the term skeleton has a wider application, as in some of the lower animals hard, protective and supporting structures are more extensively distributed, being developed in association with the integumentary system. In such animals the skeleton may be described as consisting of an internal or deep skeleton, the *endoskeleton*, and an external or superficial, the *exoskeleton*. In the human subject the exoskeleton is extremely rudimentary, its only important representatives being the teeth and nails. The term skeleton is, therefore, confined to the endoskeleton, and this is divisible into an *axial* part, which includes that of the head and trunk, and an *appendicular* part, which comprises that of the limbs.

In the skeleton of the adult there are 206 distinct bones, as follows :—

Axial Skeleton	Vertebral column	26	
	Skull . . .	22	
	Hyoid bone .	1	
	Ribs and sternum	25	
			74
Appendicular Skeleton	Upper limbs .	64	
	Lower limbs .	62	
			126
Auditory ossicles.			6
	Total		206

The patellæ are included in this enumeration, but the smaller sesamoid bones are not reckoned.

Bones are divisible into four classes: *Long*, *Short*, *Flat*, and *Irregular*.

The **Long bones** are found in the limbs, and each consists of a shaft and two extremities. The *shaft*, or diaphysis, is a hollow cylinder, the central cavity being termed the *medullary canal*; the wall consists of dense, compact tissue of considerable thickness in the middle part of the shaft, but becoming thinner towards the extremities; the cancellous tissue is scanty. The *extremities* are generally expanded, for the purposes of articulation, and to afford broad surfaces for muscular attachment. They are usually developed from separate centres of ossification termed *epiphyses*, and consist of cancellous tissue surrounded by a thin layer of compact bone. The medullary canal and the spaces in the cancellous tissue are filled with marrow. The long bones are not straight, but curved; the curve generally taking place in two planes, thus affording greater strength to the bone. The bones belonging to this class are: the *clavicle*, *humerus*, *radius*, *ulna*, *femur*, *tibia*, *fibula*, *metacarpals*, *metatarsals*, and *phalanges*.

Short bones.—Where a part of the skeleton is intended for strength and compactness combined with limited movement, it is divided into a number of small bones, as in the *carpus* and *tarsus*. These consist of cancellous tissue covered by a thin crust of compact substance. The *patellæ*, together with the other sesamoid bones, are by some regarded as short bones.

Flat bones.—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, the bones

are expanded into broad, flat plates, as in the skull and the shoulder-blade. These bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones, the layers of compact tissue are familiarly known as the *tables* of the skull; the outer one is thick and tough; the inner is thin, dense, and brittle, and hence is termed the *vitreous table*. The intervening cancellous tissue is called the *diploë*, and this, in certain regions of the skull, becomes absorbed so as to leave spaces filled with air (*air-sinuses*) between the two tables. The flat bones are: the *occipital*, *parietal*, *frontal*, *nasal*, *lachrymal*, *vomer*, *scapula*, *os innominatum*, *sternum*, *ribs*, and, according to some, the *patella*.

The **irregular bones** are such as, from their peculiar form, cannot be grouped under the preceding heads. They consist of cancellous tissue enclosed within a thin layer of compact bone. The irregular bones are: the *vertebræ*, *sacrum*, *coccyx*, *temporal*, *sphenoid*, *ethmoid*, *malar*, *maxilla*, *mandible*, *palate*, *inferior turbinated*, and *hyoid*.

Surfaces of bones.—If the surface of a bone be examined, certain eminences and depressions are seen, to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: articular and non-articular. Well-marked examples of *articular eminences* are found in the heads of the humerus and femur; and of *articular depressions* in the glenoid cavity of the scapula, and the acetabulum of the os innominatum. *Non-articular eminences* are designated according to their form. Thus, a broad, rough, uneven elevation is called a *tuberosity*, *protuberance*, or *process*; a small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a *spine*; a narrow, rough elevation, running some way along the surface, a *ridge*, *crest*, or *line*. *Non-articular depressions* are also of variable form, and are described as *fossæ*, *pits*, *depressions*, *grooves*, *furrows*, *fissures*, *notches*, &c. These non-articular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well marked in proportion to the muscularity of the subject; the grooves, fissures and notches transmit vessels and nerves.

In describing the various surfaces or aspects of a bone, or indeed of any other structure, the body is supposed to be in the erect position. Any surface, extremity, or other part directed upwards towards the head is termed *superior*, while those directed downwards towards the feet are termed *inferior*. Surfaces directed forwards towards the front of the body are termed *anterior* or *ventral*, while those directed backwards are *posterior* or *dorsal*. Those surfaces which are directed towards a median antero-posterior vertical plane are termed *internal* or *mesial*, while those directed away from this plane are *external* or *lateral*.

The minute structure, growth, and composition of bone are described on pages 24 to 34.

THE VERTEBRAL COLUMN

The **vertebral** or **spinal column** (columna vertebralis) is a flexuous and flexible column, formed of a series of bones called *vertebræ*.

The **vertebræ** are thirty-three in number, and are grouped under the names *cervical*, *thoracic* or *dorsal*, *lumbar*, *sacral*, and *coccygeal*, according to the regions they occupy; seven being found in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or it may be diminished in one region, the deficiency being supplied by an additional vertebra in another. The number of cervical vertebræ is, however, very rarely increased or diminished.

The vertebræ in the upper three regions of the column remain distinct throughout life, and are known as *true* or *movable* vertebræ; those of the sacral and coccygeal regions, on the other hand, are termed *false* or *fixed* vertebræ, because they are united in the adult to form two bones—five forming the upper bone or *sacrum*, and four the terminal bone or *coccyx*.

With the exception of the first and second cervical, the true or movable vertebræ present certain common characters which are best studied by examining one from the middle of the thoracic region.

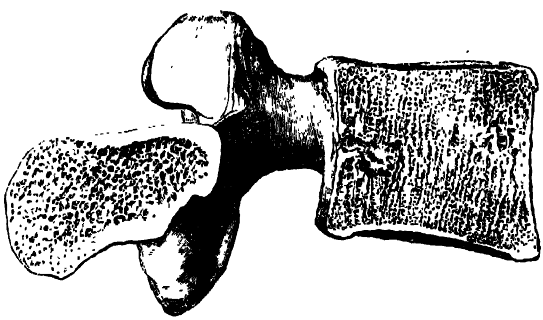
General Characters of a Vertebra

A typical **vertebra** consists of two essential parts—viz. an anterior segment, the *body* or *centrum* (corpus vertebræ), and a posterior part, the *neural arch* (arcus vertebræ); these enclose a foramen, the *spinal* or *vertebral foramen* (foramen vertebrale). The neural arch consists of a pair of *pedicles* and a pair of *laminæ*, and supports seven *processes*—viz. four *articular* (zygapophyses), two *transverse* (processus transversi), and one *spinous* (processus spinosus).

When the vertebræ are articulated with each other the bodies form a strong pillar for the support of the head and trunk, and the spinal foramina constitute a canal for the protection of the spinal cord, whilst between every pair of vertebræ are two apertures, the intervertebral foramina (foramina intervertebralia), one on either side, for the transmission of the spinal nerves and vessels. Each of these constituent parts must now be considered.

The **body** or **centrum** is the largest part of a vertebra, and is more or less cylindrical in shape. Its upper and lower surfaces are flattened and rough, and give attachment to the intervertebral fibro-cartilages, and each presents a rim around its circumference. In front, it is convex from side to side and concave from above downwards. Behind, it is flat from above downwards and slightly concave from side to side. Its anterior surface presents a few small apertures, for the passage of nutrient vessels; on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins from the body of the vertebra—the *venæ basis vertebræ*.

Fig. 248.—Sagittal section of a lumbar vertebra.



The **pedicles** are two short, thick processes of bone, which project backwards, one on either side, from the upper part of the body, at the junction of its posterior and lateral surfaces. The concavities above and below the pedicles are named the *intervertebral notches*; and when the vertebræ are articulated, the notches of each contiguous pair of bones form the *intervertebral foramina*, already referred to.

The **laminæ** are two broad plates directed backwards and inwards from the pedicles. They fuse in the middle line posteriorly, and so complete the posterior boundary of the vertebral foramen. Their upper borders and the lower parts of their anterior surfaces are rough for the attachment of the ligamenta subflava.

The **spinous process** is directed backwards and downwards from the junction of the laminæ, and serves for the attachment of muscles and ligaments.

The **articular processes,** two superior and two inferior, spring from the junction of the pedicles and laminæ. The superior project upwards, and their articular surfaces are directed more or less backwards; the inferior project downwards, and their surfaces look more or less forwards.

The **transverse processes,** two in number, project one at either side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They serve for the attachment of muscles and ligaments.

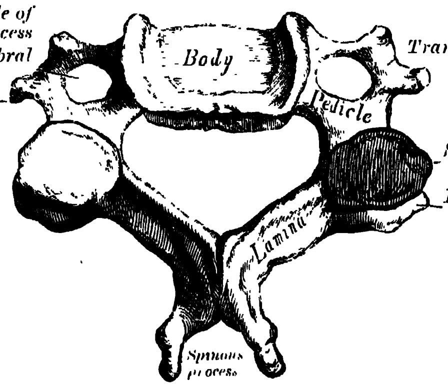
Structure of a vertebra (fig. 248).—The body is composed of cancellous tissue, covered by a thin coating of compact bone; the latter is perforated by numerous orifices, some of large size, for the passage of vessels; the interior of the bone is traversed by one or two large canals, for the reception of veins, which converge towards a single large, irregular aperture, or several small apertures, at the posterior part of the body. The arch and processes projecting from it have a thick covering of compact tissue.

Cervical Vertebræ (fig. 249)

The **cervical vertebræ** (vertebræ cervicales) are the smallest of the true vertebræ, and can be readily distinguished from those of the thoracic or lumbar regions by the presence of a foramen (foramen transversarium) in each transverse process. The first, second, and seventh present exceptional features and must be separately described; the following characters are common to the remaining four.

The *body* is small, and broader from side to side than from before backwards. The anterior and posterior surfaces are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downwards, so as to overlap the upper and fore part of the vertebra below. Its upper surface is concave transversely, and presents a projecting lip on either side; its lower surface is concave from before backwards, convex from side to side, and presents laterally a shallow concavity, which receives the corresponding projecting lip of the subjacent vertebra. The *pedicles* are directed outwards and backwards, and are attached to the body midway between its upper and lower borders, so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower. The *laminæ* are narrow, and thinner above than below; the *spinal foramen* is large, and of a triangular form. The *spinous process* is

Fig. 249.—A cervical vertebra.



short and bifid, the two divisions being often of unequal size. The *superior* and *inferior articular processes* of each side are fused to form an articular pillar, which projects outwards from the junction of the pedicle and lamina. The articular facets are flat and of an oval form: the superior look backwards, upwards, and slightly inwards; the inferior forwards, downwards, and slightly outwards. The *transverse processes* are each pierced by a *foramen transversarium*, which, in the upper six vertebræ, gives passage to the vertebral artery and vein and a plexus of sympathetic nerves. Each process consists of an anterior and a posterior part. The anterior portion is the homologue of the rib in the thoracic region, and is therefore named the *costal process or costal element*: it arises from the side of the body, is directed outwards in front of the foramen, and ends in a tubercle, the *tuberculum anterius*. The posterior part, the true transverse process, springs from the neural arch behind the foramen, and is directed forwards and outwards; it terminates in a tubercle, the *tuberculum posterius*. These two parts are joined, outside the foramen, by a bar of bone which exhibits a deep groove (sulcus n. spinalis) on its upper surface for the passage of the corresponding spinal nerve.*

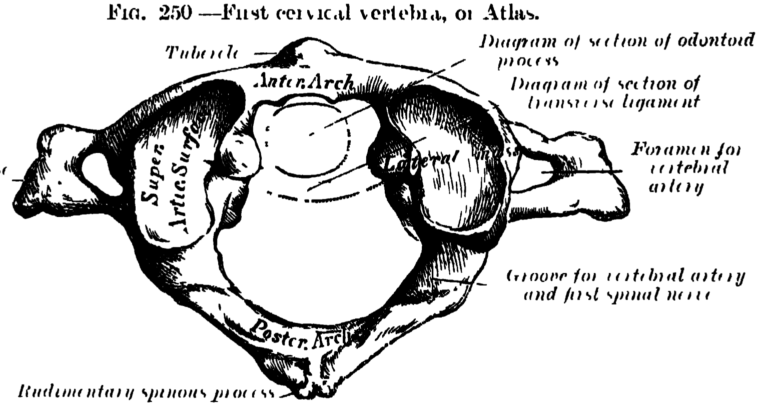
Chassaignac first pointed out that the common carotid artery can be easily compressed against the anterior tubercle of the transverse process of the sixth cervical vertebra, and

* The *costal element* of a cervical vertebra not only includes the portion which springs from the side of the body, but the anterior and posterior tubercles and the bar of bone which connects them.

therefore this tubercle is named the *tuberculum caroticum*, or Chassaignac's tubercle. It also constitutes an important guide to the vertebral artery which enters the foramen transversarium of this vertebra.

The **first cervical vertebra** (fig. 250) is named the **atlas** because it supports the globe of the head. Its chief peculiarities are that it has neither body nor spinous process, but is ring-like, and consists of an anterior and a posterior arch, and two lateral masses. The *anterior* arch (arcus anterior) forms about one-fifth of the ring: its anterior surface is convex, and presents at its centre a *tubercle* (tuberculum anterius) for the attachment of the Longus colli; posteriorly it is concave, and marked by a smooth, oval or circular facet (fovea dentis), for articulation with the odontoid process of the axis. The upper and lower borders respectively give attachment to the anterior occipito-atlantal and the anterior atlanto-axial ligaments; the former connects it with the occipital bone above and the latter with the axis below. The *posterior* arch forms about two-fifths of the circumference of the ring: it terminates behind in a *tubercle* (tuberculum posterius) which is the rudiment of a spinous process and gives origin to the Rectus capitis posticus minor. The diminutive size of this process prevents any interference with the movements between the atlas and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipito-atlantal ligament, while immediately behind each superior articular process is a groove (sulcus arteriæ vertebralis), sometimes converted into a foramen by a

FIG. 250.—First cervical vertebra, or Atlas.

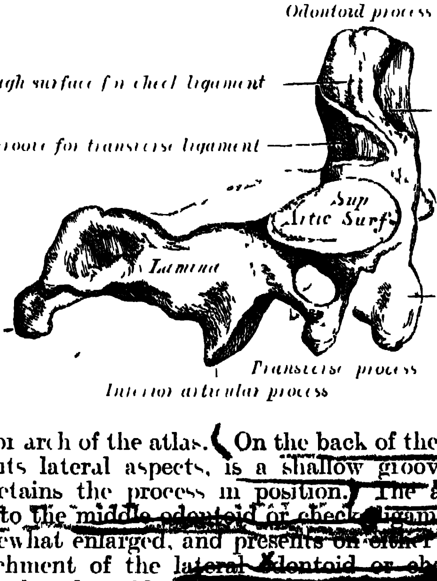


delicate bony spiculum which arches backwards from the posterior extremity of the superior articular process. This groove represents the superior intervertebral notch, and serves for the transmission of the vertebral artery, which, after ascending through the foramen in the transverse process, winds round the lateral mass in a direction backwards and inwards. It also transmits the suboccipital (first spinal) nerve. On the under surface of the posterior arch, behind the articular facets, are two shallow grooves, which represent the inferior intervertebral notches of other vertebræ. The lower border gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The *lateral masses* are the most bulky and solid parts of the atlas, in order to support the weight of the head. Each presents an articular facet above, and one below. The superior facets are of large size, oval, concave, and approach each other in front, but diverge behind: they are directed upwards, inwards, and a little backwards, each forming a cup for the corresponding condyle of the occipital bone, and are admirably adapted to the nodding movements of the head. Not infrequently they are partially subdivided by more or less deep indentations which encroach upon their lateral margins. The inferior articular facets are circular in form, flattened or slightly convex and directed downwards and inwards, articulating with the axis, and permitting the rotatory movements of the head. Just below the inner margin of each superior facet is a small tubercle, for the attachment of the transverse ligament which stretches across the ring of the atlas and divides the

vertebral foramen into two unequal parts—the anterior or smaller receiving the odontoid process of the axis, the posterior transmitting the spinal cord and its membranes. This part of the spinal canal is of considerable size, much greater than is required for the accommodation of the spinal cord, and hence lateral displacement of the atlas may occur without compression of this structure. The *transverse processes* are large; they project outwards and downwards from the lateral masses, and serve for the attachment of muscles which assist in rotating the head. They are long, and do not present anterior and posterior tubercles, since these have become fused into one mass; the foramen for the vertebral artery is directed from below, upwards and backwards.

The **second cervical vertebra** (fig. 251) is named the **axis or epistropheus** because it forms the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive character of this bone is the strong tooth-like odontoid process which rises perpendicularly from the upper surface of the body. The *body* is deeper in front than behind, and prolonged downwards anteriorly so as to overlap the upper and fore part of the third vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions for the attachment of the Longus colli muscles. Its under surface is concave from before backwards and convex from side to side. The *odontoid process* (dens) exhibits a slight constriction, or neck, where it joins the body. On its anterior surface is an oval or nearly circular facet for articulation with

Fig. 251. Second cervical vertebra, or Axis.

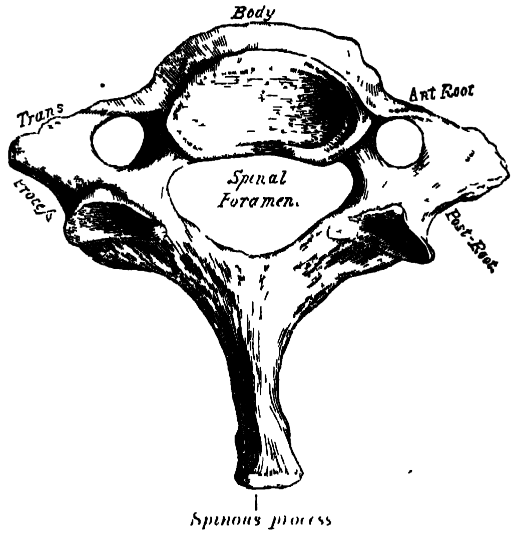


that on the anterior arch of the atlas. On the back of the neck, and frequently extending on to its lateral aspects, is a shallow groove for the transverse ligament which retains the process in position. The apex is pointed, and gives attachment to the middle odontoid or check ligament; below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the lateral odontoid or check ligament; these ligaments connect the odontoid process to the occipital bone. The internal structure of the odontoid process is more compact than that of the body. The *pedicles* are broad and strong, especially in front, where they coalesce with the sides of the body and the root of the odontoid process. They are covered above by the superior articulating surfaces. The *laminæ* are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The *transverse processes* are very small, not bifid, but terminating in a single tubercle; each is perforated by the foramen for the vertebral artery, which is directed obliquely upwards and outwards. The *superior articular surfaces* are round, slightly convex, directed upwards and outwards, and are supported on the body, pedicles, and transverse processes. The *inferior surfaces* have the same direction as those of the other cervical vertebræ. The *superior intervertebral notches* are very shallow, and lie behind the articular processes; the *inferior* lie in front of the articular processes, as in the other cervical vertebræ. The *spinous process* is large, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity

for the attachment of muscles which serve to rotate the head upon the spine.

The **seventh cervical vertebra** (fig. 252).—The most distinctive characteristic of this vertebra is the existence of a long and prominent spinous process; hence the name *vertebra prominens*. This process is thick, nearly horizontal in direction, not bifurcated, but terminating in a tubercle, to which the lower end of the ligamentum nuchæ is attached. The *transverse processes* are of considerable size, their posterior tubercles are large and prominent, while the anterior are small and faintly marked; the upper surface of each has usually a shallow groove, and its extremity seldom presents more than a trace of bifurcation. The foramen in the transverse process may be as large as that in the other cervical vertebræ, but is generally smaller on one or both sides; occasionally it is double, sometimes it is absent. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen. Sometimes the anterior root of the transverse process exists as a separate bone, and attains a large size. It is then known as a 'cervical rib.'

FIG. 252.—Seventh cervical vertebra, or **vertebra prominens.**



THORACIC OR DORSAL VERTEBRÆ

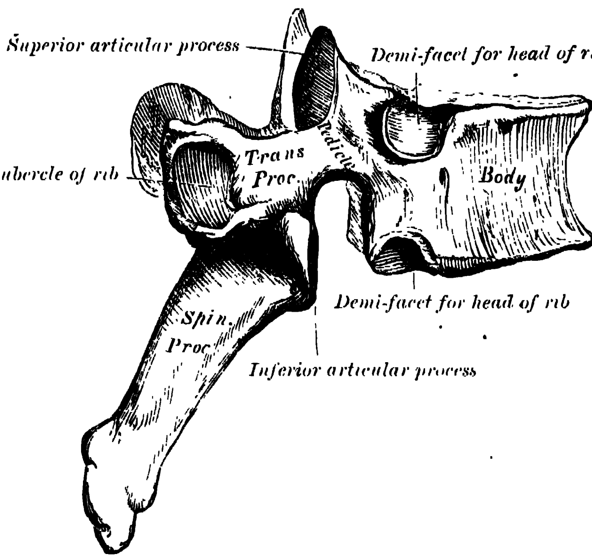
The **thoracic** or **dorsal vertebræ** (vertebræ thoracales) (fig. 253) are intermediate in size between those of the cervical and lumbar regions; they increase in size from above downwards, the upper vertebræ being much smaller than those in the lower part of the region. They are distinguished by the presence of facets on the sides of the bodies for articulation with the heads of the ribs, and facets on the transverse processes of all, except the eleventh and twelfth, for articulation with the tubercles of the ribs.

The *bodies* in the middle of the thoracic region possess a very characteristic form, being heart-shaped and as broad in the antero-posterior as in the transverse direction. At the ends of the thoracic region they resemble respectively those of the cervical and lumbar vertebræ. They are slightly thicker behind than in front, flat above and below, convex from side to side, deeply concave behind, and slightly constricted laterally and in front. They present, on either side, two costal demi-facets, one above, near the root of the pedicle, the other below, in front of the inferior intervertebral notch; these are covered with cartilage in the recent state, and, when the vertebræ are articulated with one another, form, with the intervening intervertebral discs, oval surfaces for the reception of the heads of the ribs. The *pedicles* are directed backwards and slightly upwards, and the inferior intervertebral notches are of large size, and deeper than in any other region of the vertebral column. The *laminæ* are broad, thick, and imbricated—that is to say, they overlap one another like tiles on a roof. The *spinal foramen* is small, and of a circular form. The *spinous process* is long, triangular on coronal section, directed obliquely downwards, and terminates in a tubercular extremity. These processes overlap one another from the fifth to the eighth, but are less oblique in direction above

and below.* The *superior articular processes* are thin plates of bone projecting upwards from the junctions of the pedicles and laminæ; their articular facets are practically flat, and are directed backwards and a little outwards and upwards. The *inferior articular processes* are fused to a considerable extent wit[illegible] project but slightly beyond their lower borders; their facets are directed forwards and a little inwards ~~and downwards~~. The *transverse processes* arise from the same parts of the arch as the posterior roots of the transverse processes in the neck, and are situated behind the superior articular processes and pedicles; they are thick, strong, and of considerable length, directed obliquely backwards and outwards, and each presents a clubbed extremity, on the anterior part of which is a small, concave surface, for articulation with the tubercle of a rib.

The *first, ninth, tenth, eleventh,* and *twelfth* thoracic vertebræ present certain peculiarities, and must be specially considered (fig. 254).

FIG. 253.—A thoracic vertebra.



The **first thoracic vertebra** presents, on either side of the body, an entire articular facet for the head of the first rib, and a demi-facet for the upper half of the head of the second rib. The body is like that of a cevical vertebra, being broad transversely; its upper surface is concave, and lipped on either side. The *superior articular surfaces* are oblique, directed upwards and backwards, but not outwards; the *spinous process* is thick, long, and almost horizontal. The *transverse processes* are long, and the upper intervertebral notches are deeper than in the other vertebræ of this series.

The **ninth thoracic vertebra** may have no demi-facets below. In some subjects, however, it has two demi-facets on either side; when this occurs the tenth has demi-facets at the upper part only.

The **tenth thoracic vertebra** has (except in the cases just mentioned) an entire articular facet on either side, which is placed partly on the outer surface of the pedicle.

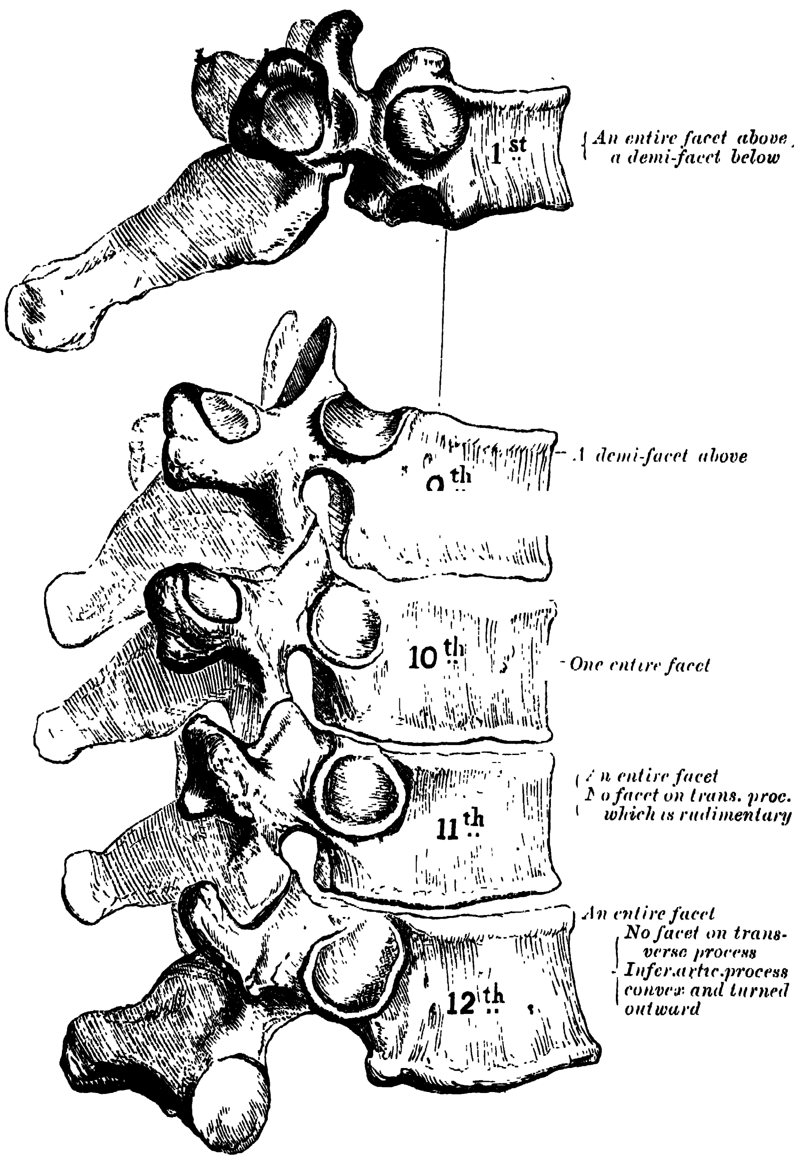
In the **eleventh thoracic vertebra** the *body* approaches in its form and size to that of the lumbar vertebræ. The articular facets for the heads of the ribs, one on either side, are of large size, and placed chiefly on the pedicles, which

* In quadrupeds the majority of the spinous processes of the thoracic vertebræ project upwards and backwards, while those of the lumbar region are directed upwards and forwards. The change in inclination is effected in one of the lower thoracic vertebræ, the spine of which points almost directly upwards. This vertebra is known as the *anticlinal*, and in man its representative is the eleventh thoracic.

are thicker and stronger in this and the next vertebra than in any other part of the thoracic region. The *spinous process* is short, and nearly horizontal in direction. The *transverse processes* are very short, tubercular at their extremities, and have no articular facets.

The **twelfth thoracic vertebra** has the same general characteristics as the eleventh, but may be distinguished from it by its inferior articular processes being convex and turned outwards, like those of the lumbar vertebræ; by

FIG. 254.—Peculiar thoracic vertebræ.

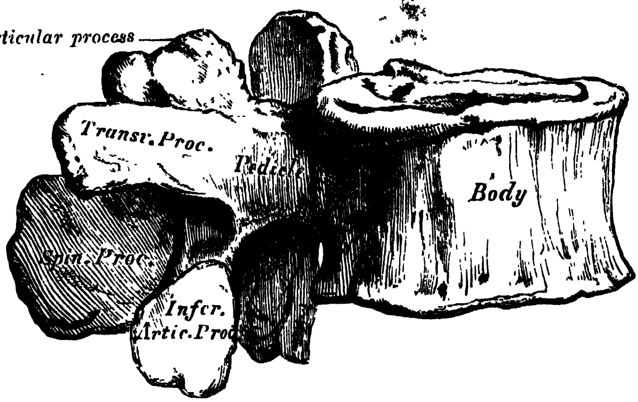


the general form of the body, laminæ, and spinous process, in which it resembles the lumbar vertebræ; and by the transverse processes being subdivided into three elevations, the superior, inferior, and external tubercles; the superior and inferior correspond to the mamillary and accessory processes of the lumbar vertebræ. Traces of similar elevations are found on the transverse processes of the tenth and eleventh thoracic vertebræ.

LUMBAR VERTEBRÆ

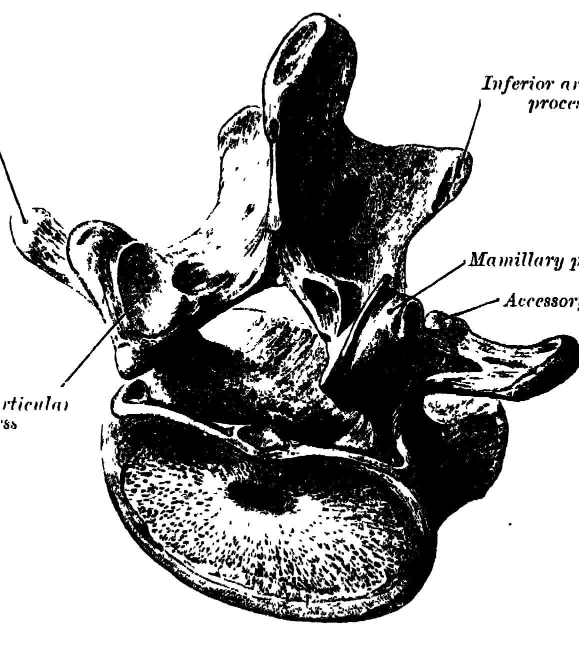
The lumbar vertebræ (vertebræ lumbales) (figs. 255 and 256) are the largest segments of the movable part of the vertebral column, and can be distinguished by the absence of a foramen in the transverse process, and by the absence of facets on the sides of the body.

FIG. 255.—A lumbar vertebra seen from the side.



The *body* is large, wider from side to side than from before backwards, and a little thicker in front than behind. It is flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the sides. The *pedicles* are very strong, directed backwards from the upper part of the body; consequently, the inferior intervertebral notches are of considerable

FIG. 256.—A lumbar vertebra seen from above and behind.



depth. The *laminæ* are broad, short, and strong; the *spinal foramen* is triangular, larger than in the thoracic, but smaller than in the cervical region. The *spinous process* is thick, broad, and somewhat quadrilateral; it projects backwards and terminates in a rough, uneven border. The *superior* and

inferior articular processes are well defined, projecting respectively upwards and downwards from the junctions of pedicles and laminæ. The facets on the superior processes are concave, and look backwards and inwards; those on the inferior are convex, and are directed forwards and outwards. The former are wider apart than the latter, since in the articulated column the inferior articular processes are embraced by the superior processes of the subjacent vertebra. The *transverse processes* are long, slender, and directed transversely outwards in the upper three lumbar vertebræ; they incline a little upwards in the lower two. In the upper three vertebræ they arise from the junctions of the pedicles and the laminæ, but in the lower two they are set further forward and arise from the pedicles and posterior parts of the bodies. They are situated in front of the articular processes instead of behind them as in the thoracic vertebræ, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the lower thoracic vertebræ, the *superior* one is connected in the lumbar region with the back part of the superior articular process, and is named the *mamillary* process; the *inferior* is situated at the back part of the base of the transverse process, and is called the *accessory* process (fig. 256). Although in man these are comparatively small, in some animals they attain considerable size, and serve to lock the vertebræ more closely together. The *external* tubercle becomes the transverse process.

The **fifth lumbar vertebra** is characterised by its body being much thicker in front than behind, which accords with the prominence of the sacro-vertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articular processes; and by the thickness of its transverse processes, which spring from the body as well as from the pedicles.

Sacral and Coccygeal Vertebræ

The **sacral** and **coccygeal vertebræ** consist at an early period of life of nine separate segments which are united in the adult, so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Sometimes the coccyx consists of five bones; occasionally the number is reduced to three.

The Sacrum

The **sacrum** (os sacrum) is a large, triangular bone, situated in the lower part of the vertebral column and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base articulates with the last lumbar vertebra, its apex with the coccyx. The sacrum is curved upon itself, and placed very obliquely, its base projecting forwards, and forming the prominent *sacro-vertebral angle* when articulated with the last lumbar vertebra; its central part is projected backwards, so as to give increased capacity to the pelvic cavity. It presents for examination an anterior, a posterior, and two lateral surfaces, a base, an apex, and a central canal.

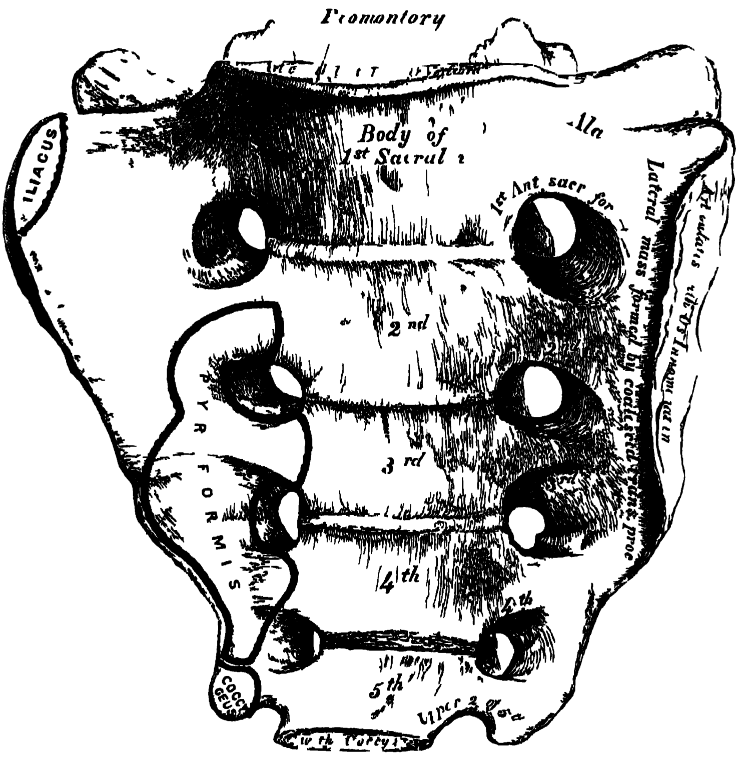
The *anterior surface* (facies pelvina) (fig. 257) is concave from above downwards, and slightly so from side to side. In the middle are seen four transverse ridges, indicating the original division of the bone into five separate pieces. The portions of bone intervening between the ridges correspond to the bodies of the vertebræ. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish from above downwards, are flattened from before backwards, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At the ends of the ridges are seen the *anterior sacral foramina* (foramina sacralia anteriora), four in number on either side, somewhat rounded in form, diminishing in size from above downwards, and directed outwards and forwards: they give exit to the anterior primary divisions of the sacral nerves and entrance to the lateral sacral arteries. External to these foramina is the *lateral mass* (pars lateralis), consisting of separate segments at an early period of life; in the adult, these become blended with the bodies and with each other. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior divisions of the sacral nerves as

they pass outwards, the grooves being separated by prominent ridges of bone which give origin to the Pyriformis.

If a sagittal section be made through the centre of the sacrum (fig. 259), the bodies are seen to be united at their circumferences by bone, wide intervals being left centrally which, in the recent state, are filled by the intervertebral discs. In some bones this union is more complete between the lower than between the upper segments.

The *posterior surface* (facies dorsalis) (fig. 258) is convex and narrower than the anterior. In the middle line it displays a crest (crista sacralis media), surmounted by three or four tubercles, the rudimentary spinous processes of the upper three or four sacral vertebræ. On either side of the spinous processes is a shallow groove, the *sacral groove*, which gives origin to the Multifidus spinæ, the floor of the groove being formed by the united laminæ of the corresponding vertebræ. The laminæ of the fifth sacral vertebra, and

Fig. 257.—Sacrum, anterior surface.

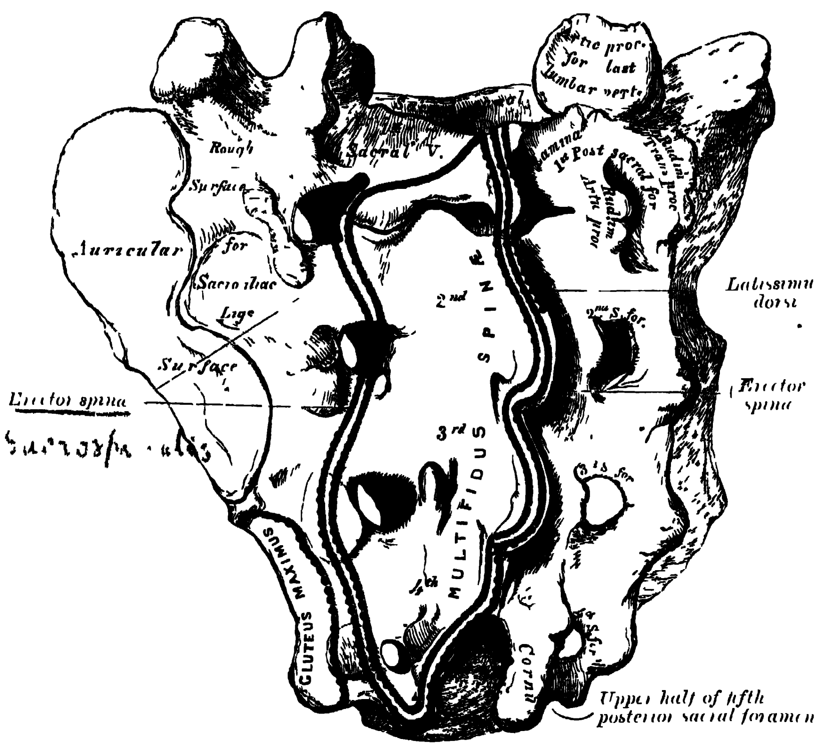


sometimes those of the fourth, fail to meet behind, and thus a deficiency (hiatus sacralis) occurs in the posterior wall of the sacral canal. On the lateral aspect of the sacral groove is a linear series of tubercles produced by the fusion of the articular processes which together form indistinct crests (cristæ sacrales articulares). The articular processes of the first sacral vertebra are large and oval in shape; their facets are concave from side to side, look backwards and inwards, and articulate with the facets on the inferior processes of the fifth lumbar vertebra. The tubercles which represent the inferior articular processes of the fifth sacral vertebra are prolonged downwards as rounded processes, which are named the *sacral cornua* (cornua sacralis), and are connected to the cornua of the coccyx. External to the articular processes are the four *posterior sacral foramina* (foramina sacralia posteriora); they are smaller in size and less regular in form than the anterior, and transmit the posterior divisions of the sacral nerves. On the outer side of the posterior sacral foramina is a series of tubercles, which represent the *transverse processes* of the

sacral vertebræ, and form the lateral crests of the sacrum (cristæ sacrales laterales). The transverse tubercles of the first sacral vertebra are of large size, very distinct, and correspond with the superior angles of the bone; they, together with the transverse tubercles of the second vertebra, give attachment to the horizontal parts of the posterior sacro-iliac ligaments; those of the third vertebra give attachment to the oblique fasciculi of the posterior sacro-iliac ligaments; and those of the fourth and fifth to the great sacro-~~sciatic~~ ligaments.

The *lateral surface*, broad above, becomes narrowed into a thin edge below. The upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the *auricular* surface (facies auricularis), and in the fresh state is coated with fibro-cartilage. Behind it are three deep and uneven impressions, for the attachment of the posterior sacro-iliac ligament. The lower half is thin, and terminates in a projection called the *inferior*

Fig. 258.—Sacrum, posterior surface.



lateral angle; internal to this angle is a notch, which is converted into a foramen by the transverse process of the upper piece of the coccyx, and transmits the anterior division of the fifth sacral nerve. The thin lower half of the lateral surface gives attachment to the great and small sacro-~~sciatic~~ ligaments, and to some fibres of the Gluteus maximus behind, and to the Coccygeus in front.

The *base* of the sacrum, which is broad and expanded, is directed upwards and forwards. In the middle is seen a large oval articular surface, the upper surface of the body of the first sacral vertebra, which is connected with the under surface of the body of the last lumbar vertebra by an intervertebral disc. Behind it, is the large triangular orifice of the sacral canal, which is completed by the laminæ and spinous process of the first sacral vertebra. The superior articular processes project from it on each side; they are oval, concave, directed backwards and inwards, like the superior articular processes of a lumbar vertebra; in front of each is an intervertebral notch, which forms

the lower part of the foramen between the last lumbar and first sacral vertebræ. On either side of the body is a broad triangular surface, which extends outwards, supports the Psoas magnus and lumbo-sacral cord; and in the articulated pelvis is continuous with the iliac fossa. This is called the *ala* (ala sacralis); it is slightly concave from side to side, convex from before backwards, and gives attachment to a few of the fibres of the Iliacus. The posterior part of the ala represents the transverse process, and its anterior part the costal process of the first sacral segment.

The *apex* is directed downwards and presents an oval facet for articulation with the coccyx.

The *spinal canal* (fig. 259) runs throughout the greater part of the bone; it is large and triangular in form above; small and flattened from before backwards; below, its posterior wall is incomplete, from the non-development of the laminæ and spinous processes. It lodges the sacral nerves, and its walls are perforated by the anterior and posterior sacral foramina, through which these pass out.

FIG. 259.—Sagittal section of the sacrum.

Structure.—The sacrum consists of cancellous tissue invested externally by a thin layer of compact bone.

Articulations.—The sacrum articulates with four bones; the last lumbar vertebra above, the coccyx below, and the innominate bone on either side.

Differences in the sacrum of the male and female.—In the female the sacrum is shorter and wider than in the male; the lower half forms a greater angle with the upper; the upper half is nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backwards; this increases the size of the pelvic cavity and renders the sacro-vertebral angle more prominent. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Variations.—The sacrum, in some cases, consists of six pieces; occasionally the number is reduced to four. Sometimes the uppermost transverse tubercles are not joined to the rest of the bone on one or both sides, or the sacral canal may be open throughout a considerable part of its length, in consequence of the imperfect development of the laminæ and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature.

THE COCCYX

The **coccyx** (os coccygis) (fig. 260), so called from having been compared to a cuckoo's beak, is usually formed of four rudimentary vertebræ; the number may however be increased to five or diminished to three. In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone. All the segments are destitute of pedicles, laminæ, and spinous processes, and, consequently, of intervertebral and spinal foramina. The first is the largest; it resembles the lowest sacral vertebra, and often exists as

a separate piece; the last three, diminishing in size from above downwards, are usually fused to form a single bone. The gradual diminution in the size of the segments gives this bone a triangular form, the base of the triangle joining the end of the sacrum. It presents for examination an anterior and a posterior surface, two borders, a base, and an apex. The *anterior surface* is slightly concave, and marked with three transverse grooves, indicating the lines of junction of the different segments. It gives attachment to the anterior sacro-coccygeal ligament and Levator ani, and supports the middle part of the rectum. The *posterior surface* is convex, marked by transverse grooves similar to those on the anterior surface; and presents on either side a linear row of tubercles, the rudimentary articular processes of the coccygeal vertebræ. Of these, the superior pair are large, and are called the *cornua coccygea*; they project upwards, and articulate with the cornua of the sacrum, and on either side complete the fifth posterior sacral foramen for the transmission of the posterior primary division of the fifth sacral nerve. The *lateral borders* are thin, and exhibit a series of small eminences, which represent the transverse processes of the coccygeal vertebræ. Of these, the first is the largest; it is flattened from before backwards, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior primary division of the fifth sacral nerve; the others diminish in size from above downwards, and are often wanting. The *borders* of the coccyx are narrow, and give attachment on either side to the sacro-sciatic ligaments, to the Coccygeus in front of the ligaments, and to the Gluteus maximus behind them. The *base* presents an oval surface for articulation with the sacrum. The *apex* is rounded, and has attached to it the tendon of the external Sphincter muscle of the anus. It may be bifid, and is sometimes deflected to one or other side.

Fig. 260.—Coccyx.

Ossification of the vertebral column.—Each vertebra is ossified from three primary centres (fig. 261), two for the neural arch, and one for the body.* Ossification commences in the neural arches of the upper cervical vertebræ about the sixth week of fœtal life, and gradually extends down the column. The ossific granules first appear in the situations where the transverse processes afterwards project, and spread backwards to the spine, forwards into the pedicles, and outwards into the transverse and articular processes. Ossification of the body commences about the eighth week in the lower thoracic region, and subsequently extends upwards and downwards along the column. At birth these three pieces are perfectly separate. The ossific centre for the body does not give rise to the whole of the body of the adult vertebra; the postero-lateral portions of the body are ossified by extensions from the neural arch centres. The body of the vertebra during the first few years of life shows, therefore, two synchondroses (*neurocentral synchondroses*) traversing it along the lines of junction of the three centres. In the thoracic region, the facets for the heads of the ribs lie behind the neuro-central synchondroses and are ossified from the centres for the neural arch. During the first year the laminæ become united behind, union taking place first in the lumbar region and then extending upwards through the thoracic and lower cervical regions. About the third year the bodies of the upper cervical vertebræ are joined to the arches on either side; in the lower lumbar vertebræ the union is not completed until the sixth year. Before puberty, no other changes

* A vertebra is occasionally found in which the body consists of two lateral portions—a condition which proves that the body is sometimes ossified from two primary centres, one on either side of the middle line.

occur, excepting a gradual increase in the growth of these primary centres, the upper and under surfaces of the bodies, and the ends of the transverse and spinous processes, being cartilaginous. About the sixteenth year (fig. 262), five secondary centres appear, one for the tip of each transverse process, one for the extremity of the spinous process, and two epiphysial plates, one for the upper and the other for the lower surface of the body (fig. 263). These fuse with the rest of the bone about the age of twenty-five.

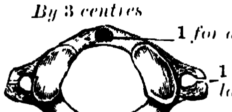

FIG. 265.—Axis.

By 7 centres

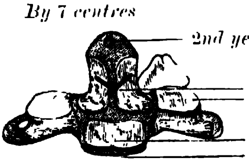

FIG. 266.—Lumbar vertebra.

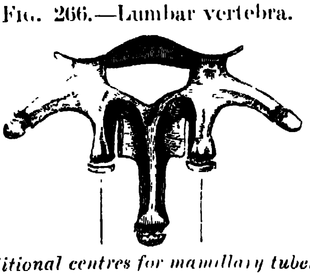

Exceptions to this mode of development occur in the first, second, and seventh cervical vertebræ, and in those of the lumbar region.

The **atlas** is usually ossified from three centres (fig. 264). Two of these are destined for the lateral masses, the ossification of which commences about the seventh week of fœtal life near the articular processes, and extends backwards; at birth, these portions of bone are separated from one another behind by a narrow interval filled with cartilage. Between the third and fourth years they unite either directly or through the medium of a separate centre developed in the cartilage. The anterior arch, at birth, is altogether cartilaginous and consists of the hypochordal brace or bar (see page 103), which persists in the case of this vertebra; in this a separate nucleus appears about the end of the first year after birth, and joins the lateral masses from the sixth to the eighth year—their lines of union extending across the anterior portions of the superior articular facets. Sometimes two nuclei, one on either side of the median line, are developed in the cartilage, and join to form a single mass. Occasionally there is no separate centre, the anterior arch being formed by the forward extension and ultimate junction of the two lateral masses.

The **axis** is ossified from five primary and two secondary centres (fig. 265). The body and neural arch are ossified in the same manner as the corresponding parts in the other vertebræ, viz., one centre for the lower part of the body, and two for the neural arch. The centres for the neural arch appear about the

seventh or eighth week of fœtal life, that for the body about the fourth or fifth month. The odontoid process consists originally of an extension upwards of the cartilaginous mass, in which the lower part of the body is formed. About the sixth month of fœtal life, two centres make their appearance in the base of this process: they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage. The base of the process is separated from the body by a cartilaginous disc, which gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age.* In this cartilage, rudiments of the lower epiphysial lamella of the atlas and the upper epiphysial lamella of the axis may sometimes be found. Finally, as Humphry has demonstrated, the apex of the odontoid process has a separate centre, which appears in the second year and joins about the twelfth year. This is the upper epiphysial lamella of the atlas. In addition to these there is a secondary centre for a thin epiphysial plate on the under surface of the body of the bone.

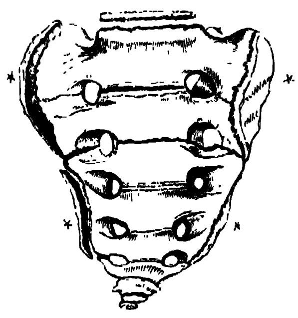
At 25th year



The **seventh cervical vertebra**. The anterior or costal part of the transverse process of this vertebra is sometimes ossified from a separate centre which appears about the sixth month of fœtal life, and joins the body and posterior part of the transverse process between the fifth and sixth years. Occasionally the costal part persists as a separate piece, and, becoming lengthened outwards and forwards, constitutes what is known as a cervical rib. Separate ossific centres have also been found in the costal processes of the fourth, fifth, and sixth cervical vertebræ.

The **lumbar vertebræ** (fig. 266) have *two additional centres* for the mamillary tubercles. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently ununited with the rest of the bone, thus forming a lumbar rib—a peculiarity, however, rarely met with.

Sacrum (figs. 267 to 270).—The *body* of each sacral vertebra is ossified from a primary centre and two epiphysial plates, one for its upper and another for its under surface, whilst each neural arch is ossified from two centres.

The anterior portions of the *lateral masses* have six additional centres, two for each of the first three vertebræ; these represent the costal elements, and make their appearance above and to the outer side of the anterior sacral foramina (figs. 268 and 269).†

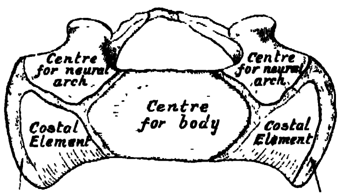
* See Cunningham, *Journ. Anat.*, vol. xx., p. 238.

† The extremities of the spinous processes of the upper three sacral vertebræ are sometimes developed from separate epiphyses, and Fawcett (*Anatomischer Anzeiger*, Band XXX., 1907) states that a number of epiphysial nodules may be seen in the sacrum at the age of eighteen years. These are distributed as follows: One for each of the mamillary processes of the first sacral vertebra; twelve—six on either side—in connection with the costal elements (two each for the first and second and one each for the third and fourth) and eight for the

On each *lateral surface* two epiphysial plates are developed (fig. 269): one for the auricular surface, and another for the remaining part of the thin lateral edge of the bone.

Periods of Ossification.—About the eighth or ninth week of fœtal life, ossification of the central part of the body of the first sacral vertebra commences, and is rapidly followed by deposit of ossific matter in the second and third; but ossification does not commence in the bodies of the lower two segments until between the fifth and eighth months of fœtal life. Between the sixth and eighth months ossification of the neural arches takes place; and about the same time the costal centres for the lateral masses of the first three sacral vertebræ make their appearance. The junction of the neural arches with the bodies takes place in the lower vertebræ as early as the second year, but is not effected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphysial plates for the upper and under surfaces of the bodies are formed; and between the eighteenth and twentieth years, those for the lateral surfaces make their appearance. The bodies of the sacral vertebræ are, during early life, separated from each other by intervertebral discs, but about the eighteenth year the two lowest segments become united by bone, and the process of bony union gradually extends upwards, with the result that between the twenty-fifth and thirtieth years of life all the segments are united. On examining a sagittal section of the sacrum, the situations of the intervertebral discs are indicated by a series of oval cavities (fig. 259).

FIG. 270.—Base of young sacrum.



Coccyx.—The coccyx is ossified from four centres, one for each segment. The ossific nuclei make their appearance in the following order: in the first segment between the first and fourth years; in the second between the fifth and tenth years; in the third between the tenth and fifteenth years; in the fourth between the fourteenth and twentieth years. As age advances, the segments become united with each other, the union between the first and second segments being frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in females, the coccyx is often joined to the sacrum.

VERTEBRAL COLUMN AS A WHOLE

The **vertebral column** is situated in the median line, at the posterior part of the trunk; its average length in the male is about 71 centimetres (28 inches). Of this length the cervical part measures 12·5 cm. (5 in.), the thoracic about 28 cm. (11 in.), the lumbar 18 cm. (7 in.), and the sacrum and coccyx 12·5 cm. (5 in.). The female column is about 61 cm. (24 in.) in length.

Curves.—Viewed laterally (fig. 271), the vertebral column presents several curves, which correspond to the different regions of the column, and are called cervical, thoracic, lumbar, and pelvic. The *cervical* curve, convex forwards, begins at the apex of the odontoid process, and ends at the middle of the second thoracic vertebra; it is the least marked of all the curves. The *thoracic* curve, concave forwards, begins at the middle of the second and ends at the middle of the twelfth thoracic vertebra. Its most prominent point behind corresponds to the spine of the seventh thoracic. The *lumbar* curve is more marked in the female than in the male; it begins at the middle of the last thoracic vertebra, and ends at the sacro-vertebral angle. It is convex anteriorly; the convexity of the lower three vertebræ being much greater than that of the upper two. The *pelvic* curve begins at the sacro-vertebral articulation, and ends at the

transverse processes—four on either side—one each for the first, third, fourth, and fifth. He is further of opinion that the lower part of each lateral surface of the sacrum is formed by the extension and union of the third and fourth 'costal' and fourth and fifth 'transverse' epiphyses.

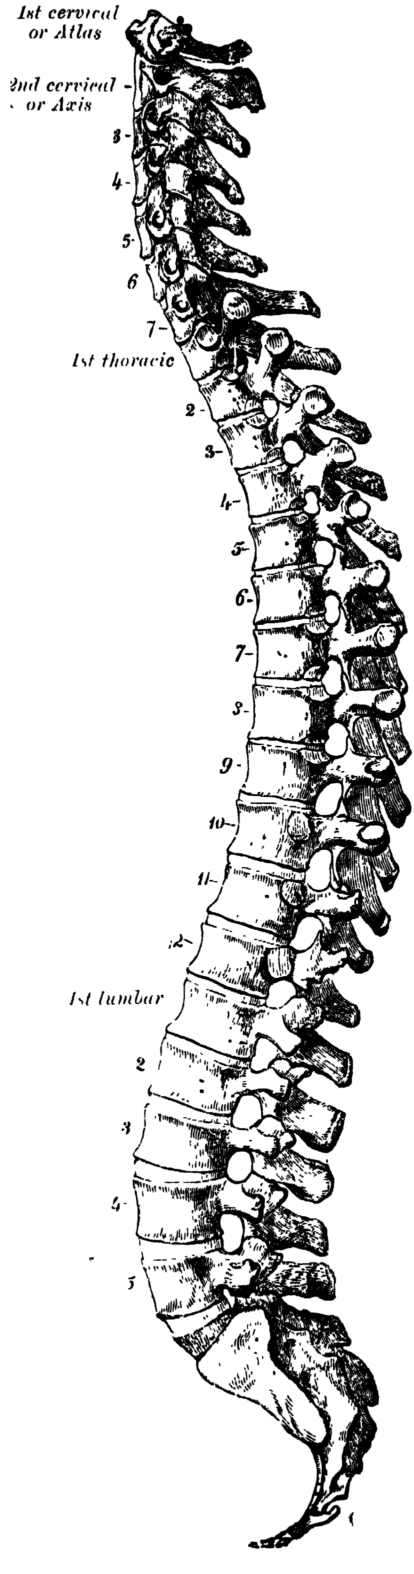
point of the coccyx; its concavity is directed downwards and forwards. The thoracic and pelvic curves are termed primary curves, because they alone are present during fœtal life. The cervical and lumbar curves are compensatory or secondary, and are developed after birth, the former when the child is able to sit upright and hold up its head, the latter when the child begins to walk.

If a body be enveloped in plaster of Paris and divided in the median plane it will be found, as pointed out by Humphry, that a plumb-line dropped from the middle of the odontoid process of the axis will pass through the middle of the bodies of the second and twelfth thoracic vertebræ, through the middle and antero-inferior edge of the last lumbar, and will bisect a line drawn transversely through the heads of the thigh bones. It is known from experiment that the line of gravity of the head passes through the middle of the odontoid process; it therefore follows that this line passes through the points of confluence of the three superior curves of the vertebral column and through a line joining the heads of the thigh bones, so that the weight of the skull and its contents is directly transmitted to the pelvis and lower extremities when the body is in the erect position.

The vertebral column has also a slight *lateral* curvature, the convexity of which is directed towards the right side. This, as Bichat first explained, may be produced by muscular action, most persons using the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation it has been found, by Béclard, that in one or two individuals who were left-handed, the lateral curvature was directed to the left side. Others regard this curvature as being produced by the aortic arch and upper part of the descending thoracic aorta—a view which is supported by the fact that in cases where the viscera are transposed and the aorta is on the right side, the convexity of the lateral curvature is directed to the left side.

Anterior surface.—Viewed from in front, the width of the bodies of the vertebræ will be seen to increase from the second cervical to the first thoracic; there is then a slight diminution in the next three vertebræ; below this there

Fig. 271.—**Lateral view of the vertebral column.**



is again a gradual and progressive increase in width as low as the sacro-vertebral angle. From this point there is a rapid diminution, to the apex of the coccyx.

The *posterior surface* of the vertebral column presents in the median line the spinous processes. In the cervical region these are short and horizontal, with bifid extremities. In the upper part of the thoracic region they are directed obliquely; in the middle they are almost vertical, and in the lower part they are horizontal, with a slight inclination downwards. The spinous processes of the lumbar vertebræ are nearly horizontal. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the thoracic region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the vertebral column. On either side of the spinous processes is the *vertebral groove* formed by the laminæ in the cervical and lumbar regions, where it is shallow, and by the laminæ and transverse processes in the thoracic region, where it is deep and broad; these grooves lodge the deep muscles of the back. External to the vertebral grooves are the articular processes, and still more externally the transverse processes. In the thoracic region, the latter processes stand backwards, on a plane, considerably posterior to the same processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed in front of the articular processes, on the outer sides of the pedicles and between the intervertebral foramina. In the thoracic region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar region they are placed in front of the articular processes, but behind the intervertebral foramina.

The *lateral surfaces* are separated from the posterior by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. These surfaces present, in front, the sides of the bodies of the vertebræ, marked in the thoracic region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar. They transmit the spinal nerves and are situated between the transverse processes in the cervical region, and in front of them in the thoracic and lumbar regions.

The *base* of that portion of the vertebral column which is made up of the twenty-four movable vertebræ is formed by the under surface of the body of the fifth lumbar vertebræ; and the *summit*, by the upper surface of the atlas.

The *vertebral* or *spinal canal* follows the different curves of the column; it is large and triangular in those regions of the column which enjoy the greatest freedom of movement, viz. the neck and loins; and is small and rounded in the thoracic region, where motion is more limited.

Surface Form.—The only parts of the vertebral column which are subcutaneous, and so directly influence the surface form, are the apices of the spinous processes. These are distinguishable at the bottom of a furrow, which, more or less evident, runs down the mesial line of the back from the external occipital protuberance to the middle of the sacrum. In the neck the furrow is broad, and ends below in a conspicuous projection caused by the spinous processes of the seventh cervical and first thoracic vertebræ. Above this the spinous process of the sixth cervical vertebra sometimes forms a projection; the other cervical spinous processes are sunken, but that of the axis can be felt. In the thoracic region the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible; the markings produced by them are small and close together. In the lumbar region the furrow is deep, and the situation of the spinous processes is frequently indicated by little pits or depressions, especially when the muscles in the loins are well developed. They are much larger and farther apart than in the thoracic region. In the sacral region the furrow is shallower, presenting a flattened area which ends below at the most prominent part of the posterior surface of the sacrum, formed by the spinous process of the third sacral vertebra. At the bottom of the furrow the irregular posterior surface of the bone may be felt, and below this, in the deep groove leading to the anus, the coccyx. In order to identify any particular spinous process, it is customary to count from the prominence caused by the seventh cervical and first thoracic: of these two the spinous process of the first thoracic is the more prominent. It is useful, how-

ever, to bear in mind that the root of the spine of the scapula is on a level with the interval between the spinous processes of the third and fourth thoracic vertebræ and the inferior angle with the interval between the seventh and eighth thoracic ; the highest point of the crest of the ilium is on a level with the spinous process of the fourth lumbar and the posterior superior spine of the ilium with that of the second sacral. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebræ—viz. the first, the sixth, and the seventh. That of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, at the anterior border of the Sterno-mastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck, in the course of the carotid artery, opposite the cricoid cartilage, the prominent anterior tubercle of this process can be felt. This has been named *Chassaignac's tubercle*, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can be often felt. Sometimes its costal process is large and segmented off, forming a cervical rib.

Applied Anatomy.—Occasionally the coalescence of the laminæ is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (dura mater and arachnoid), and generally of the spinal cord itself, takes place, constituting the malformation known as *spina bifida*. This condition is most common in the lumbo-sacral region, but it may occur in the thoracic or cervical region, or the arches throughout the whole length of the canal may remain incomplete.

The construction of the movable part of the vertebral column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, but permitting of a very considerable range as a whole, allows a sufficient degree of mobility without any material diminution of strength. The many joints of which the column is composed, together with the very varied movements to which it is subjected, render it liable to sprains ; but, so closely are the individual vertebræ articulated that these sprains are rarely severe, and an amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its slight liability to injury is provided for by its disposition in curves, instead of in a straight line. For it is an elastic column, and must bend before it breaks ; under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one that is equal to it in breadth and material. Again, the safety of the column is largely provided for by the presence between the bodies of the intervertebral discs, which act as buffers in counteracting the effects of violent jars or shocks.

Fracture-dislocation of the vertebral column may be caused by direct or indirect violence. Fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, while the arches are torn asunder ; in fracture from direct violence, on the other hand, the arches are compressed and the bodies of the vertebræ separated from each other It will therefore be seen that in both classes of injury the spinal cord is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. When a fracture-dislocation is produced by indirect violence, the displacement is almost always the same ; the upper segment being driven forwards on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

Diseases of the Spine.—Spinal caries, or tuberculous disease affecting the cancellous tissue of the bodies of the vertebræ, is a very common condition. When the bodies, having been destroyed, begin to fall together, the spinous processes are necessarily thrown backwards and stand out prominently, especially if the disease affect the thoracic region, which is most commonly the case. The condition then goes by the name of *angular curvature* and great rigidity of the muscles in the affected region accompanies it. Pressure, by the inflammatory thickenings of the disease, is apt to involve the spinal nerves in the affected region, giving rise to peripheral pains, and if the disease be in the lower thoracic vertebræ the pains are referred to the epigastric or umbilical regions, and often the chief thing complained of is 'belly-ache.' Chronic abscess formation in spinal caries is very frequent, and it nearly always forms in front of the vertebral bodies. When the disease is in the lower thoracic region, the abscess usually tracks down behind the Diaphragm and enters the psoas sheath, forming the well-known *psoas abscess*, which may present above Poupart's ligament, or may pass beneath it into the thigh. In other cases the abscess takes a backward course between the transverse processes and presents as a *dorsal* or *lumbar abscess* ; if the disease affect the cervical region of the spine, a *post-pharyngeal abscess* results.

Lateral curvature of the spine is a common affection in girls who are outgrowing their strength and who sit or stand long at lessons, and is due to the uneven transmission of weight down the column. In addition to the lateral displacement of the spinous processes there is a marked rotation of the bodies of the vertebræ, the displacement of which is far in excess of that of the spinous processes. When the curve is severe and the bones have actually become distorted, the condition is past treatment.

Kyphosis is an affection in which there is an increase in the normal thoracic curve, and is due to bending forwards of the upper part of the body carrying the weight of

the head. It is seen in rickety children, in rapidly growing adolescents, in senile conditions, and in certain diseases, such as osteo-arthritis and osteitis deformans. In the senile kyphosis often met with in aged labourers, the head is firmly fixed and bent forwards and downwards on to the chest, and the spinal column is curved and rigid. The ribs are immobilised, the chest is flattened antero-posteriorly, and breathing becomes almost entirely abdominal. *Post-mortem*, bony ankylosis of the ligaments and capsules of the intervertebral joints is found, with ossification of the ligamenta subflava, interspinous and other ligaments.

It may be noted that in marked cases of spinal deformity the trachea and aorta follow closely along the line of a spinal curvature occurring in their vicinity, whereas the œsophagus between the tracheal bifurcation and the stomach often passes like a bowstring across the concavity of the curve.

Lordosis, on the other hand, is an exaggeration of the normal lumbar curve, the trunk being thrown backwards. This is always a compensatory curve, and is seen in any enlargement of the abdomen, such as pregnancy or tumours; but it is more strongly marked in cases of disease of the hip-joint where the latter is permanently retained in a flexed position, so that in order to bring the foot down to the ground the pelvis has to be tilted forwards, and this is accomplished by an increase of the normal lumbar curve forwards.

Laminectomy.—The operation of laminectomy is performed in cases of pressure on the spinal cord, where the continuity of the nerve-tracts has not been completely destroyed. It consists of cutting down on and removing the laminæ and spinous processes in the affected region, so as to relieve the cord from pressure; but it is useless in cases of complete destruction of the cord. Laminectomy is chiefly performed (i) for fracture-dislocation, (ii) for localised cord-pressure in cases of spinal caries, the object here being to remove the laminæ against which the cord is pressed by the inflammatory mass; and (iii) for the removal of tumours growing inside the spinal canal and compressing the cord. If such cases be taken early, very satisfactory results are obtained.

THE THORAX

The skeleton of the **thorax,** or **chest,** is an osseo-cartilaginous cage, containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backwards, and longer behind than in front. It is somewhat reniform on transverse section on account of the projection of the vertebral bodies into the cavity.

Boundaries.—The *posterior surface* is formed by the twelve thoracic vertebræ and the posterior parts of the ribs. It is convex from above downwards, and presents on either side of the middle line a deep groove, in consequence of the direction backwards and outwards which the ribs take from their vertebral extremities to their angles. The *anterior surface* formed by the sternum and costal cartilages is flattened or slightly convex, and inclined from above downwards and forwards. The *lateral surfaces* are convex; they are formed by the ribs, separated from each other by the *intercostal spaces.* These spaces are eleven in number, and are occupied by the Intercostal muscles and membranes.

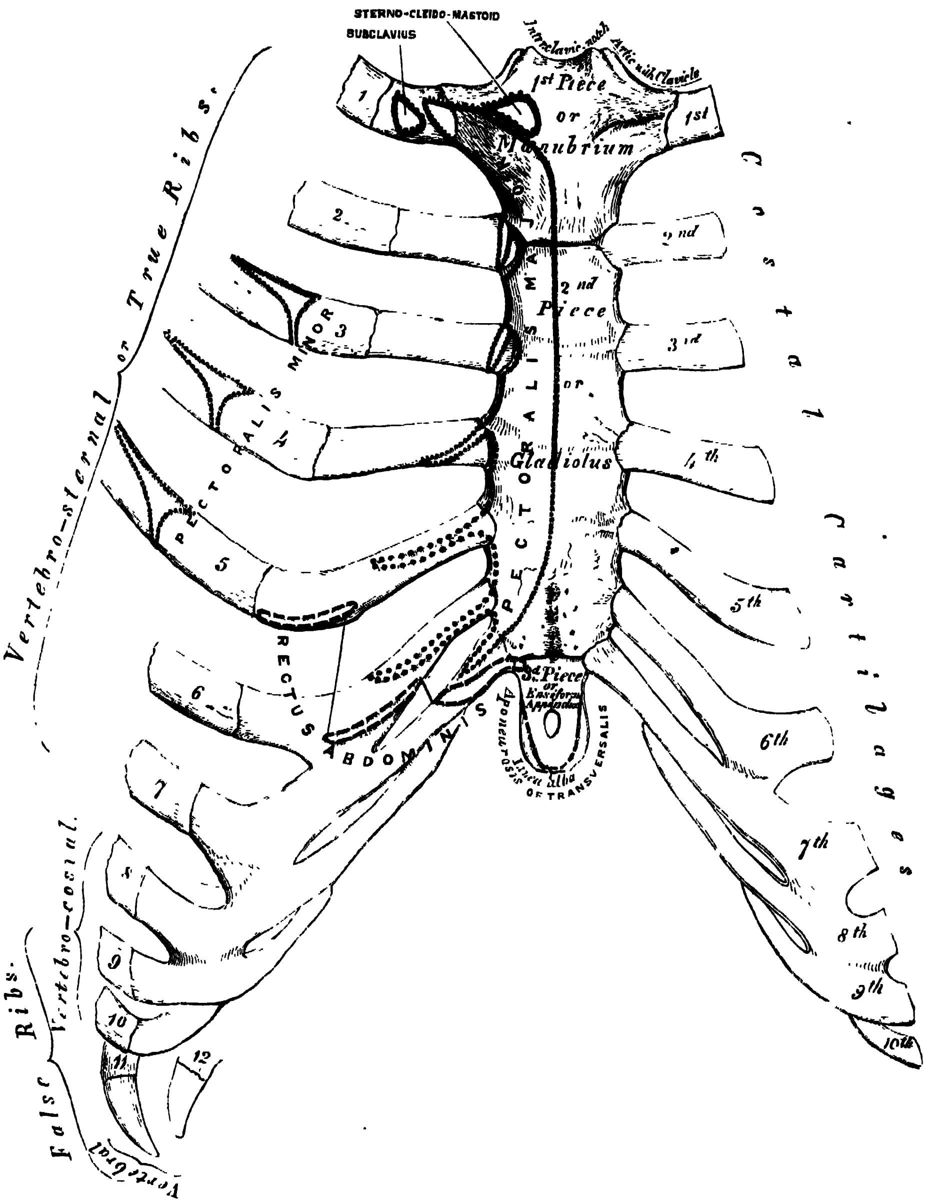
The *upper opening* of the thorax is reniform in shape, being broader from side to side than from before backwards. It is formed by the first thoracic vertebra behind, the upper margin of the sternum in front, and the first rib on either side. It slopes downwards and forwards, so that the anterior part of the ring is on a lower level than the posterior. Its antero-posterior diameter is about two, and its transverse diameter about four inches. The *lower opening* is formed by the twelfth thoracic vertebra behind, by the eleventh and twelfth ribs at the sides, and in front by the cartilages of the tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the *subcostal angle*, into the apex of which the ensiform cartilage projects. It is wider transversely than from before backwards, and slopes obliquely downwards and backwards. The Diaphragm closes the lower opening and forms the floor of the thorax.

The thorax of the female differs from that of the male as follows: 1. Its capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third thoracic vertebra, whereas in the male it is on a level with the lower part of the body of the second. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax.

The Sternum

The **sternum** (figs. 272 and 273) is an elongated, flattened bone, forming the middle portion of the anterior wall of the thorax. Its upper end supports the clavicles and its margins articulate with the cartilages of the first seven pairs of ribs. It consists of three parts, named from above downwards, the

Fig. 272.—Anterior surface of sternum and costal cartilages.



manubrium (presternum), the *body* or *gladiolus* (mesosternum), and the *xiphoid* or *ensiform process* (metasternum); in early life the gladiolus consists of four segments or *sternebræ*. In its natural position its inclination is oblique from above, downwards and forwards. It is slightly convex in front and concave behind; broad above, becoming narrowed at the point where the manubrium joins the gladiolus, after which it again widens a little, and

then rapidly narrows to its lower extremity. Its average length in the adult is about seven inches, and is rather greater in the male than in the female.

The **manubrium** (manubrium sterni) is of a somewhat quadrangular form, broad and thick above, narrow below at its junction with the gladiolus. Its *anterior surface*, convex from side to side, concave from above downwards, is smooth, and affords attachment on either side to the sternal origins of the Pectoralis major and Sterno-mastoid muscles. In well-marked bones the ridges limiting the attachments of these muscles are very distinct. Its *posterior surface*, concave and smooth, affords attachment on either side to the Sterno-hyoid and Sterno-thyroid muscles. The *superior border* is the thickest and presents at its centre the *presternal notch* (incisura jugularis); on either side of the notch is an oval articular surface, directed upwards, backwards, and outwards, for articulation with the sternal end of the clavicle. The *inferior border*, oval and rough, is covered in a recent state with a thin layer of cartilage, for articulation with the gladiolus. The *lateral borders* are each marked above by a depression for the first costal cartilage, and below by a small facet, which, with a similar facet on the upper angle of the gladiolus forms a notch for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downwards and inwards.

FIG. 273.—Posterior surface of sternum.

The **gladiolus** (corpus sterni), considerably longer, narrower, and thinner than the manubrium, attains its greatest breadth close to the lower end. Its *anterior surface* is nearly flat, directed upwards and forwards, and marked by three transverse ridges which cross the bone opposite the third, fourth, and fifth articular depressions.* It affords attachment on either side to the sternal origin of the Pectoralis major. At the junction of the third and fourth pieces is occasionally seen an orifice, the *sternal foramen*, of varying size and form. The *posterior surface*, slightly concave, is also marked by three transverse lines, less distinct, however, than those in front; it affords attachment below, on either side, to the Triangularis sterni. The *superior border* is oval and articulates with the manubrium, the junction of the two forming the *angulus Ludovici* (angulus sterni). The *inferior border* is narrow, and articulates with the ensiform appendix. Each *lateral border*, at its superior angle, has a small facet, which with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; below this are four angular depressions which receive the cartilages of the third, fourth, fifth, and sixth ribs, while the inferior angle has a small facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downwards, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the lines of junction of its primitive component segments. This is well seen in many of the lower animals where the separate parts of the bone remain ununited longer than in man.

The **ensiform process or xiphoid appendix** (processus xiphoideus) is the smallest of the three pieces: it is thin and elongated in form, cartilaginous

* Paterson (*The Human Sternum*, 1901), who examined 521 specimens, points out that these ridges are altogether absent in 26·7 per cent.; that in 69 per cent. a ridge exists opposite the third costal attachment; in 39 per cent. opposite the fourth; and in 4 per cent. only, opposite the fifth.

Fig. 274.—Ossification of the sternum, by six centres.

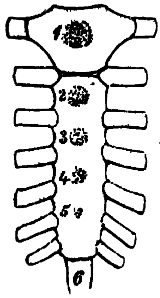


Fig. 275.

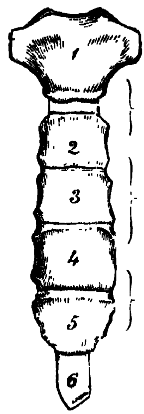

Fig. 276.—Peculiarities.

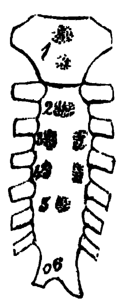

Fig. 277.

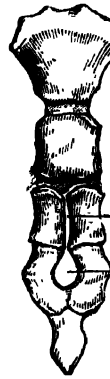


in structure in youth, but more or less ossified at its upper part in the adult. Its *anterior surface* affords attachment to the chondro-xiphoid ligament and a small part of the Rectus abdominis; its *posterior surface*, to some of the fibres of the Diaphragm and Triangularis sterni: its *lateral borders*, to the aponeuroses of the abdominal muscles. Above, it articulates with the lower end of the gladiolus, and at each superior angle presents a facet for the lower half of the cartilage of the seventh rib; below, by its pointed extremity, it gives attachment to the linea alba. This portion of the sternum varies much in form; it may be broad and thin, pointed, bifid, perforated, curved, or deflected considerably to one or other side.

Structure.—The sternum is composed of delicate, highly vascular cancellous tissue, covered by a thin layer of compact bone which is thickest in the manubrium between the articular facets for the clavicles.

Ossification.—The cartilaginous sternum originally consists of two bars, situated one on either side of the mesial plane and connected with the cartilages of the upper nine ribs of its own side. These two bars fuse with each other along the middle line and the bone is ossified from *six* centres: one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform process (fig. 274). Up to the middle of fœtal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the intervals between the articular depressions for the costal cartilages, in the following order: in the manubrium and first piece of the gladiolus, during the sixth month; in the second and third pieces of the gladiolus, during the seventh month; in its fourth piece, during the first year, or between the first and second years; and in the ensiform process, between the fifth and eighteenth years. The centres make their appearance at the upper parts of the segments, and proceed gradually downwards.* To these may be added the occasional existence, as described by Breschet, of two small episternal centres, which make their appearance one on either side of the presternal notches; they are probably vestiges of the episternal bone of the monotremata and lizards. It occasionally happens that some of the segments are formed from more than one centre, the number and position of which vary (fig. 276). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper being the larger; the second piece has seldom more than one; the third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which will serve to explain the rare occurrence of the sternal foramen (fig. 277), or of the vertical fissure which occasionally intersects this part of the bone; these conditions are further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed. Union of the various centres of the gladiolus commences about puberty, and proceeds from below upwards; by the age of twenty-five they are all united (fig. 275). The ensiform process may become joined to the gladiolus before the age of thirty, but this occurs more frequently after forty; on the other hand, it sometimes remains ununited in old age. The manubrium is occasionally joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, the central portion of the intervening cartilage remaining unossified.

Articulations.—The sternum articulates on either side with the clavicle and upper seven costal cartilages.

THE RIBS

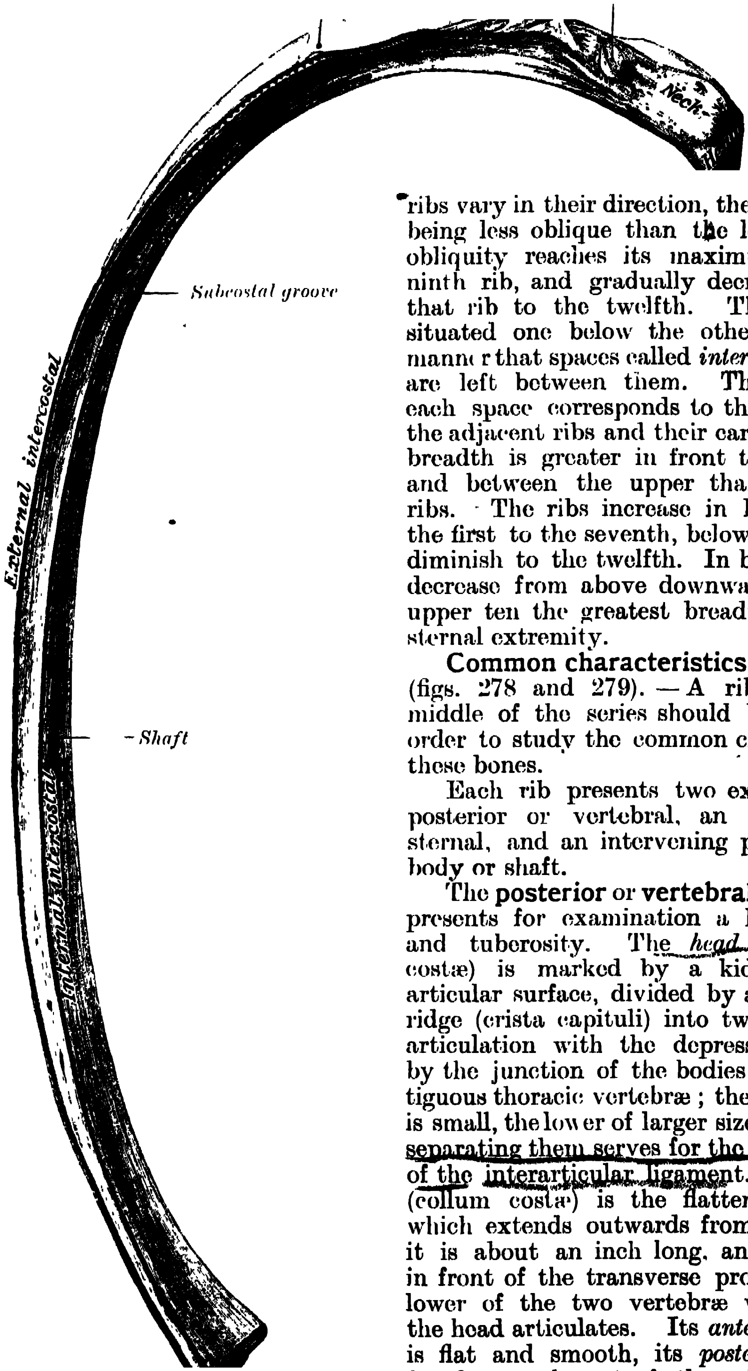
The **ribs** are elastic arches of bone, which form the chief part of the thoracic walls. They are twelve in number on either side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the vertebral column, and in front, through the intervention of the costal cartilages, with the sternum; they are called *vertebro-sternal*, or *true* ribs (costæ veræ).† The remaining five are *false* ribs (costæ spuriæ); of these, the first three have their cartilages

* Out of 141 sterna between the ages of birth and sixteen years, Paterson (*op. cit.*) found the fourth or lowest centre for the gladiolus present only in thirty-eight cases—*i.e.* 26·9 per cent.

† Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right than on the left side.

attached to the cartilage of the rib above (*vertebro-chondral*): the last two are free at their anterior extremities and are termed *floating* or *vertebral* ribs. The

FIG. 278.—A central rib of the left side. Inferior aspect.



ribs vary in their direction, the upper ones being less oblique than the lower. The obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces called *intercostal spaces* are left between them. The length of each space corresponds to the lengths of the adjacent ribs and their cartilages; the breadth is greater in front than behind, and between the upper than the lower ribs. The ribs increase in length from the first to the seventh, below which they diminish to the twelfth. In breadth they decrease from above downwards; in the upper ten the greatest breadth is at the sternal extremity.

Common characteristics of the ribs (figs. 278 and 279).—A rib from the middle of the series should be taken in order to study the common characters of these bones.

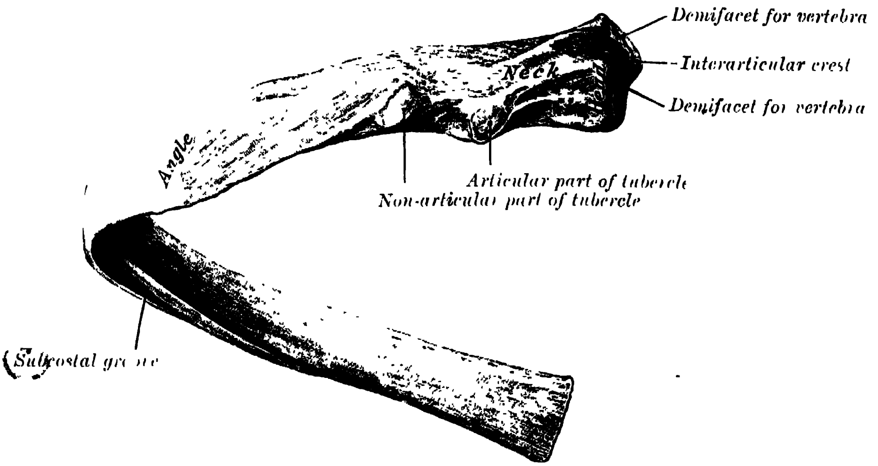
Each rib presents two extremities, a posterior or vertebral, an anterior or sternal, and an intervening portion—the body or shaft.

The **posterior** or **vertebral extremity** presents for examination a head, neck, and tuberosity. The *head* (capitulum costæ) is marked by a kidney-shaped articular surface, divided by a horizontal ridge (crista capituli) into two facets for articulation with the depression formed by the junction of the bodies of two contiguous thoracic vertebræ; the upper facet is small, the lower of larger size; the ridge separating them serves for the attachment of the interarticular ligament. The *neck* (collum costæ) is the flattened portion which extends outwards from the head; it is about an inch long, and is placed in front of the transverse process of the lower of the two vertebræ with which the head articulates. Its *anterior surface* is flat and smooth, its *posterior* rough, for the attachment of the middle costo-transverse ligament, and perforated by numerous foramina. Of its two borders the *superior* presents a rough crest (crista colli costæ) for the

attachment of the anterior costo-transverse ligament; its *inferior border* is rounded. On the posterior surface at the junction of the neck and shaft, and nearer the lower than the upper border, is an eminence—the *tubercle* (tuberculum costæ); it consists of an articular and a non-articular portion. The *articular portion*, the inner and lower of the two, presents a small, oval surface for articulation with the extremity of the transverse process of the lower of the two vertebræ to which the head is connected. The *non-articular portion* is a rough elevation, and affords attachment to the posterior costo-transverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

The **shaft** (corpus costæ) is thin and flat, with two surfaces, an external and an internal; and two borders, a superior and an inferior. The *external surface* is convex, smooth, and marked, a little in front of the tuberosity, by a prominent line, directed obliquely from above downwards and outwards; this gives attachment to a tendon of the Ilio-costalis or of one of its accessory portions, and is called the *angle* (angulus costæ). At this point the rib is bent in two directions, and at the same time twisted on its long axis. If the rib be laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, and that the portion behind the angle is bent inwards and at the same time tilted upwards; as the result

FIG. 279.—A central rib of the left side, viewed from behind.



of the twisting, the external surface, behind the angle, looks downwards, and in front of the angle, slightly upwards. The distance between the angle and the tuberosity is progressively greater from the second to the tenth ribs. The portion between the angle and the tuberosity is rounded, rough, and irregular, and serves for the attachment of the Longissimus dorsi. The external surface presents, towards its sternal extremity, an oblique line, the *anterior angle*. The *internal surface* is concave, smooth, directed a little upwards behind the angle, a little downwards in front of it, and is marked by a ridge which commences at the lower extremity of the head; this ridge is strongly marked as far as the inner side of the angle, and gradually becomes lost at the junction of the anterior and middle thirds of the bone. Between it and the inferior border is a groove, the *subcostal groove* (sulcus costæ), for the intercostal vessels and nerve. At the back part of the bone, this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded and serves for the attachment of the Internal intercostal muscle; the inferior edge corresponds to the lower margin of the rib, and gives attachment to the External intercostal. Within the groove are seen the orifices of numerous small foramina for nutrient vessels, which traverse the shaft obliquely from before backwards. The *superior border*, thick and rounded, is marked by an external and an internal lip, more

distinct behind than in front, which serves for the attachment of the External and Internal intercostal muscles. The *inferior border*, thin and sharp, has attached to it the External intercostal muscle.

The **anterior or sternal extremity** is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

The first, second, tenth, eleventh, and twelfth ribs present certain

Peculiar ribs.

FIG. 280.

FIG. 281.

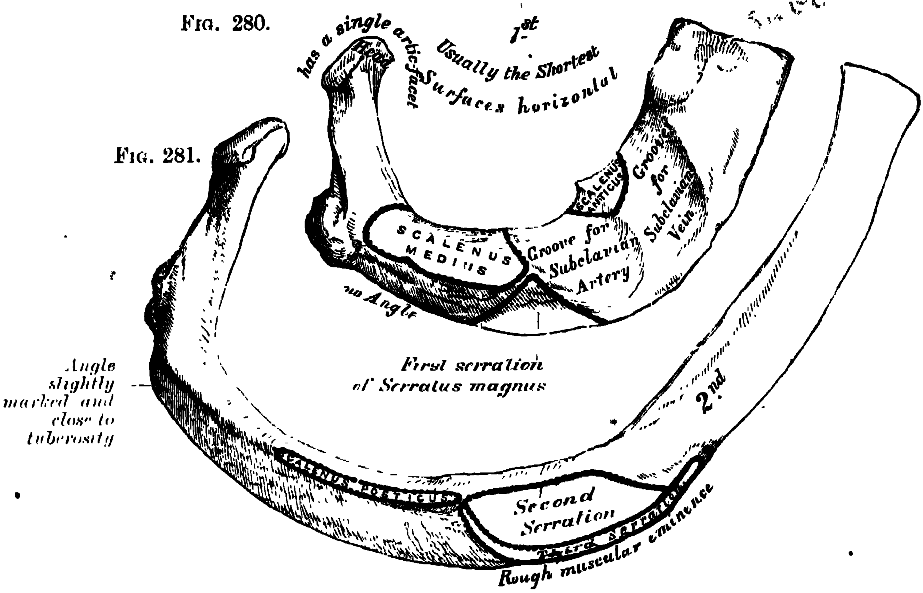


FIG. 282.

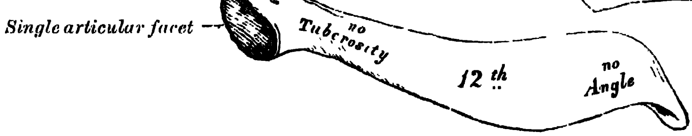
FIG. 283.

FIG. 284.



variations from the common characters described above, and require special consideration.

The **first rib** (fig. 280) is the most curved and usually the shortest of all the ribs; it is broad and flat, its surfaces looking upwards and downwards, and its borders inwards and outwards. The *head* is small, rounded, and presents only a single articular facet, for articulation with the body of the first thoracic vertebra. The *neck* is narrow and rounded. The *tuberosity*, thick and prominent, is placed on the outer border. There is no angle, but at the tuberosity the rib is slightly bent, with the convexity of the bend upwards,

so that the head of the bone is directed downwards. The *upper surface of the shaft* is marked by two shallow grooves, separated from each other by a slight ridge prolonged internally into a tubercle, the *scalene tubercle* (tuberculum scaleni [Lisfranci]), for the attachment of the Scalenus anticus; the anterior groove transmits the subclavian vein, the posterior the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a rough surface for the attachment of the Scalenus medius. The *under surface* is smooth, and destitute of a subcostal groove. The *outer border* is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the *inner* is concave, thin, and sharp, and marked about its centre by the scalene tubercle. The *anterior extremity* is larger and thicker than that of any of the other ribs.

The **second rib** (fig. 281) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-articular portion of the *tuberosity* is occasionally only feebly marked. The *angle* is slight, and situated close to the tuberosity. The *shaft* is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a bend, with its convexity upwards, similar to, though smaller than that found in the first rib. The shaft is not flattened horizontally like that of the first rib. Its *external surface*, which is convex, looks upwards and a little outwards; it presents, near the middle, a rough eminence for the attachment of the lower part of the first and the whole of the second digitation of the Serratus magnus; behind and above this is attached the Scalenus posticus. The *internal surface*, smooth and concave, is directed downwards and a little inwards: it presents a short subcostal groove towards its posterior part.

The **tenth rib** (fig. 282) has only a single articular facet on its head.

The **eleventh** and **twelfth ribs** (figs. 283 and 284) have each a single articular facet on the head, which is of rather large size; they have no necks or tuberosities, and are pointed at their extremities. The eleventh has a slight angle and a shallow subcostal groove. The twelfth has neither, and is much shorter than the eleventh, and the head has a little inclination downwards. Sometimes the twelfth rib is even shorter than the first.

Structure.—The ribs consist of highly vascular cancellous tissue, enclosed in a thin layer of compact bone.

Ossification.—Each rib, with the exception of the last two, is developed by *three* centres; a primary centre for the shaft, and two epiphyses, one for the head and one for the tubercle. The eleventh and twelfth ribs have only *two* centres, that for the tubercle being wanting. Ossification begins in the shaft at a very early period, before its appearance in the vertebræ. The epiphysis for the head, of a slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.

Applied Anatomy.—*Cervical ribs* derived from the seventh cervical vertebra (page 187) are of not infrequent occurrence, and are important clinically because they may give rise to obscure nervous or vascular symptoms. The cervical rib may be a mere epiphysis articulating only with the transverse process of the vertebra, but more commonly it consists of a defined head, neck and tubercle, with or without a body. It extends outwards, or forwards and outwards, into the posterior triangle of the neck, where it may terminate in a free end or may join the first thoracic rib, the first costal cartilage, or the sternum.* It varies much in shape, size, direction, and mobility. If it reach far enough forwards, part of the brachial plexus and the subclavian artery and vein cross over it, and are apt to suffer compression in so doing. Pressure on the artery may obstruct the circulation so much that arterial thrombosis results, causing gangrene of the finger-tips. Pressure on the nerves is commoner, and affects the eighth cervical and first thoracic nerves, causing paralysis of the muscles they supply, and neuralgic pains and paræsthesia in the area of skin to which they are distributed; no oculo-pupillary changes are to be found. If these symptoms be severe, removal of the rib or as much of it as causes pressure on the vessels and nerves is called for. The operation is not free from difficulty, and has been followed by paralysis of the muscles and by subclavian aneurysm, due to injuries inflicted in the course of the operation.

* W. Thorburn, *The Med. Chronicle*, Manchester, 1907, 4th series, xiv., No. 3.

The Costal Cartilages

The **costal cartilages** (cartilagines costales) (fig. 272) are bars of white, hyaline cartilage, which serve to prolong the ribs forward to the front of the chest, and contribute very materially to the elasticity of its walls. The first seven pairs are connected with the sternum; the next three are each articulated with the lower border of the cartilage of the preceding rib; the last two have pointed extremities, which end in the walls of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. Their breadth, as well as that of the intervals between them, diminishes from the first to the last. They are broad at their attachments to the ribs, and taper towards their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. They also vary in direction: the first descends a little, the second is horizontal, the third ascends slightly, while the others follow the course of the ribs for a short distance, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities. The *anterior surface* is convex, and looks forwards and upwards: that of the first gives attachment to the costo-clavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major.* The others are covered by, and give partial attachment to, some of the flat muscles of the abdomen. The *posterior surface* is concave, and directed backwards and downwards; the first gives attachment to the Sterno-thyroid, the third to the sixth inclusive to the Triangularis sterni, and the six or seven inferior ones to the Transversalis abdominis and the Diaphragm. Of the two borders, the *superior* is concave, the *inferior* convex; they afford attachment to the Internal intercostal muscles: the upper border of the sixth gives attachment also to the Pectoralis major. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate with one another. Of the two extremities, the *outer* one is continuous with the osseous tissue of the rib to which it belongs. The *inner* extremity of the first is continuous with the sternum; the six succeeding ones have rounded ends, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage immediately above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than those of the true. In old age they become of a deep yellow colour, and are prone to undergo superficial ossification.

Surface Form.—The bones of the chest are to a very considerable extent covered by muscles, so that in the strongly developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral regions, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the middle line, in front, the superficial surface of the sternum can be felt throughout its entire length, at the bottom of a deep median furrow, the *sternal furrow*, situated between the Pectoralis major muscles. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous, and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wide at its upper and lower part, but narrow in the middle. The centre of the upper border of the sternum constitutes the *presternal notch*, and is in the same horizontal plane as the lower border of the body of the second thoracic vertebra; the lateral parts of this border are obscured by the tendinous origins of the Sterno-mastoid muscles, which appear as oblique tendinous cords, narrowing and deepening the notch. Lower down on the subcutaneous surface a well-defined transverse ridge, the *angulus Ludovici*, is always to be felt. This denotes the line of junction of the manubrium and gladiolus; it lies at the level of the fifth thoracic vertebra, and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found, through its costal cartilage, it is easy to count downwards and find any

* The first and seventh in addition occasionally give origin to the same muscle.

other. From the middle of the sternum the furrow spreads out, and, exposing more of the surface of the bone, terminates at the junction of the gladiolus with the ensiform cartilage, on the same level as the disc between the ninth and tenth thoracic vertebræ. Immediately below this is the *infrasternal notch*; between the points of junction of the seventh costal cartilages to the sternum, and below the notch is a triangular depression, the *epigastric fossa*, or pit of the stomach (scrobiculus cordis), bounded laterally by the cartilages of the seventh ribs; in it the ensiform cartilage can be felt. The sternum in its vertical diameter presents a general convexity forwards, the most prominent point of which is at the joint between the manubrium and gladiolus.

On either side of the sternum the costal cartilages and ribs on the front of the chest are partially obscured by the Pectoralis major, through which, however, they can be felt as ridges, with yielding intervals between them, corresponding to the intercostal spaces. Of these spaces, that between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the Pectoralis major corresponds to the fifth rib, and below this, on the front of the chest, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the *abdomino-thoracic arch*, which is most plainly seen by bending the body backwards, is formed by the ensiform cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the cartilages of the eleventh and twelfth ribs.

On either side of the chest, from the axilla downwards, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which, when strongly developed, obscure their outline to a certain extent. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front and sides of the chest without difficulty. The first rib, being almost completely covered by the clavicle and scapula, can only be distinguished in a small portion of its extent. At the back, the angles of the ribs lie on a slightly marked oblique line, on either side of and some distance from the spinous processes of the vertebræ. This line diverges somewhat as it descends, and external to it is a broad, convex surface, caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

For clinical purposes and convenience of description, the surface of the chest has been mapped out by arbitrary lines into certain definite areas. On the front of the chest the most important vertical lines are the *mid-sternal*, which runs down the median line of the sternum, and the *mammary*, which runs vertically downwards from a point midway between the centre of the presternal notch and the tip of the acromion process. This line, if prolonged, will cross Poupart's ligament at a point midway between the anterior superior spine of the ilium and the symphysis pubis. The lateral area is bounded by two vertical lines—that in front, the *anterior axillary line*, being drawn from the anterior fold of the axilla; and that behind, the *posterior axillary line*, from the posterior fold. By some this lateral area of the thorax is further divided by a *mid-axillary* line, drawn downwards from the apex of the axilla. On the posterior aspect of the thorax the *scapular line* is drawn vertically through the inferior angle of the scapula.

Applied Anatomy.—Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages which support it like so many springs. The fracture usually occurs in the upper half of the gladiolus. Dislocation of the gladiolus from the manubrium may take place, and is sometimes described as a fracture.

The bone is frequently the seat of gummatous tumours and not uncommonly is affected with caries.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle ones of the series are the most liable to fracture. The first and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest wall, and the bone then gives way at its weakest part, i.e., just in front of the angle. But the ribs may also be broken by direct violence, in which case the bone is driven inwards at the point struck. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity; this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages or separation of the cartilages from the ribs, may also take place, though they are comparatively rare injuries. In workmen the pressure of tools may displace the ensiform cartilage inwards.

The ribs are frequently the seat of tuberculous disease, with the formation of a chronic abscess in the chest wall. This may not immediately overlie the carious portion of rib, as the pus is often directed a considerable distance along the subcostal groove before appearing beneath the integument.

Resection of a portion of a rib is often required in order to give efficient drainage to an empyema; this is referred to in the description of the respiratory organs.

The *thorax* is frequently found to be altered in shape in certain diseases.

In *rickets*, the ends of the ribs, where they join the costal cartilages, become enlarged, giving rise to the so-called 'rickety rosary,' which in mild cases is only found on the internal aspect of the chest-wall. Outside these enlargements the softened ribs sink in, so as to present a groove passing downwards and outwards on either side of the sternum. This bone is forced forwards by the bending of the ribs, and the antero-posterior diameter of the chest is increased. The ribs from the second to the eighth are the ones affected, the lower ones being prevented from falling in by the presence of the liver, stomach, and spleen; and when the abdomen is distended, as it often is in rickets, the lower ribs may be pushed outwards, causing a transverse groove (Harrison's sulcus) just above the costal arch. This deformity is known under the name of 'pigeon-breast,' and is primarily due to some chronic obstruction to the entry of air into the thorax, though it is more prone to occur in the softened bones of rickety children than in the healthy, where the resistance of the thoracic walls is greater. The *phthisical chest* is often long and narrow, flattened from before backwards, and with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the '~~barrel-shaped~~ chest.' In severe cases of *lateral curvature of the spine* the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebræ, which takes place in this disease, the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same tim flattened in front, so that the two ends of the same rib are almost parallel. Coincident with this the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind, and bulging and convex in front.

It is commonly said that in tuberculosis of the lungs the chest is characteristically 'flat,' that is to say, that the ratio of its antero-posterior to its transverse diameter is less than the normal. But by careful measurement in a large number of cases, Woods Hutchinson has shown that this is not so. Taking the transverse diameter of the chest at the nipple level as = 100, he finds that in the normal adult man between the ages of 20 and 44 the antero-posterior diameter = 71. In 82 phthisical subjects it was = 79·5, and in 30 'flat-chested' persons was = 80. He explains the error as an optical illusion, due to rolling forwards of the shoulders in the 'flat-chested'; the back is seen to be correspondingly rounded and protuberant, while the forward position of the shoulders and clavicles lends an appearance of flattening to the chest.

More or less shrinkage of one side of the thorax is often seen as a consequence of adhesive pleurisy, in which the visceral and parietal pleuræ adhere closely to one another and the lung becomes collapsed and fibrosed. If this process be at all complete, great deformity of the chest results, the ribs on the affected side falling in, together with obliteration of the intercostal spaces; the contents of the mediastina are pulled over towards the affected side, the other lung becomes emphysematous compensatorily. The vertebral column becomes scoliotic, with the concavity of the curve towards the affected side.

THE SKULL

The **skull** is supported on the summit of the vertebral column, and is of an oval shape, wider behind than in front. It is composed of a series of flattened or irregular bones which, with one exception (the mandible, or lower jaw), are immovably jointed together. It consists of two parts: (1) the *cranium*, which lodges and protects the brain and comprises eight bones (ossa cranii), and (2) the *skeleton of the face*, which consists of fourteen bones (ossa faciei), as follows:

Skull, 22 bones	*Ossa cranii*, 8 bones	Occipital.
		Two Parietals.
		Two Temporals.
		Sphenoid.
		Frontal.
		Ethmoid.
	Ossa faciei, 14 bones	Two Nasals.
		Two Lachrymals.
		Two Maxillæ.
		Two Palates.
		Two Inferior Turbinateds.
		Two Malars.
		Vomer.
		Mandible.

According to the Basle nomenclature, certain bones developed in association with the nasal capsule, viz. the inferior turbinateds, the lachrymals, the nasals, and the vomer, are grouped as cranial and not as facial bones.

The Hyoid bone, situated at the root of the tongue and attached to the base of the skull by ligaments, has also to be considered in this section.

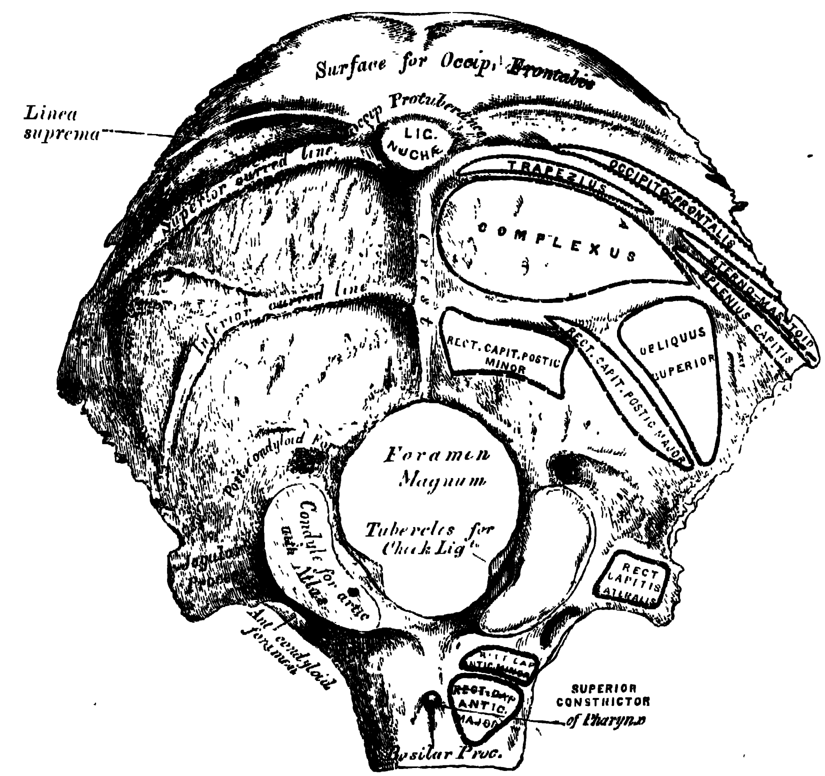
OSSA CRANII

The Occipital Bone

The **occipital bone** (os occipitale) (figs. 285 and 286), situated at the back and lower part of the cranium, is trapezoid in shape and much curved on itself. It is pierced by a large oval aperture, the *foramen magnum*, through which the cranial cavity communicates with the vertebral canal.

The curved, expanded plate behind the foramen magnum is named the *tabular* or *squamous portion*: the thick, somewhat quadrilateral piece in front of the foramen is called the *basilar process*, whilst that on either side of the foramen constitutes the *lateral* or *condylic portion*.

Fig. 285.—Occipital bone. Outer surface.

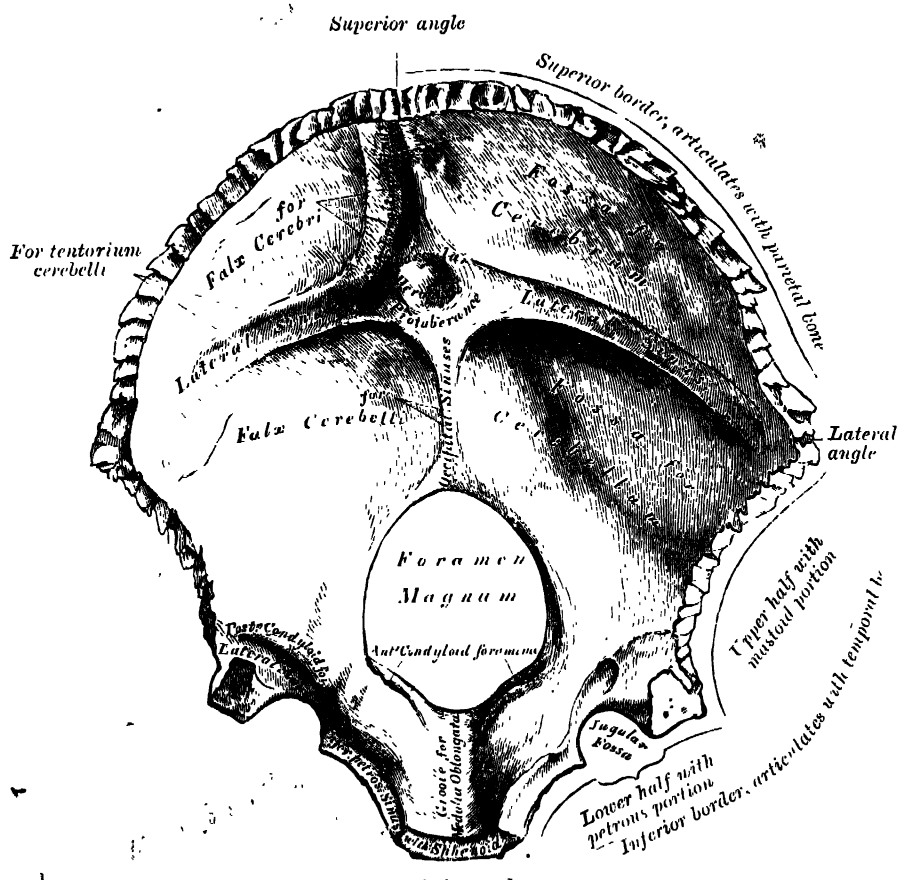


The **tabular portion** (squama occipitalis), situated above and behind the foramen magnum, is curved from above downwards and from side to side.

The *external surface* is convex and presents midway between the summit of the bone and the foramen magnum a prominence, the *inion* or *external occipital protuberance* (protuberantia occipitalis externa). Extending outwards from this on either side are two curved lines, one a little above the other. The upper, often faintly marked, is named the *highest curved line* (linea nuchæ suprema) and to it the epicranial aponeurosis is attached. The lower is termed the *superior curved line* (linea nuchæ superior). That part of the squama which lies above the lineæ supremæ is named the *planum occipitale*, and is

covered by the Occipito-frontalis muscle; that below, termed the *planum nuchale*, is rough and irregular for the attachment of several muscles. From the external occipital protuberance a ridge or crest (linea nuchæ mediana), often faintly marked, descends to the foramen magnum, and affords attachment to the ligamentum nuchæ; running outwards from the middle of this crest across each half of the nuchal plane is the *inferior curved line* (linea nuchæ inferior). Several muscles are attached to the outer surface of the squama occipitalis, thus: the superior curved line gives origin to the Occipito-frontalis and Trapezius, and insertion to the Sterno-mastoid and Splenius; into the surface between the superior and inferior curved lines the Complexus and the Superior oblique are inserted, whilst the inferior curved line and the area below it receive the insertions of the Recti capitis postici major and minor. The

FIG. 286.—Occipital bone. Inner surface.



posterior occipito-atlantal ligament is attached around the postero-lateral part of the foramen magnum, just outside the margin of the foramen.

The *internal surface* is deeply concave and divided into four fossæ by a crucial ridge, the *eminentia cruciata*. The upper two fossæ are triangular and lodge the occipital lobes of the cerebrum; the lower two are quadrilateral and accommodate the hemispheres of the cerebellum. At the point of intersection of the four divisions of the crucial ridge is the *internal occipital protuberance* (protuberantia occipitalis interna). From this eminence the upper division of the ridge runs to the superior angle of the bone, and on one side of it (generally the right) is a deep groove, the *sulcus sagittalis*, which lodges the hinder part of the superior longitudinal sinus; to the margins of this sulcus the falx cerebri is attached. The lower division of the crucial ridge is prominent, and is named

the *crista occipitalis interna* ; it bifurcates near the foramen magnum and gives attachment to the falx cerebelli ; in the attached margin of this falx is the occipital sinus, which is sometimes duplicated. Transverse grooves, one on either side, extend outwards from the internal occipital protuberance to the lateral angles of the bone ; these grooves accommodate the lateral sinuses, and their prominent margins give attachment to the tentorium cerebelli. The groove on the right side is usually larger than that on the left, and is continuous with that for the superior longitudinal sinus. Exceptions to this condition are, however, not infrequent ; the left may be larger than the right or the two may be almost equal in size. The angle of union of the superior longitudinal and lateral sinuses is named the *torcular Herophili*,* and its position is indicated by a depression situated on one or other side of the protuberance.

The **lateral** or **condylic portions** (partes laterales) are situated at the sides of the foramen magnum ; on their under surfaces are the *condyles* for articulation with the superior facets of the atlas. The condyles are oval or reniform in shape, and their anterior extremities, directed forwards and inwards, are closer together than their posterior, and encroach on the basilar portion of the bone. Their surfaces are convex from before backwards and from side to side, and look downwards and outwards. To their margins are attached the capsular ligaments of the occipito-atlantal articulations, and on the inner side of each is a rough impression or tubercle for the lateral odontoid ligament. At the base of each condyle the bone is tunnelled by a short canal, the *anterior condyloid foramen* (canalis hypoglossi). This commences on the cranial surface of the bone immediately above the foramen magnum, and is directed outwards and forwards above the condyle. It may be partially or completely divided into two by a spicule of bone ; it gives exit to the hypoglossal or twelfth cranial nerve, and entrance to a meningeal branch of the ascending pharyngeal artery. Behind each condyle is a fossa (*fossa condyloidea*) which receives the posterior margin of the superior facet of the atlas when the head is bent backwards ; the floor of this fossa is sometimes perforated by a foramen, the *posterior condyloid foramen*, through which an emissary vein passes from the lateral sinus. Extending outwards from the posterior half of the condyle is a quadrilateral plate of bone, the *processus jugularis*. This process is excavated in front by a deep notch (incisura jugularis), which, in the articulated skull, forms the posterior part of the jugular foramen ; this notch may be divided into two by a bony spicule, the *processus intrajugularis*, which projects outwards above the anterior condyloid foramen. The under surface of the processus jugularis is rough, and gives attachment to the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament ; from this surface an eminence, the *paramastoid process*, sometimes projects downwards, and may be of sufficient length to reach, and articulate with, the transverse process of the atlas. Externally the processus jugularis presents a rough quadrilateral or triangular area which is joined to the jugular surface of the temporal bone by a plate of cartilage ; after the age of twenty-five this plate tends to become ossified.

The *upper surface* of the lateral part presents an oval eminence, the *tuberculum jugulare*, which overlies the canalis hypoglossi and is sometimes crossed by an oblique groove for the ninth, tenth, and eleventh cranial nerves. On the upper surface of the processus jugularis is a deep groove which curves inwards and forwards and is continuous with the notch on the anterior surface. This groove lodges the terminal part of the lateral sinus, and opening into it, close to its inner margin, is the orifice of the posterior condyloid foramen.

The **basilar process** (pars basilaris) extends forwards and upwards from the foramen magnum, and presents *in front* an area more or less quadrilateral in outline. In the young skull this area is rough and uneven, and is joined to the body of the sphenoid by a plate of cartilage. By the twenty-fifth year this cartilaginous plate is ossified, and the occipital and sphenoid must be severed by a saw.

On its *lower surface*, about half an inch in front of the foramen magnum,

* The columns of blood coming in different directions were supposed to be pressed together at this point (*torcular*, a wine-press).

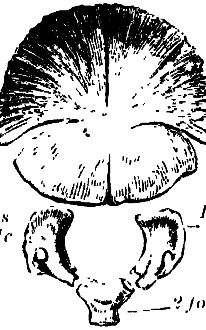
is the *pharyngeal tubercle* (tuberculum pharyngeum) which gives attachment to the fibrous raphe of the pharynx. On either side of the middle line the Recti capitis antici major and minor are inserted, and immediately in front of the foramen magnum the anterior occipito-atlantal ligament is attached.

The *upper surface* presents a broad, shallow groove which inclines upwards and forwards from the foramen magnum; it supports the *medulla oblongata*, and near the margin of the foramen magnum gives attachment to the *membrana tectoria* or occipito-axial ligament. On the lateral margins of this surface are faint grooves for the inferior petrosal sinuses.

The *foramen magnum* is a large oval aperture with its long diameter antero-posterior; it is wider behind than in front where it is encroached upon by the condyles. It transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments.

The *superior angle* of the occipital bone articulates with the postero-superior angles of the two parietal bones and, in the fœtal skull, corresponds in position with the *posterior fontanelle*. The *inferior angle* is represented by the sawn surface of the basilar process, already referred to. The *lateral angles* are situated at the outer extremities of the transverse grooves: each is received into the interval between the postero-inferior angle of the parietal and the mastoid portion of the temporal

Fig. 287.—Ossification of occipital bone. Usually by seven centres.



The *superior borders* extend from the superior to the lateral angles: they are deeply serrated for articulation with the posterior borders of the parietal, and form by this union the *lambdoid suture*. The *inferior borders* extend from the lateral angles to the inferior angle; the upper half of each articulates with the mastoid portion of the corresponding temporal, the lower half with the petrous part of the same bone. These two portions of the inferior border are separated from one another by the jugular process, the notch on the anterior surface of which forms the posterior part of the jugular foramen.

Structure.—The occipital, like the other cranial bones, consists of two compact lamellæ, called the *outer* and *inner tables*, between which is the cancellous tissue or diploë; the bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar process; in the inferior fossæ it is thin, semi-transparent, and destitute of diploë.

Ossification (fig. 287).—The upper portion of the squama occipitalis, viz. that above the linea suprema, is developed in membrane, and may remain separate throughout life when it constitutes the *interparietal* bone; the rest of the bone is developed in cartilage. The number of nuclei for the interparietal part of the squama is four, two appearing near the middle line about the second month, and two some little distance from the middle line about the third month of fœtal life. The cartilaginous portion of the squama is ossified from two centres, which appear about the seventh week of fœtal life and soon unite to form a single piece. Union of the upper and lower portions of the squama takes place about the third or fourth month after birth. Each of the condylic parts begins to ossify from a single centre about the end of the eighth week of fœtal life. The basilar portion is ossified from two centres, one in front of the other; these appear about the sixth week of fœtal life and rapidly coalesce, so that this part is frequently described as ossifying from one centre. About the fourth year the tabular and the two condylic portions unite, and about the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the occipital and sphenoid become united, forming a single bone.

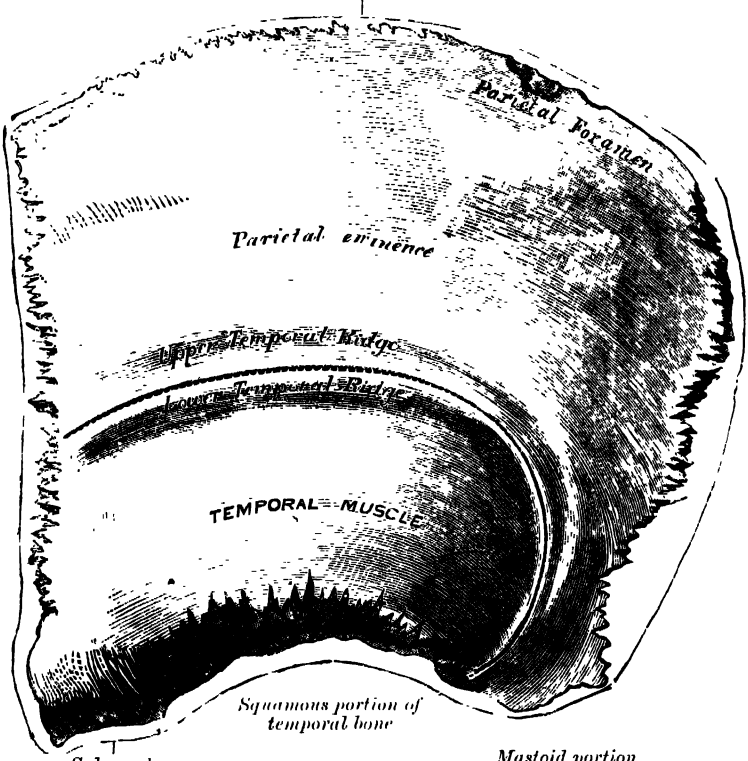
Articulations.—The occipital articulates with six bones: the two parietals, the two temporals, the sphenoid, and the atlas.

The Parietal Bones

The **parietal bones** (ossa parietales) form, by their union, the sides and roof of the skull. Each is irregularly quadrilateral in form, and presents for examination two surfaces, four borders, and four angles.

The *external surface* (fig. 288) is convex, smooth, and marked about its centre by an eminence, the *parietal eminence* (tuber parietale), which indicates the point where ossification commenced. Crossing the middle of the bone in an arched direction are two curved lines, the *superior* and *inferior temporal lines* (lineæ temporales); the former gives attachment to the temporal fascia, while the latter indicates the upper limit of the muscular origin of the Temporal muscle. Above these lines the bone is covered by the aponeurosis of the Occipito-frontalis; below them it forms part of the temporal fossa, and

Fig. 288.—Left parietal bone. External surface.



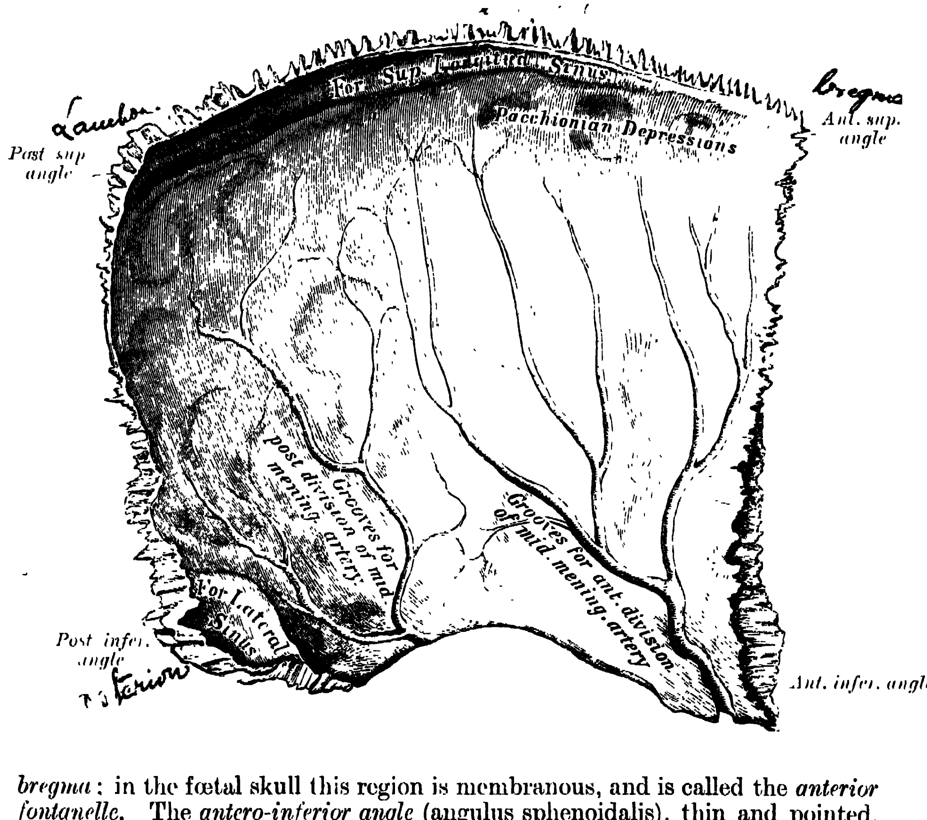
affords attachment to the Temporal muscle. At the back part of the superior border, close to the sagittal suture, is the *parietal foramen* (foramen parietale), which transmits a vein to the superior longitudinal sinus, and sometimes a small branch of the occipital artery. It is not constantly present, and its size varies considerably.

The *internal surface* (fig. 289) is concave; it presents depressions corresponding to the cerebral convolutions, and numerous furrows for the ramifications of the middle meningeal artery; the latter run upwards and backwards from the antero-inferior angle, and from the central and posterior part of the lower border. Along the upper margin is a shallow groove, which, together with that on the opposite parietal, forms a channel (sulcus sagittalis) for the superior longitudinal sinus; the edges of the sulcus afford attachment to the falx cerebri. Near the groove are seen several depressions, best marked in the skulls of old persons, for the Pacchionian bodies. The internal opening of the parietal foramen is also seen when that aperture exists.

The *superior border* (margo sagittalis), the longest and thickest, is dentated and articulates with its fellow of the opposite side, forming the sagittal suture. The *inferior border* (margo squamosus) is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squamous portion of the temporal; the posterior part is thick and serrated for articulation with the mastoid portion of the temporal. The *anterior border* (margo frontalis) is deeply serrated, and bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming one half of the *coronal suture*. The *posterior border* (margo occipitalis), deeply denticulated, articulates with the occipital, forming one half of the *lambdoid suture*.

The *antero-superior angle* (angulus frontalis), thin and pointed, corresponds with the union of the sagittal and coronal sutures; this point is named the

FIG. 289.—Left parietal bone. Internal surface.



bregma; in the fœtal skull this region is membranous, and is called the *anterior fontanelle*. The *antero-inferior angle* (angulus sphenoidalis), thin and pointed, is received into the interval between the frontal and the great wing of the sphenoid. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. The *postero-superior angle* (angulus occipitalis) corresponds with the point of junction of the sagittal and lambdoid sutures—a point which is termed the *lambda*; in the fœtus this part of the skull is membranous, and is called the *posterior fontanelle*. The *postero-inferior angle* (angulus mastoideus) articulates with the occipital and with the mastoid portion of the temporal, and presents on its inner surface a broad, shallow groove which lodges part of the lateral sinus. The point of union of this angle with the occipital and the mastoid part of the temporal is named the *asterion*.

Ossification.—The parietal bone is ossified in membrane from a single centre, which appears at the parietal eminence about the seventh or eighth

week of fœtal life. Ossification gradually extends in a radial manner from the centre towards the margins of the bone; the angles are consequently the parts last formed, and it is here that the fontanelles exist. Occasionally the parietal bone is divided into two parts, upper and lower, by an antero-posterior suture

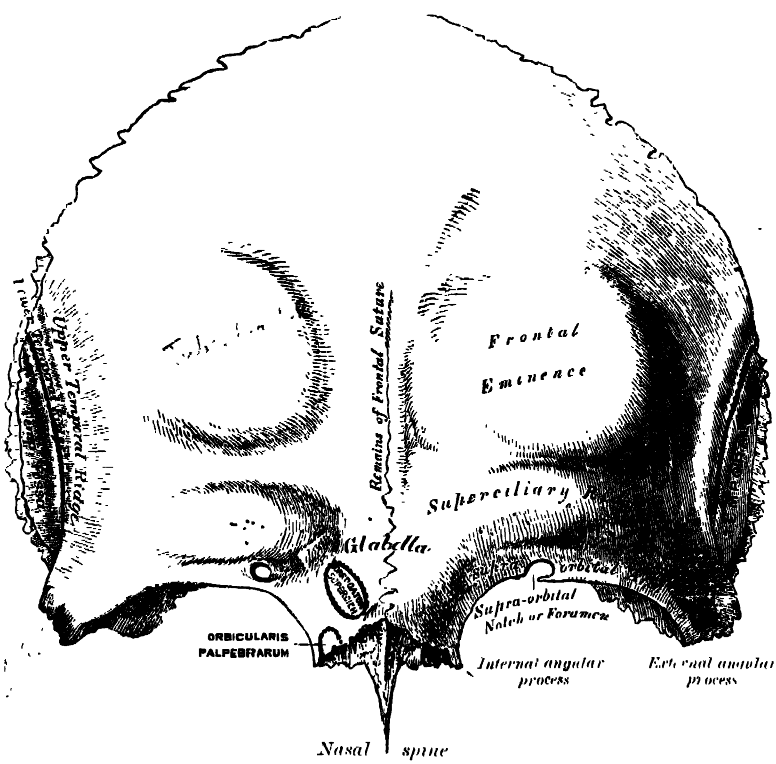
Articulations.—The parietal articulates with five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

The Frontal Bone

The **frontal bone** (os frontale) resembles a cockle-shell in form, and consists of two portions—a *frontal* or *vertical* portion corresponding with the region of the forehead; and an *orbital* or *horizontal* portion, which enters into the formation of the roofs of the orbits and nasal fossæ.

Frontal or vertical portion (squama frontalis).—The *external surface* (fig. 290) of this portion is convex and usually exhibits, in the lower part of the middle line, the remains of the *frontal* or *metopic suture*; in infancy this *suture* divides the bone into right and left halves, a condition which may

Fig. 290.—Frontal bone. Outer surface.



persist throughout life. On either side of this suture, a little more than an inch above the supra-orbital margin, is a rounded elevation, the *frontal eminence* (tuber frontale). These eminences vary in size in different individuals, are occasionally unsymmetrical, and are especially prominent in young skulls; the surface of the bone above them is smooth, and covered by the aponeurosis of the Occipito-frontalis. Below the frontal eminences, and separated from them by a shallow groove, are two arched elevations, the *superciliary ridges* (arcus superciliares); these are prominent internally, and are joined across the middle line by a smooth elevation named the *glabella*. These ridges are larger in the male than in the female, and their degree of prominence depends to

some extent on the size of the frontal air sinuses,* but it must be noted that prominent ridges are occasionally associated with small air sinuses and *vice versa*. Beneath each superciliary ridge is a curved and prominent margin, the *supra-orbital margin* (margo supraorbitalis), which forms the upper boundary of the base of the orbit, and separates the frontal from the orbital portion of the bone. The outer part of this margin is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the inner part is rounded. At the junction of its inner and middle thirds is a notch, sometimes converted into a foramen, the *supra-orbital notch* or *foramen* (incisura sive foramen supraorbitalis), which transmits the supra-orbital vessels and nerve. A small aperture in the upper part of the notch transmits a vein from the diploë to join the supra-orbital vein. The supra-orbital margin terminates externally in the *external angular process*, and internally in the *internal angular process*. The external angular process (processus zygomaticus) is strong, prominent, and articulates with the malar bone. Running upwards and backwards from this process is a well-marked ridge, the *temporal ridge* (linea temporalis); this ridge divides into the *upper* and *lower temporal lines*, which are continuous, in the articulated skull, with the corresponding lines on the parietal bone. The area below and behind the temporal ridge forms the anterior part of the temporal fossa, and gives origin to the Temporal muscle. The internal angular processes descend to a lower level than the external, and articulate with the lachrymal bones; between them is a rough, uneven interval, the *nasal notch*, which articulates on either side of the middle line with the nasal bone, and laterally with the frontal process of the maxilla. The term *nasion* is applied to the middle of the fronto-nasal suture. From the centre of the notch a process, the *nasal process*, projects downwards and forwards beneath the nasal bones and frontal processes of the maxillæ, and supports the bridge of the nose. The nasal process terminates below in a sharp spine, the *nasal spine*, and on either side of this is a small grooved surface which enters into the formation of the roof of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the crest of the nasal bones and behind with the perpendicular plate of the ethmoid.

The *internal surface* (fig. 291) of the frontal portion is concave and presents in the upper part of the middle line a vertical groove, the *sulcus sagittalis*, the edges of which unite below to form a ridge, the *frontal crest* (crista frontalis); the sulcus lodges the superior longitudinal sinus, while its margins and the crest afford attachment to the falx cerebri. The crest ends below in a small notch which is converted into a foramen, the *foramen cæcum*, by articulation with the ethmoid. This foramen varies in size in different subjects, and is frequently impervious; when open, it transmits a vein from the nose to the superior longitudinal sinus. On either side of the middle line the bone presents depressions for the convolutions of the brain, and numerous small furrows for the anterior branches of the middle meningeal arteries. Several small, irregular fossæ may also be seen on either side of the sulcus sagittalis, for the reception of the Pacchionian bodies.

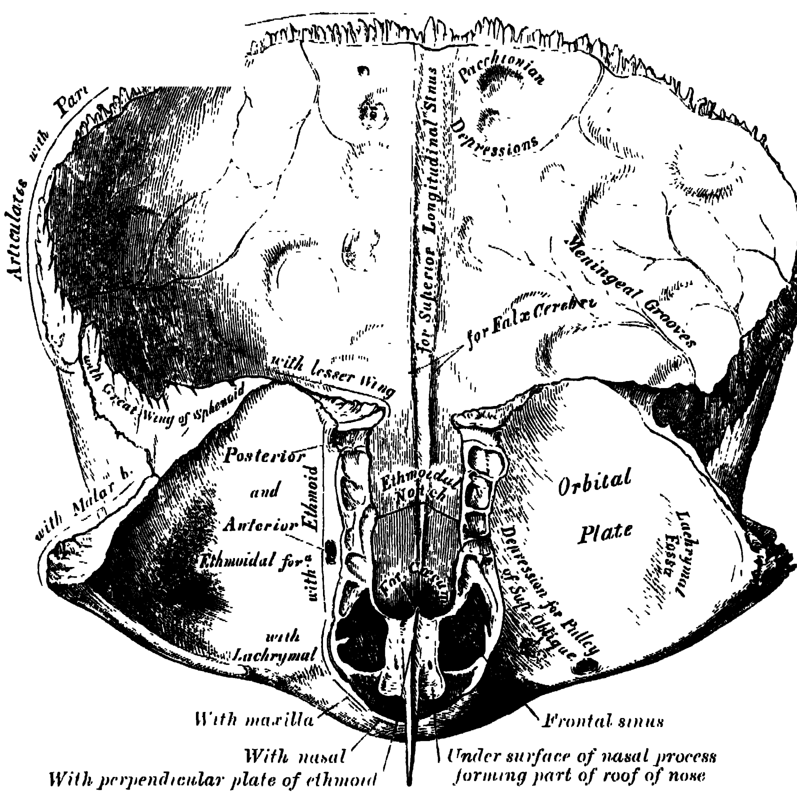
Orbital or horizontal portion (pars orbitalis).—This portion consists of two thin triangular plates, the *orbital plates*, which form the vaults of the orbits, and are separated from one another by a median gap, the *ethmoidal notch*.

The *inferior surface* (fig. 291) of each orbital plate is smooth and concave, and presents, under cover of the external angular process, a shallow depression, the *lachrymal fossa* (fossa glandulæ lacrimalis), for the lachrymal gland; near the internal angular process is a depression, the *fovea trochlearis*, for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eyeball. The *superior surface* is convex, and marked by depressions for the convolutions of the frontal lobes of the brain, and faint grooves for the meningeal branches of the ethmoidal arteries.

* Some confusion is occasioned to students commencing the study of anatomy by the name 'sinus' having been given to two different kinds of space connected with the skull. It may be as well, therefore, to state here that the 'sinuses' in the interior of the cranium which produce the grooves on the inner surfaces of the bones are venous channels which convey the blood from the brain, while the 'sinuses' external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nasal cavities, and contain air.

The *ethmoidal notch* (incisura ethmoidalis) separates the two orbital plates; it is quadrilateral, and filled up, in the articulated skull, by the cribriform plate of the ethmoid. The margins of the notch present several half-cells which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the ethmoidal air-cells. Two grooves cross these edges transversely; they are converted into the *anterior* and *posterior ethmoidal canals* by the ethmoid bone, and open on the inner wall of the orbit. The anterior canal transmits the nasal nerve and anterior ethmoidal vessels; the posterior, the posterior ethmoidal vessels. In front of the ethmoidal notch, on either side of the nasal spine, are the openings of the *frontal air sinuses*. These are two irregular cavities, which extend backwards, upwards and outwards, for a variable distance between the two tables of the skull, and are separated from one another by a thin bony septum, which often deviates to one or other side, with the result that the sinuses are rarely symmetrical. Absent at birth, they

FIG. 291.—Frontal bone. Inner surface.

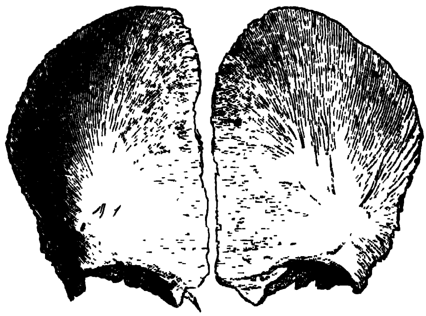


are usually fairly well developed between the ninth and twelfth years, but only reach their full size after puberty. They vary in size in different persons, and are larger in men than in women. Aldren Turner (*The Accessory Sinuses of the Nose*, 1901) gives the following measurements for a sinus of average size: height, 1¼ in.; breadth, 1 in.; depth from before backwards, 1 in. They are lined by mucous membrane, and each communicates with the corresponding nasal fossa by means of a passage called the *infundibulum*.

The *border of the vertical portion* is thick, strongly serrated, bevelled at the expense of the inner table above, where it rests upon the parietal bones, and at the expense of the outer table on either side, where it receives the lateral pressure of those bones; this border is continued below into a triangular, rough surface, which articulates with the great wing of the sphenoid. The *posterior borders of the orbital plates* are thin, serrated, and articulate with the lesser wings of the sphenoid.

Structure.—The frontal portion and external angular processes are very thick, consisting of diploic tissue contained between two compact laminæ; in the regions described above the diploic tissue is replaced by the frontal air sinuses. The orbital portion is thin, translucent, and composed entirely of compact tissue; hence the facility with which instruments can penetrate the cranium through this part of the orbit; when the frontal sinuses are exceptionally large they may extend backwards for a considerable distance between the two tables of the orbital portion.

Fig. 292.—Frontal bone at birth. Ossified from two primary centres.



Ossification (fig. 292).—The frontal bone is ossified in membrane from *two primary* centres, one for each lateral half, which appear about the seventh week of fœtal life, above the orbital arches. From each of these centres ossification extends upwards to form the corresponding half of the frontal portion, and backwards to form the orbital plate. The nasal spine is ossified from a pair of *secondary* centres, one on either side of the middle line; and similar centres appear in the regions of the internal and external angular processes. At birth the bone consists of two pieces, which afterwards become united, along the middle line, by the *metopic* suture which runs from the vertex of the bone to the root of the nose. This suture usually becomes obliterated within a few years after birth; but it occasionally persists throughout life.

Articulations.—The frontal articulates with twelve bones: the sphenoid, the ethmoid, the two parietals, the two nasals, the two maxillæ, the two lachrymals, and the two malars.

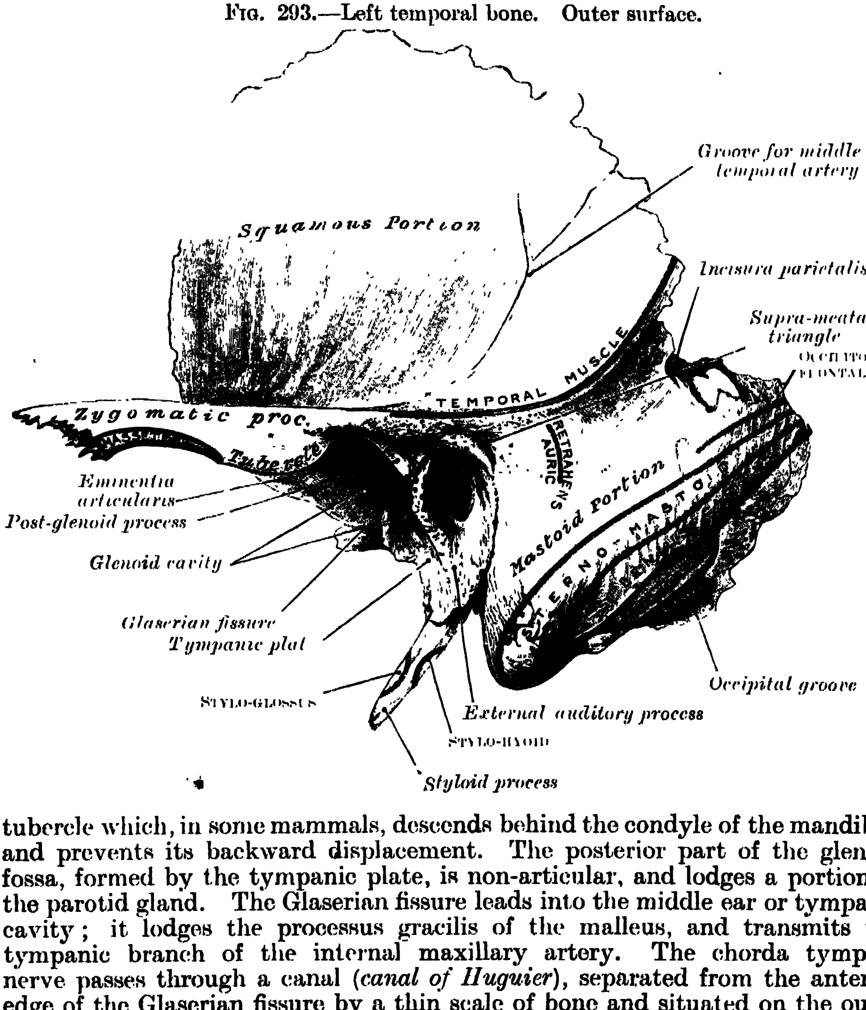
The Temporal Bones

The **temporal bones** (ossa temporalia) are situated at the sides and base of the skull. Each consists of four parts, viz. the *squamous* or *squamo-zygomatic*, the *petro-mastoid*, the *tympanic plate*, and the *styloid process*.

The **squamous portion** (squama temporalis), the anterior and upper part of the bone, is scale-like, thin and translucent. Its *outer surface* (fig. 293) is smooth and convex; it affords attachment to the Temporal muscle, and forms part of the temporal fossa; on its hinder part is a vertical groove for the middle temporal artery. A curved ridge, the *temporal ridge*, or *supra-mastoid crest*, runs backwards and upwards across its posterior part; it serves for the attachment of the temporal fascia, and limits the origin of the Temporal muscle. The boundary between the squamous and mastoid portions of the bone, as indicated by traces of the original suture, lies about half an inch below this ridge. Projecting from the lower part of the squamous portion is a long, arched process, the *zygomatic process* (processus zygomaticus). This process is at first directed outwards, its two surfaces looking upwards and downwards; it then appears as if twisted inwards upon itself, and runs forwards, its surfaces now looking inwards and outwards. The superior border of the process is long, thin, and sharp, and serves for the attachment of the temporal fascia; the inferior, short, thick, and arched, has attached to it some fibres of the Masseter. The outer surface is convex and subcutaneous; the inner is concave, and affords attachment to the Masseter. The extremity is deeply serrated and articulates with the malar bone. The zygomatic process is connected to the squamous portion by two *roots*—anterior and posterior. The anterior root, continuous with the lower border, is short but broad and strong; it is directed inwards and terminates in a rounded eminence, the *eminentia articularis* (tuberculum articulare). This eminence forms the front boundary of the glenoid fossa, and in the recent state is covered with cartilage. In front of the articular eminence is a small triangular area which assists in forming the zygomatic fossa; this area is separated from the outer surface of the squamous portion by a ridge which is continuous posteriorly with the anterior root of the zygoma, and anteriorly, in the articulated

skull, with the infra-temporal crest on the greater wing of the sphenoid. The posterior root, a prolongation of the upper border, is strongly marked; it runs backwards above the external auditory meatus, and is continuous with the *supra-mastoid crest* already referred to. At the junction of the anterior root with the zygomatic process is a projection, called the *tubercle*, for the attachment of the external lateral ligament of the temporo-mandibular joint; and behind the anterior root is an oval depression, forming part of the glenoid fossa, for the reception of the condyle of the mandible. The *glenoid fossa* (fossa mandibularis) is bounded, in front, by the eminentia articularis; behind, by the *tympanic plate* which separates it from the external auditory meatus; it is divided into two parts by a narrow slit, the *Glaserian fissure* (fissura petro-tympanica). The anterior part, formed by the squamous portion of the bone, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the mandible. Behind this part of the fossa is a small conical eminence, the *post-glenoid process*; this is the representative of a prominent

FIG. 293.—Left temporal bone. Outer surface.



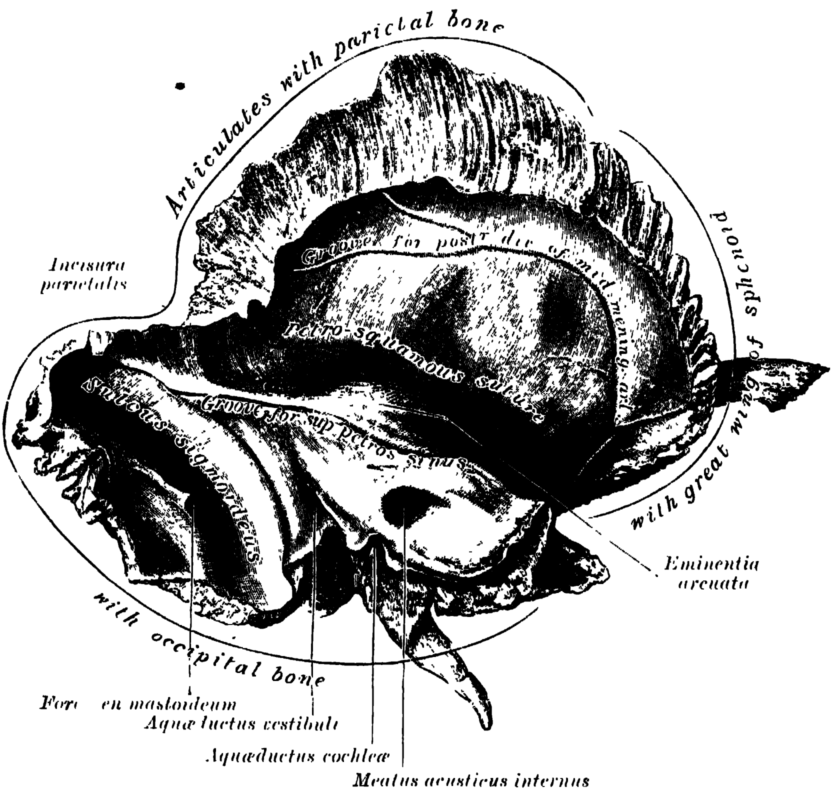
tubercle which, in some mammals, descends behind the condyle of the mandible, and prevents its backward displacement. The posterior part of the glenoid fossa, formed by the tympanic plate, is non-articular, and lodges a portion of the parotid gland. The Glaserian fissure leads into the middle ear or tympanic cavity; it lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a canal (*canal of Huguier*), separated from the anterior edge of the Glaserian fissure by a thin scale of bone and situated on the outer side of the Eustachian tube, in the retiring angle between the squamous and petrous portions of the temporal. This thin scale of bone is derived from the tegmen tympani, and forms the greater part of the outer wall of the bony portion of the Eustachian tube. Between the posterior wall of the external auditory meatus and the posterior root of the zygoma is the area called the *suprameatal triangle* of Macewen, through which an instrument may be pushed into the mastoid antrum.

The *internal surface* of the squamous portion (fig. 294) is concave; it presents depressions corresponding to the convolutions of the temporal lobe of the brain, and grooves for the branches of the middle meningeal artery.

The *superior border* is thin, and bevelled at the expense of the internal table, so as to overlap the lower border of the parietal bone, forming with it the squamous suture. The *antero-inferior border* is thick, serrated, and bevelled at the expense of the inner table above and of the outer below, for articulation with the greater wing of the sphenoid. Posteriorly, the superior border forms an angle (*incisura parietalis*) with the mastoid portion of the bone.

The **petro-mastoid portion** consists of (*a*) the *mastoid process*, a prominent, nipple-like mass behind the external auditory meatus; and (*b*) the *petrous portion*, which is pyramidal in shape, and projects inwards and forwards to form part of the floor of the skull.

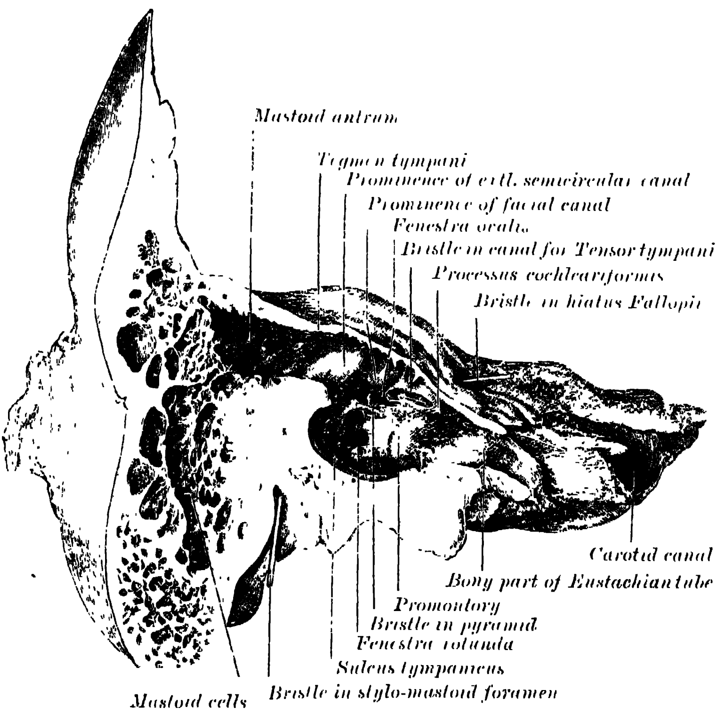
Fig. 294.—Left temporal bone. Inner surface.



The **mastoid portion** (pars mastoidea) forms the posterior part of the bone. Its *outer surface* (fig. 293) is rough, and gives attachment to the Occipito-frontalis and Retrahens auriculam. It is perforated by numerous foramina; one of these, of large size, situated near the posterior border, is termed the *foramen mastoideum*; it transmits a vein to the lateral sinus and a small branch of the occipital artery to the dura mater. The position and size of this foramen are very variable; it is not always present; sometimes it is situated in the occipital bone, or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the *mastoid process* (processus mastoideus), the size and form of which vary somewhat; it is larger in the male than in the female. This process serves for the attachment of the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid. On the inner side of the process is a deep groove, the *digastric fossa* (incisura mastoidea), for the attachment of the Digastric; internal to this is a shallow furrow, the *occipital groove*, which lodges the occipital artery.

The *inner surface* of the mastoid portion presents a deep, curved groove, the *sulcus sigmoideus*, which lodges part of the lateral sinus; in it may be seen the opening of the mastoid foramen. The groove for the lateral sinus is separated from the innermost of the mastoid air-cells by only a thin lamina of bone, and even this may be partly deficient. A section of the mastoid process (fig. 295) shows it to be hollowed out into a number of spaces, the *mastoid cells* (cellulæ mastoideæ), which exhibit the greatest possible variety as to their size and number. At the upper and front part of the bone they are large and irregular and contain air, but towards the lower part of the bone they diminish in size, while those at the apex of the process are frequently quite small and contain marrow. Occasionally they are entirely absent, and the mastoid is then solid throughout. In addition to these a large irregular cavity is situated at the upper and front part of the bone. It is called the *mastoid antrum* (antrum tympanicum), and must be distinguished from the mastoid cells, though it communicates with them. Like the mastoid cells it is filled with air and lined by a prolongation of the mucous membrane of the tympanic cavity, with which

Fig. 295.—Coronal section of right temporal b



it communicates. The mastoid antrum is bounded above by a thin plate of bone, the *tegmen tympani*, which separates it from the middle fossa of the base of the skull; below by the mastoid process; externally by the squamous portion of the bone just below the supra-mastoid crest, and internally by the external semicircular canal of the internal ear which projects into its cavity. It opens in front into that portion of the tympanic cavity which is known as the *attic* or *epitympanic recess*.

The mastoid antrum is a cavity of some considerable size at the time of birth, and is derived, together with the tympanic cavity and the Eustachian tube, from the inner part of the first visceral cleft. The mastoid air-cells may be regarded as diverticula from the antrum, and begin to appear at or before birth; by the fifth year they are well marked, but their development is not completed until towards puberty.

Applied Anatomy.—In consequence of the direct continuity which exists between the tympanic cavity and mastoid antrum, inflammation of the lining membrane of the

former cavity is always associated with a similar condition in the latter, and may easily spread thence into the mastoid air-cells, leading to caries and necrosis of their walls and the risk of transference of the inflammation to the lateral sinus or brain. The mastoid antrum in fact forms a reservoir for pus which, if unable to drain away, may set up serious and often fatal intracranial complications.

The *superior border* of the mastoid portion is broad and serrated, for articulation with the postero-inferior angle of the parietal. The *posterior border*, also serrated, articulates with the inferior border of the occipital between the lateral angle and jugular process. Anteriorly the mastoid portion is fused with the descending process of the squamous portion above, and below it enters into the formation of the external auditory meatus and the cavity of the tympanum.

The **petrous portion** (pars petrosa or pyramis), so named from its extreme density and hardness, is pyramidal and wedged in at the base of the skull between the sphenoid and occipital bones. Directed inwards, forwards, and a little upwards, it presents for examination a base, an apex, three surfaces, and three borders, and contains, in its interior, the essential parts of the organ of hearing.

The *base* is fused with the internal surfaces of the squamous and mastoid portions.

The *apex* (apex pyramidis), rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal, and forms the postero-external boundary of the foramen lacerum medium.

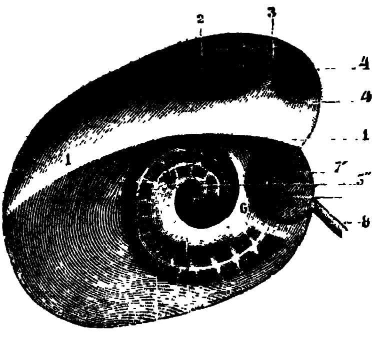
The *anterior surface* (fig. 294) forms the posterior part of the middle fossa of the base of the skull. This surface is continuous with the inner surface of the squamous portion, to which it is united by the *petro-squamous suture*, remains of which are distinct even at a late period of life. It is marked by depressions for the convolutions of the brain, and presents six points for examination: (1) an eminence (*eminentia arcuata*) near the centre, which indicates the situation of the superior semicircular canal; (2) in front of and a little to the outer side of this eminence a depression, indicating the position of the tympanic cavity: here the layer of bone which separates the tympanic from the cranial cavity is extremely thin, and is known as the *tegmen tympani*; (3) a shallow groove, sometimes double, leading outwards and backwards to an oblique opening, the *hiatus Fallopii* (hiatus canalis facialis), for the passage of the large superficial petrosal nerve and the petrosal branch of the middle meningeal artery; (4) a smaller opening, occasionally seen, external to the last, for the passage of the small superficial petrosal nerve; (5) near the apex of the bone, the termination of the carotid canal, the wall of which in this situation is deficient in front; (6) above this canal a shallow depression (impressio trigemini) for the reception of the Gasserian ganglion.

The *posterior surface* forms the front part of the posterior fossa of the base of the skull, and is continuous with the inner surface of the mastoid portion. It presents three points for examination. (1) Near the centre is a large orifice, the *meatus acusticus internus*, the size of which varies considerably; its margins are smooth and rounded, and it leads into a short canal, about one-third of an inch in length, which runs directly outwards. It transmits the seventh and eighth cranial nerves and the auditory branch of the basilar artery. This canal is closed externally by a vertical plate, the *lamina cribrosa*, which is divided by a horizontal crest, the *crista falciformis*, into two unequal portions (fig. 296). Each portion is further subdivided by a vertical ridge into an anterior and a posterior part. The portion beneath the crista falciformis presents three sets of foramina; one group, just below the posterior part of the crest, situated in the *area cribrosa media*, consists of a number of small openings for the nerves to the saccule; below and posterior to this is the *foramen singulare*, or opening for the nerve to the posterior semicircular canal; in front of and below the first is the *tractus spiralis foraminosus*, consisting of a number of small spirally arranged openings, which encircle the *canalis centralis cochleæ* and transmit the nerves to the cochlea. The portion above the crista presents behind the *area cribrosa superior*, pierced by a series of small openings, for the

passage of filaments to the utricle and the superior and external semicircular canals, and, in front, the *area facialis*, with one large opening, the commencement of the *aquæductus Fallopii* (canalis facialis), for the passage of the facial nerve. (2) Behind the meatus acusticus is a small slit almost hidden by a thin plate of bone, leading to a canal, the *aquæductus vestibuli*, which transmits the *ductus endolymphaticus* together with a small artery and vein. (3) In the interval between these two openings, but above them, is an irregular depression which lodges a process of the dura mater and transmits a small vein. In the infant this depression is represented by a large fossa, the *fossa subarcuata*, which extends backwards as a blind tunnel under the superior semicircular canal.

The *inferior surface* (fig. 297) is rough and irregular, and forms part of the exterior of the base of the skull. It presents eleven points for examination: (1) near the apex a rough surface, quadrilateral in form, which serves partly for the attachment of the Levator palati and the cartilaginous portion of the Eustachian tube, and partly for connection with the basilar process of the occipital bone through the intervention of the dense fibrous tissue; (2) behind this the large circular aperture of the *carotid canal* (canalis caroticus), which ascends at first vertically, and then, making a bend, runs horizontally forwards and inwards; it transmits into the cranium the internal carotid artery, and the carotid plexus of nerves; (3) to the inner side of the opening for the carotid canal and close to the posterior border, in front of the jugular fossa, is a triangular depression, on the floor of which is a small opening, the *aquæductus cochleæ*, which lodges a tubular prolongation of the dura mater and transmits a vein from the cochlea to join the internal jugular; (4) behind these openings a deep depression, the *jugular fossa*, of variable depth and size in different skulls; it lodges the bulb of the internal jugular vein, and, with a similar depression on the front of the jugular process of the occipital bone, forms the jugular foramen; (5) a small foramen for the passage of Jacobson's nerve (the tympanic branch of the glosso-pharyngeal); this foramen is seen in the bony ridge dividing the carotid canal from the jugular fossa; (6) a small foramen in the outer part of the jugular fossa, for the entrance of the auricular branch of the pneumogastric nerve (Arnold's nerve); (7) behind the jugular fossa, a quadrilateral area, the *jugular surface*, which is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone; (8) the *vaginal process*, a sheath-like plate of bone, which extends backwards from the carotid canal and divides behind into two laminæ; the outer lamina is continuous with the tympanic plate, the inner with the outer margin of the jugular surface; between these laminæ is (9) the *styloid process*, a sharp spine, about an inch in length; (10) the *stylo-mastoid foramen*, a rather large orifice, placed between the styloid and mastoid processes; it is the termination of the aquæductus Fallopii, and transmits the facial nerve and stylo-mastoid artery; (11) the *auricular fissure* (fissura tympanomastoidea), situated between the tympanic plate and mastoid process, for the exit of the auricular branch of the pneumogastric nerve.

Fig. 296. — Diagrammatic view of the fundus of the right internal auditory meatus. (Testut.)

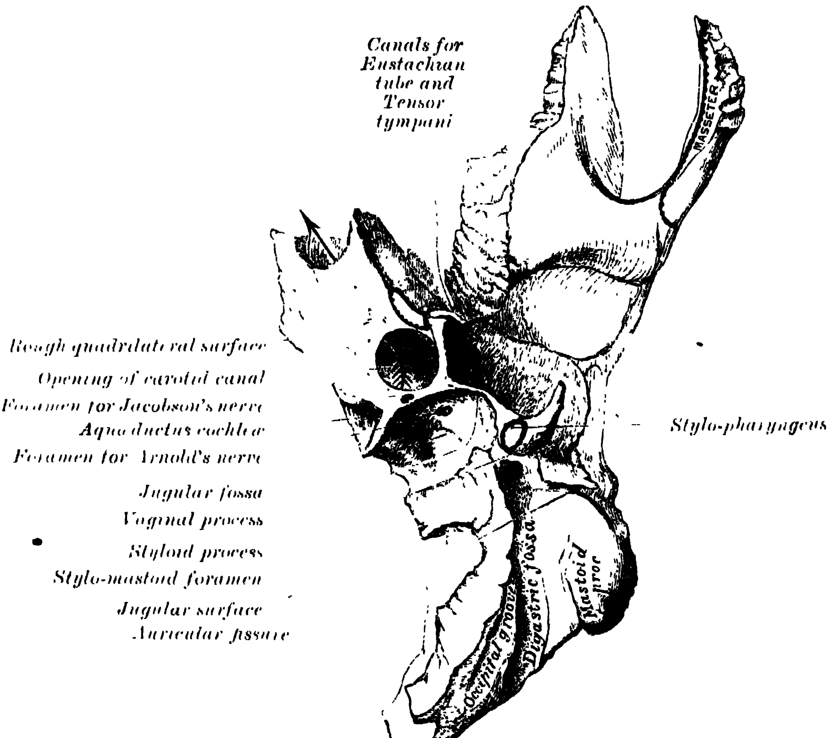


1. Crista falciformis. 2. Area facialis, with (2') Internal opening of the aquæductus Fallopii 3. Ridge separating the area facialis from the area cribrosa superior. 4. Area cribrosa superior, with (4') Openings for nerve filaments. 5. Anterior inferior cribriform area, with (5') the tractus spiralis foraminosus, and (5'') the canalis centralis of the cochlea. 6. Ridge separating the tractus spiralis for from the area cribrosa media. 7. Area media, with (7') Orifices for nerves to 8. Foramen singulare.

The *superior border*, the longest, is grooved for the superior petrosal sinus, and gives attachment to the tentorium cerebelli; at its inner extremity is a notch, in which the fifth cranial nerve lies. The *posterior border* is intermediate in length between the superior and the anterior. Its inner half is marked by

a sulcus, which forms, with a corresponding sulcus on the occipital bone, the channel for the inferior petrosal sinus. Its outer half presents an excavation – the *jugular fossa* –which, with a similar notch on the occipital, forms the jugular foramen. A projecting eminence occasionally stands out from the centre of the notch, and divides the foramen into two. The *anterior border* is divided into two parts—an outer joined to the squamous portion by a suture (*petro-squamous*), the remains of which are more or less distinct; an inner, free, which articulates with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions are seen two canals, one above the other, and separated by a thin plate of bone, the *processus cochleariformis* (septum canalis musculotubarii); they both lead into the tympanum. The upper one (semicanalis m. tensoris tympani) transmits the Tensor tympani, the lower one (semicanalis tubæ auditivæ) forms the bony part of the Eustachian tube.

FIG. 297.—Left temporal bone. Inferior surface.



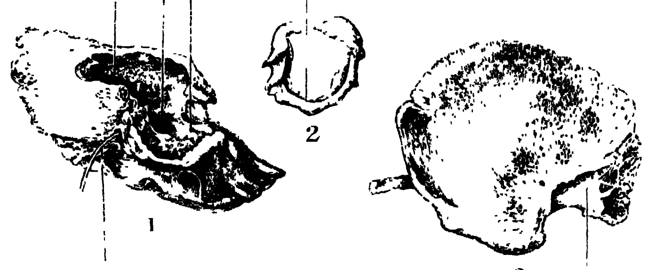
The tympanic cavity and auditory ossicles, and the internal ear, are described with the organ of hearing.

The **tympanic plate** (pars tympanica) consists of a curved plate of bone lying below the squamous portion and in front of the mastoid process. Its *postero-superior surface* is concave, and forms the anterior wall, the floor, and part of the posterior wall of the bony external auditory meatus. Internally, it presents a narrow furrow, the *sulcus tympanicus*, for the attachment of the membrana tympani. Its *antero-inferior surface* is quadrilateral and slightly concave; it constitutes the posterior boundary of the glenoid cavity, and is in contact with the retro-mandibular part of the parotid gland. Its *outer border* is free and rough; it is named the *external auditory process*, and gives attachment to the cartilaginous part of the external auditory meatus. Internally, the tympanic plate is fused with the petrous portion, and appears in the retreating angle between it and the squamous portion, where it lies below and to the outer side of the orifice of the Eustachian tube. Posteriorly, it blends with the squamous and mastoid parts, and forms the anterior boundary

of the auricular fissure. Its *antero-superior border* fuses externally with the back of the post-glenoid process, while internally it bounds the Glaserian fissure. The *lower border* is thin and sharp at its inner part; its outer part splits to enclose the root of the styloid process, and is therefore named the *vaginal process*. The central portion of the tympanic plate is thin, and in a considerable percentage of skulls is perforated by a hole, the *foramen of Huschke*.

The *external auditory meatus* (meatus acusticus externus) is directed inwards and slightly forwards: at the same time it forms a slight curve, so that the floor of the canal is convex upwards. It measures about three-quarters of an inch in length, and presents an oval or elliptical shape—its long axis being directed downwards and slightly backwards. As has been pointed out, its anterior wall, its floor, and the lower part of its posterior wall are formed by the tympanic plate; the roof and upper part of the posterior wall are constituted by the squamous portion. Its inner end is closed, in the recent state, by the membrani tympani; the upper limit of its outer orifice is formed by the posterior root of the zygoma, immediately below which there is sometimes seen a small spine, the *suprameatal spine*, situated at the upper and posterior part of the orifice.

FIG. 298.—The three principal parts of the temporal bone at birth.



1. Outer surface of petro-mastoid part. 2. Outer surface of tympanic 3. Inner surface of

The **styloid process** is slender, pointed, and of varying length: it projects downwards and forwards, from the under surface of the temporal bone, beyond the tympanic plate. Its proximal part (*tympano-hyal*) is ensheathed by the vaginal process, while its projecting portion (*stylo-hyal*) gives attachment to the stylo-hyoid and stylo-mandibular ligaments, and to the Stylo-glossus, Stylo-hyoid and Stylo-pharyngeus muscles. The stylo-hyoid ligament extends from the apex of the process to the lesser cornu of the hyoid bone, and may undergo partial or complete ossification.

Structure.—The structure of the squamous portion is like that of the other cranial bones: the mastoid portion is cellular, and the petrous portion dense and hard.

Ossification.—The temporal bone is ossified from eight centres, exclusive of those for the internal ear and the tympanic ossicles—viz. one for the squamous portion including the zygoma, one for the tympanic plate, four for the petro-mastoid part, and two for the styloid process. Just before the close of fœtal life (fig. 298) the temporal bone consists of three principal parts. 1. The *squamo-zygomatic* is ossified in membrane from a single nucleus, which appears near the root of the zygoma about the second month. 2. The *petro-mastoid* is developed from four centres, which make their appearance in the cartilaginous ear-capsule about the fifth or sixth month. One (*prootic*) appears in the neighbourhood of the enimentia arcuata, spreads in front and above the internal auditory meatus

and extends to the apex of the bone; it forms part of the cochlea, vestibule, superior semicircular canal, and inner wall of the tympanic cavity. A second (*opisthotic*) appears at the promontory on the inner wall of the tympanum and surrounds the fenestra rotunda; it forms the floor of the tympanum and vestibule, surrounds the carotid canal, invests the outer and lower part of the cochlea, and spreads inwards below the internal auditory meatus. A third (*pterotic*) roofs in the antrum and tympanic cavity; while the fourth (*epiotic*) appears near the posterior semicircular canal and extends to form the mastoid process (Vrolik). 3. The *tympanic ring* is an incomplete circle in the concavity of which is a groove, the *sulcus tympanicus*, for the attachment of the circumference of the membrana tympani. This ring expands to form the tympanic plate, and is ossified in membrane from a single centre which appears about the third month. A fourth part, the *styloid process*, is developed from the proximal part of the cartilage of the second visceral or hyoid arch by two centres: one for the base appears before birth and is termed the *tympano-hyal*: the other, comprising the rest of the process, is named the *stylo-hyal*, and does not appear until after birth. The tympanic ring unites with the squamous portion shortly before birth; the petromastoid and squamous portions join during the first year, and the tympano-hyal portion of the styloid process about the same time (figs. 299 and 300). The stylo-hyal does not unite with the rest of the bone until after puberty, and in some skulls never at all. The chief subsequent changes in the temporal bone apart from increase in size are: (1) The tympanic ring extends outwards and backwards to form the tympanic plate. This extension does not, however, take place at an equal rate all round the circumference of the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the *foramen of Huschke*: this foramen is usually closed about the fifth year, but may persist throughout life. (2) The glenoid cavity is at first extremely shallow, and looks outwards as well as downwards; it becomes deeper and is ultimately directed downwards. Its change in direction is accounted for as follows: The part of the squamous temporal which supports it lies at first *below* the level of the zygoma. As, however, the base of the skull increases in width, this lower part of the squama is directed horizontally inwards to contribute to the middle fossa of the skull, and its surfaces therefore come to look upwards and downwards; the attached portion of the zygomatic arch also becomes everted, and projects like a shelf at right angles to the squama. (3) The mastoid portion is at first quite flat, and the stylo-mastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the air-cells the outer part

FIG. 299.—Temporal bone at birth. Outer aspect.

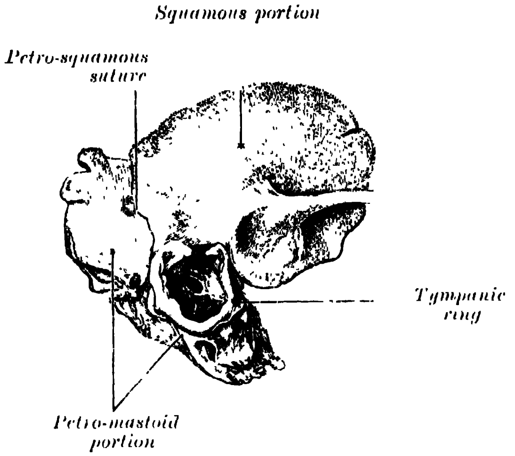


FIG. 300.—Temporal bone at birth. Inner aspect.

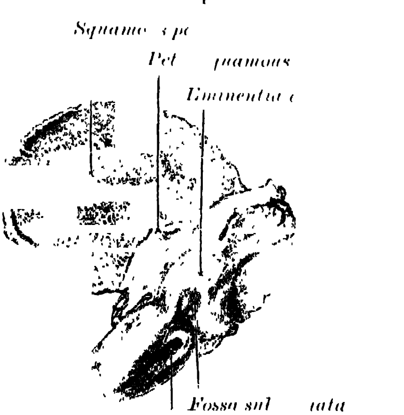


of the mastoid portion grows downwards and forwards to form the mastoid process, and the styloid process and stylo-mastoid foramen now come to lie on the under surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the aqueduct of Fallopius. (4) The downward and forward growth of the mastoid process also pushes forward the tympanic plate, so that the portion of it which formed the original floor of the meatus and contained the foramen of Huschke is ultimately found in the anterior wall. (5) The *fossa subarcuata* becomes filled up and almost obliterated.

Articulations.—The temporal articulates with five bones: occipital, parietal, sphenoid, mandible, and malar.

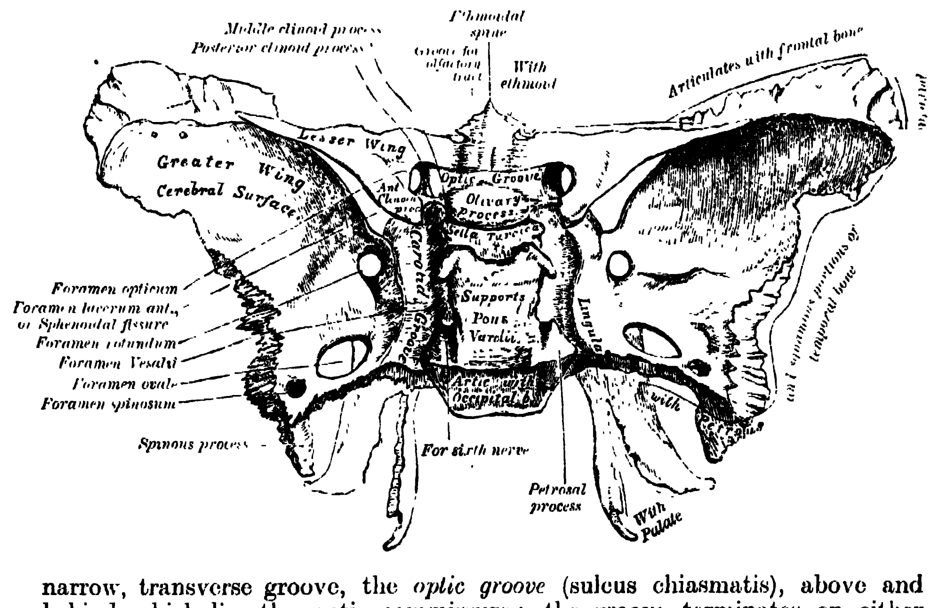
The Sphenoid Bone

The **sphenoid bone** (os sphenoidale) is situated at the base of the skull in front of the temporals and basilar part of the occipital. It somewhat resembles a bat with its wings extended, and is divided into a central portion or body, two greater and two lesser wings extending outwards from the sides of the body, and two pterygoid processes which project from it below.

The **body** (corpus), more or less cubical in shape, is hollowed out in its interior to form two large cavities, the *sphenoidal air sinuses*, which are separated from each other by a septum.

The *superior surface* of the body (fig. 301) presents in front a prominent spine, the *ethmoidal spine*, for articulation with the cribriform plate of the ethmoid; behind this is a smooth surface slightly raised in the middle line, with a depression on either side for the olfactory lobes of the brain. This surface is bounded behind by a ridge, which forms the anterior border of a

FIG. 301.—Sphenoid bone. Upper surface.



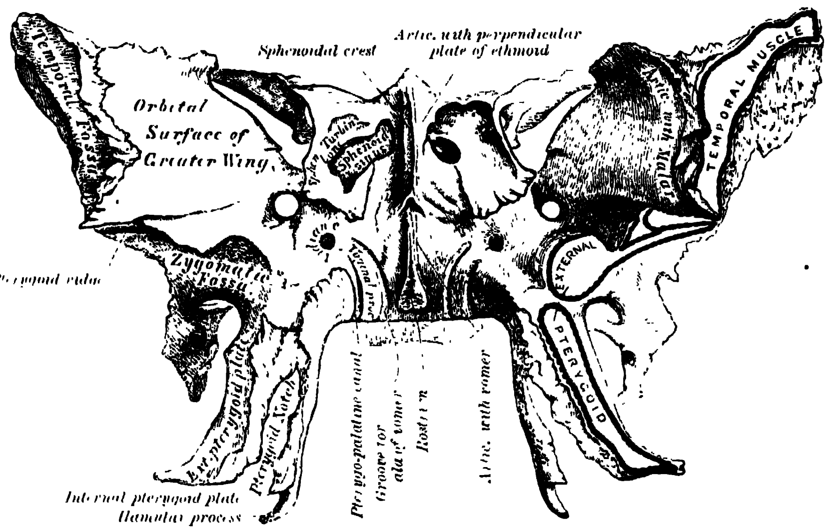
narrow, transverse groove, the *optic groove* (sulcus chiasmatis), above and behind which lies the optic commissure; the groove terminates on either side in the *optic foramen* (foramen opticum) which transmits the optic nerve and ophthalmic artery. Behind the optic groove is an olive-like elevation, the *olivary eminence* (tuberculum sellæ); and still more posteriorly, a deep depression, the *pituitary fossa*, or *sella turcica* (fossa hypophyseos), which lodges the pituitary body. This fossa is bounded in front by two small eminences, one on either side, called the *middle clinoid processes* (processus clinoidei medii), and behind by a square-shaped plate of bone, the *dorsum sellæ*, terminating at its superior angles in two tubercles, the *posterior clinoid processes* (processus clinoidei posteriores), the size and form of which vary considerably in different individuals. The posterior clinoid processes deepen the pituitary fossa, and give attachment to the tentorium cerebelli. On

either side of the dorsum sellæ is a notch for the passage of the sixth nerve, and below it presents a sharp process, the *petrosal process*, which articulates with the apex of the petrous portion of the temporal bone, forming the inner boundary of the foramen lacerum medium. Behind the dorsum sellæ, the bone presents a shallow depression, the *clivus*, which slopes obliquely backwards, and is continuous with the basilar groove of the occipital bone; it supports the upper part of the pons Varolii.

The *lateral surfaces* of the body are united with the greater wings and internal pterygoid plates. Above the attachment of each of the greater wings is a broad groove, curved something like the italic letter *f*; it lodges the internal carotid artery and the cavernous sinus, and is named the *carotid groove* (sulcus caroticus). Along the posterior part of the outer margin of this groove, in the angle between the body and greater wing, is a ridge of bone, called the *lingula*.

The *posterior surface*, quadrilateral in form (fig. 303), is joined, during infancy and adolescence, to the basilar process of the occipital bone by a plate of cartilage. Between the eighteenth and twenty-fifth years this

FIG. 302.—Sphenoid bone. Anterior surface.*



becomes ossified, ossification commencing above and extending downwards, and the two bones then form one piece.

The *anterior surface* of the body (fig. 302) presents, in the middle line, a vertical crest, the *crista sphenoidalis*, which articulates with the perpendicular plate of the ethmoid, and forms part of the septum of the nose. On either side of the crest is an irregular opening leading into the corresponding *sphenoidal air sinus*. These sinuses are two large, irregular cavities hollowed out of the interior of the body of the sphenoid bone, and separated from one another by a bony septum, which is seldom quite vertical, being commonly bent to one or the other side. They vary considerably in form and size,† are seldom symmetrical, and are often partially subdivided by irregular osseous laminæ. Occasionally, they extend into the basilar process of the occipital nearly as far as the foramen magnum. They begin to be developed in the third year, and are of a considerable size by the age of six. They are partially closed, in front and below, by two thin, curved plates of bone, the *sphenoidal turbinated bones* (see p. 236), leaving in the articulated skull a round opening at the upper part of each sinus by which it communicates with the upper and back part of the nose and occasionally with the posterior

* In this figure both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.

† Aldren Turner (*op. cit.*) gives the following as their average measurements: vertical height, ⅞ in.; antero-posterior depth, ⅞ in.; transverse breadth, ⅘ in.

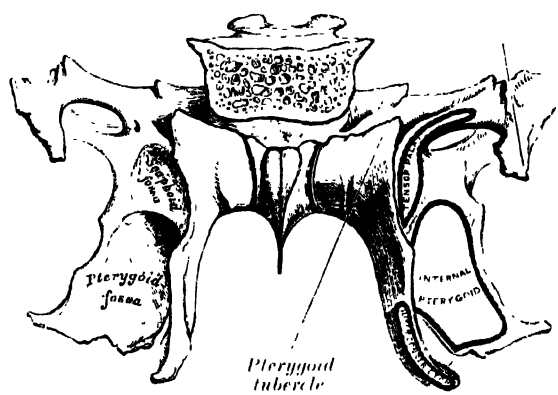
ethmoidal air-cells. The lateral margin of the anterior surface is serrated, and articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin articulates with the orbital process of the palate bone, and the upper with the orbital plate of the frontal bone.

The *inferior surface* presents, in the middle line, a triangular spine, the *rostrum sphenoidale*, which is continuous with the crista sphenoidalis on the anterior surface, and is received in a deep fissure between the alæ of the vomer. On either side of the rostrum is a projecting lamina, the *processus vaginalis*, directed inwards from the base of the internal pterygoid plate, with which it will be described.

The **greater wings**, or ali-sphenoids (alæ magnæ), are two strong processes of bone, which arise from the sides of the body, and are curved in a direction outwards, upwards, and backwards; the posterior part of each projects outwards and backwards as a triangular process which fits into the angle between the squamous and petrous portions of the temporal and presents at its apex a downwardly directed process, the *sphenoidal spine* (spina angularis).

The *superior* or *cerebral surface* of each greater wing (fig. 301) forms part of the middle fossa of the skull; it is deeply concave, and presents depressions for the convolutions of the temporal lobe of the brain. At its anterior and internal part is a circular aperture, the *foramen rotundum*, for the transmission of the second division of the fifth cranial nerve. Behind and external to this

FIG. 303.—Sphenoid bone. Posterior surface.



is a large, oval opening, the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small superficial petrosal nerve.* At the inner side of the foramen ovale, a small aperture, the *foramen Vesalii*, may occasionally be seen opposite the root of the pterygoid process; it opens below near the scaphoid fossa, and transmits a small vein from the cavernous sinus. Lastly, in the posterior angle, near to and in front of the spine, is a short canal, sometimes double, the *foramen spinosum*, which transmits the middle meningeal artery and vein and a recurrent branch from the third division of the fifth cranial nerve.

The *external surface* (fig. 302) is convex, and divided by a transverse ridge, the *infratemporal crest* (crista infratemporalis), into two portions. The superior or larger (facies temporalis), convex from above downwards, concave from before backwards, forms a part of the temporal fossa, and gives attachment to the Temporal muscle. The inferior portion (facies infratemporalis), smaller in size and concave, enters into the formation of the zygomatic fossa, and, together with the infratemporal crest, affords attachment to the External pterygoid muscle. It presents the openings of the foramen ovale and foramen spinosum, and, at its posterior part, the sphenoidal spine, which is frequently grooved on its inner aspect for the chorda tympani nerve. To the sphenoidal

* The small superficial petrosal nerve sometimes passes through a special canal (*canaliculus innominatus* of Arnold) situated on the inner side of the foramen spinosum.

sphenoid

spine are connected the internal lateral ligament of the temporo-mandibular joint and the Tensor palati. Internal to the anterior extremity of the infra-temporal crest is a triangular process which serves to increase the attachment of the External pterygoid; extending downwards and inwards from this process on to the front part of the external pterygoid plate is a ridge which forms the anterior limit of the zygomatic surface, and, in the articulated skull, the posterior boundary of the *pterygo-maxillary fissure*.

The *anterior* or *orbital surface* of the greater wing (facies orbitalis) (fig. 302), smooth, and quadrilateral in shape, is directed forwards and inwards and forms the posterior part of the outer wall of the orbit. It is bounded above by a serrated edge, for articulation with the orbital plate of the frontal; below, by a rounded border, which forms the postero-external boundary of the spheno-maxillary fissure. Internally, it is limited by a sharp margin, which forms the lower boundary of the sphenoidal fissure and has projecting from about its centre a little tubercle of bone, which gives attachment to the inferior head of the External rectus muscle of the eyeball; at the upper part of this margin is a notch for the transmission of a recurrent branch of the lachrymal artery. Externally, it presents a serrated margin for articulation with the malar bone. At the inner and lower part of the anterior surface, immediately below the inner end of the sphenoidal fissure, is a grooved surface, which forms the posterior wall of the spheno-maxillary fossa, and on which the foramen rotundum opens.

Circumference (fig. 301).—Commencing from behind, that portion of the circumference of the greater wing which extends from the body to the spine is irregular. Its inner half forms the anterior boundary of the foramen lacerum medium, and presents the posterior aperture of the Vidian canal for the passage of the Vidian nerve and artery. Its outer half articulates, by means of a synchondrosis, with the petrous portion of the temporal, and between the two bones, on the under surface of the skull, is a furrow, the *sulcus tubæ*, for the lodgment of the cartilaginous part of the Eustachian tube. In front of the spine the circumference presents a concave, serrated edge, bevelled at the expense of the inner table below, and of the outer table above, which articulates with the squamous portion of the temporal bone. At the tip of the great wing is a triangular portion, bevelled at the expense of the internal surface, for articulation with the antero-inferior angle of the parietal bone; this region is named the *pterion*. Internal to this is a triangular, serrated surface, for ~~articulation with the frontal bone~~; this surface is continuous internally with the sharp inner edge, which forms the lower boundary of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

The **lesser wings** or orbitosphenoids (alæ parvæ) are two thin, triangular plates, which arise from the upper and anterior parts of the body, and, projecting transversely outwards, terminate in sharp points (fig. 301). The *superior surface* of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the brain. The *inferior surface* forms the back part of the roof of the orbit, and the upper boundary of the *sphenoidal fissure* (fissura orbitalis superior). This fissure is of a triangular form, and leads from the cavity of the cranium into that of the orbit: it is bounded internally by the body; above, by the lesser wing; below, by the inner margin of the orbital surface of the greater wing; and is completed externally by the frontal bone. It transmits the third, the fourth and the sixth nerves, the three branches of the ophthalmic division of the fifth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The *anterior border* is serrated for articulation with the frontal bone. The *posterior border*, smooth and rounded, is received into the Sylvian fissure of the brain; the inner extremity of this border forms the *anterior clinoid process* (processus clinoideus anterius), which gives attachment to the tentorium cerebelli; it is sometimes joined to the middle clinoid process by a spicule of bone, and when this occurs the termination of the groove for the internal carotid artery is converted into a foramen (*carotico-clinoid*). The lesser wing is connected to the body by two roots, the upper thin and flat, the lower thick and triangular; between the two roots

is the *optic foramen* (foramen opticum), for the transmission of the optic nerve and ophthalmic artery.

The **pterygoid processes** (processus pterygoidei), one on either side, descend perpendicularly from the points where the body and greater wings unite. Each process consists of an internal and an external plate, fused above and in front, but separated below by an angular cleft, the *pterygoid notch* (fissura pterygoidea), the margins of which are rough for articulation with the tuberosity of the palate bone. The two plates diverge behind and enclose between them a V-shaped fossa, the *pterygoid fossa* (fossa pterygoidea), which contains the Internal pterygoid and Tensor palati. Above this fossa is a small, oval, shallow depression, the *fossa scaphoidea*, which gives origin to the Tensor palati. The anterior surface of the pterygoid process is broad and triangular near its root, where it forms the posterior wall of the spheno-maxillary fossa and presents the anterior orifice of the Vidian canal.

The *external pterygoid plate* (lamina lateralis processus pterygoidei) is broad, thin, and everted; its *outer surface* forms part of the inner wall of the zygomatic fossa, and gives attachment to the External pterygoid; its *inner surface* forms part of the pterygoid fossa, and gives attachment to the Internal pterygoid.

The *internal pterygoid plate* (lamina medialis processus pterygoidei) is much narrower and longer than the external; it curves outwards, at its lower extremity, into a hook-like process, the *hamular process* (hamulus pterygoidei), around which the tendon of the Tensor palati muscle glides. The *outer surface* of this plate forms part of the pterygoid fossa, the *inner surface* constitutes the outer boundary of the posterior aperture of the nares. Superiorly the internal pterygoid plate is carried inwards on the under surface of the body as a thin lamina, named the *vaginal process*; which articulates in front with the sphenoidal process of the palate and internally with the ala of the vomer. The angular prominence between the posterior margin of the vaginal process and the inner margin of the scaphoid fossa is named the *pterygoid tubercle*, immediately above which is the posterior opening of the Vidian canal (canalis pterygoideus). On the under aspect of the vaginal process is a furrow, the *sulcus pterygopalatinus*, which is converted into the *pterygo-palatine canal* by the sphenoidal process of the palate bone, and transmits the pterygo-palatine vessels and the pharyngeal nerve. Projecting backwards from near the middle of the posterior edge of the internal pterygoid plate is an angular process, the *processus tubarius*, which supports the pharyngeal end of the Eustachian tube. The pharyngeal aponeurosis is attached to the entire length of the posterior edge of the internal plate, and the Superior constrictor of the pharynx takes origin from its lower third. The anterior margin of the internal pterygoid plate articulates with the posterior border of the vertical plate of the palate.

The **sphenoidal turbinated bones** (conchæ sphenoidales) are two thin, curved plates, situated at the anterior and inferior part of the body of the sphenoid; they exist as separate pieces until puberty, and occasionally are not joined to the sphenoid in the adult. An aperture of variable size exists in the anterior wall of each, and through this the sphenoidal sinus opens into the nasal fossa. Each is irregular in form, and tapers to a point behind, being broader and thinner in front. Its upper surface, which looks towards the cavity of the sinus, is concave; its under surface is convex, and forms part of the roof of the corresponding nasal fossa. Each bone articulates in front with the ethmoid, externally with the palate; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side and the rostrum of the sphenoid on the inner.*

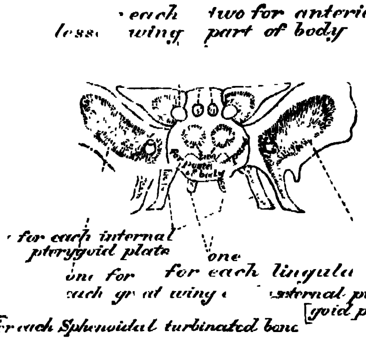
Ossification.—Until the seventh or eighth month of fœtal life the body of the sphenoid consists of two parts—viz. one in front of the olivary eminence, the *pre-sphenoid*, with which the lesser wings are continuous; the other, comprising the sella turcica, the *post-sphenoid*, with which are associated the greater wings

* A small portion of sphenoidal turbinated bone sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above. Cleland, *Roy. Soc. Trans.* 1862.

and pterygoid processes. With the exception of the internal pterygoid plates, the bone is ossified in cartilage. There are fourteen centres in all (fig. 304), six for the pre-sphenoid and eight for the post-sphenoid division.

Pre-sphenoid division.—About the ninth week of fœtal life an ossific centre appears for each of the lesser wings (orbito-sphenoids) just outside the optic foramen. Shortly afterwards two nuclei for the pre-sphenoid part of the body appear on the inner sides of the optic foramina. The sphenoidal turbinated bones are each developed from a centre which makes its appearance about the fifth month;* at birth they consist of small triangular laminæ, and it is not till the third year that they become hollowed out and cone-shaped; about the fourth year they fuse with the lateral masses of the ethmoid, and between the ninth and twelfth years they unite with the sphenoid.

Fig. 304.—Plan of ossification of the sphenoid.



Post-sphenoid division.—The first ossific nuclei are those for the greater wings (ali-sphenoids). They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates also are formed.† Soon after, the centres for the post-sphenoid part of the body appear, one on either side of the sella turcica, and become blended together about the middle of fœtal life. Each internal pterygoid plate (with the exception of its hamular process) is ossified in membrane, and its centre probably appears about the ninth or tenth week; the hamular process becomes chondrified during the third month, and almost at once undergoes ossification (Fawcett, *op. cit.*). The internal joins the external pterygoid plate about the sixth month. About the fourth month a centre appears for each lingula and speedily joins the rest of the bone.

The pre-sphenoid is united to the post-sphenoid about the eighth month, and at birth (fig. 305) the bone consists of three pieces: a central, consisting of the body and lesser wings, and two lateral, each comprising a greater wing and pterygoid process. In the first year after birth the greater wings and body become united, and the orbito-sphenoids extend inwards above the anterior part of the body, and, meeting with each other in the middle line, form an elevated smooth surface, termed the *jugum sphenoidale*. By the twenty-fifth year the sphenoid and occipital are completely fused. Between the pre- and post-sphenoid divisions there are occasionally seen the remains of a canal, the *canalis craniopharyngeus*, through which, in early fœtal life, the pituitary diverticulum (or pouch of Rathke) of the buccal ectoderm is transmitted (see page 155).

Fig. 305.—Sphenoid bone at birth. Posterior aspect.

The sphenoid has attached to it certain intrinsic ligaments, which have received special names. The most important of these are: the *pterygo-spinous*, which stretches between the sphenoidal spine and the external pterygoid plate (see *cervical fascia*); the *interclinoid*, a fibrous process which passes from the anterior to the posterior clinoid process; and the *carotico-clinoid*, which passes from the anterior to the middle clinoid process. These ligaments occasionally ossify, and form adventitious foramina.

* According to Cleland, the sphenoidal turbinated bones are ossified from four distinct centres.

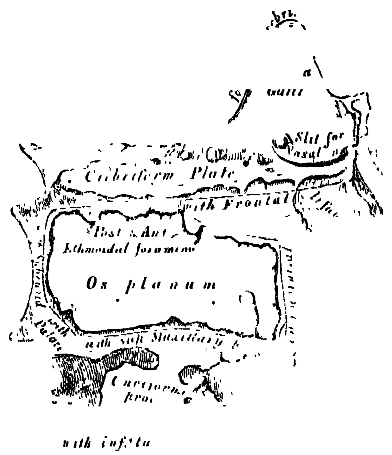
† Fawcett (*Anatomischer Anzeiger*, March 1905) states that the external pterygoid plate is ossified in membrane, and is not a downward continuation of the cartilaginous great wing.

Articulations.—The sphenoid articulates with twelve bones: four single, the vomer, ethmoid, frontal and occipital; and four paired, the parietal, temporal, malar, and palate. The exact extent of articulation with each bone is shown in the accompanying figures.*

THE ETHMOID BONE

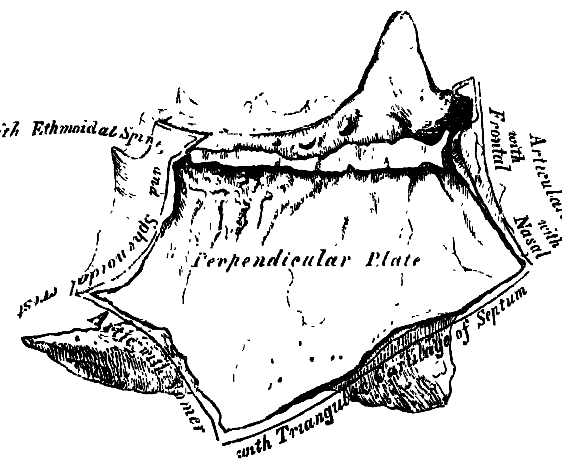
The **ethmoid bone** (os ethmoidale) is an exceedingly light, spongy bone, of a cubical shape; it is situated at the anterior part of the base of the cranium, between the two orbits, at the roof of the nose, and contributes to each of these cavities. It consists of four parts: a horizontal or cribriform plate, which forms part of the base of the cranium; a perpendicular plate, which constitutes part of the nasal septum; and two lateral masses.

FIG. 306.—Ethmoid bone. Outer surface of right lateral mass (enlarged).



The **cribriform plate** (lamina cribrosa) (fig. 306) is received into the ethmoid notch of the frontal bone and roofs in the nasal fossæ. Projecting upwards from the middle line of this plate is a thick, smooth, triangular process, the *crista galli*, so called from its resemblance to a cock's comb. Its base joins the cribriform plate. Its posterior border, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting *alar processes*, which are received into corresponding depressions in the frontal bone and complete the foramen cæcum. Its sides are smooth, and sometimes bulging from the presence of a small air-

FIG. 307. Perpendicular plate of ethmoid (enlarged). Shown by removing the right lateral mass.



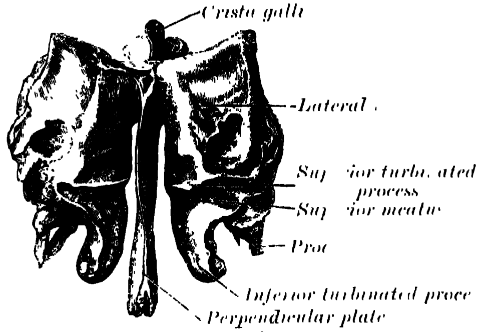
sinus in the interior. On each side of the crista galli, the cribriform plate is narrow and deeply grooved; it supports the bulb of the olfactory lobe of the brain, and is perforated by foramina for the passage of the olfactory nerves. The foramina in the middle of the groove are small and transmit the nerves

* It also sometimes articulates with the tuberosity of the maxilla (see page 242).

to the roof of the nose; those at the inner and outer parts of the groove are larger—the former transmit the nerves to the upper part of the nasal septum, the latter those to the superior turbinated process. At the front part of the cribriform plate, on either side of the crista galli, is a small fissure which is occupied by a process of dura mater. External to this fissure is a notch or foramen which transmits the nasal branch of the ophthalmic nerve; from it a groove extends backwards to the anterior ethmoidal foramen.

The **perpendicular plate** (lamina perpendicularis) (figs. 307 and 308) is a thin, flattened lamella, polygonal in form, which descends from the under surface of the cribriform plate, and assists in forming the septum of the nose; it is generally deflected a little to one or other side. Its *anterior border* articulates with the nasal spine of the frontal bone and the crest of the nasal bones. Its *posterior border* articulates by its upper half with the crista sphenoidalis, by its lower half with the vomer. The *inferior border* is thicker than the posterior, and serves for the attachment of the septal cartilage of the nose. The surfaces of the plate are smooth, except above, where numerous grooves and canals are seen; these lead from the inner foramina on the cribriform plate and lodge filaments of the olfactory nerves.

Fig. 308.—Ethmoid bone from behind.



The **lateral mass** (labyrinthus ethmoidalis) (fig. 308) consists of a number of thin-walled cellular cavities, the *ethmoidal cells*, arranged in three groups, *anterior*, *middle*, and *posterior*, and interposed between two vertical plates of bone; the outer plate forms part of the orbit, the inner, part of the corresponding nasal fossa. In the disarticulated bone many of these cells are opened into; but when the bones are articulated, they are closed in at every part, except where they open into the nasal fossa. The *upper surface* of the lateral mass presents a number of half-broken cells, the walls of which are completed, in the articulated skull, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves, converted into canals by articulation with the frontal; they are the *anterior* and *posterior ethmoidal canals*, and open on the inner wall of the orbit. The *posterior surface* presents large irregular cellular cavities, which are closed in by articulation with the sphenoidal turbinated bone and orbital process of the palate.

Fi 309. - Ethmoid bone. Inner surface ight lateral mass (enlarged).

The *outer surface* is formed of a thin, smooth, oblong plate, the *os planum* (lamina papyracea), which covers in the middle and posterior ethmoidal cells and forms a large part of the inner wall of the orbit; it articulates above with the orbital plate of the frontal, below with the maxilla and orbital process of the palate, in front with the lachrymal, and behind with the sphenoid.

In front of the lamina papyracea are some broken air-cells which are overlapped and completed by the lachrymal bone and the frontal process of the maxilla. An irregular lamina, the *processus uncinatus*, projects downwards and backwards from this part of the lateral mass. This process, which is often

broken in disarticulating the bones, forms a small part of the inner wall of the maxillary sinus or antrum of Highmore, and articulates with the ethmoidal process of the inferior turbinated bone.

The *inner surface* of the lateral mass (fig. 309) forms part of the outer wall of the corresponding nasal fossa. It consists of a thin lamella, which descends from the under surface of the cribriform plate, and terminates below in a free, convoluted margin, the *middle turbinated process* (concha nasalis media). The whole of this surface is rough, and marked above by numerous grooves, which run nearly vertically downwards from the cribriform plate; they lodge branches of the olfactory nerves, which are distributed to the mucous membrane covering the superior turbinated process. The back part of this surface is subdivided by a narrow oblique fissure, the *superior meatus* of the nose, which is bounded above by a thin, curved plate, the *superior turbinated process* (concha nasalis superior); the posterior ethmoidal cells open into this meatus. Below, and in front of the superior meatus, is seen the convex inner surface of the middle turbinated process. It extends along the whole length of the inner surface of the lateral mass, and its lower margin is free and thick; its outer surface is concave, and assists in forming the *middle meatus* of the nose. The middle ethmoidal cells open into the central part of this meatus and from its front part a sinuous passage, termed the *infundibulum*, extends upwards and forwards through the lateral mass and communicates with the frontal sinus and the anterior ethmoidal cells.

Ossification.—The ethmoid is ossified in the cartilage of the nasal capsule by *three* centres: one for the perpendicular plate, and one for each lateral mass.

The lateral masses are first developed, ossific granules making their appearance in the region of the os planum between the fourth and fifth months of fœtal life, and extending into the turbinated processes. At birth, the bone consists of the two lateral masses, which are small and ill developed. During the first year after birth, the perpendicular plate and crista galli begin to ossify from a single nucleus, and are joined to the lateral masses about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the lateral masses. The formation of the ethmoidal cells does not commence until about the fourth or fifth year.

Articulations.—The ethmoid articulates with fifteen bones: four of the cranium—the sphenoid, two sphenoidal turbinateds, and the frontal; and eleven of the face—the two nasals, two maxillæ, two lachrymals, two palates, two inferior turbinateds, and the vomer

Supernumerary or Wormian* Bones (ossa suturarum)

In addition to the constant centres of ossification of the cranium, additional ones may be found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and termed *Wormian bones* or *ossa triquetra*. They are most frequently found in the course of the lambdoid suture, but are occasionally seen at the fontanelles, especially the posterior. One, the *pterion ossicle*, sometimes exists between the antero-inferior angle of the parietal and the greater wing of the sphenoid. They have a tendency to be more or less symmetrical on the two sides of the skull, and vary much in size, being in some cases not larger than a pin's head, and confined to the outer table, in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines, as described by Béclard and Ward. Their number is generally limited to two or three; but more than a hundred have been found in the skull of an adult hydrocephalic subject. In their development, structure, and mode of articulation, they resemble the other cranial bones.

Congenital Fissures and Gaps

An arrest in the ossifying process may give rise to deficiencies, gaps, or fissures which are of importance from a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins towards the centre of a bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become filled with thin laminæ of bone. In many of these cases, however, the gaps must be regarded as due to absorption of bone already formed rather

* Ole Worm, Professor of Anatomy at Copenhagen, 1624–1639, was erroneously supposed to have given the first detailed description of these bones.

than as congenital deficiencies; this is especially the case when they appear in the centre of a bone such as the parietal, the ossification of which has already been described as occurring in a regular manner radiating from one centre. The condition is most commonly seen in very badly nourished children affected with congenital syphilis, and is called *craniotabes*.

OSSA FACIEI

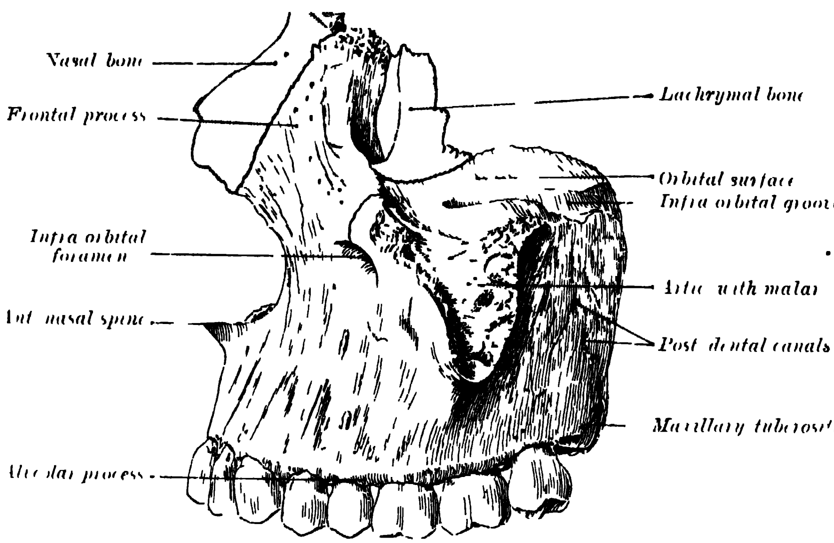
The bones of the face (ossa faciei) fourteen in number, comprise the

Two Nasals	Two Palates
Two Maxillæ	Two Inferior Turbinateds
Two Lachrymals	Vomer
Two Malars	Mandible

Nasal Bones

The **Nasal Bones** (ossa nasalia) are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the

Fig. 310.—Nasal bone and lachrymal bone *in situ*.



middle and upper part of the face, and form by their junction, 'the bridge' of the nose (fig. 310). Each presents two surfaces and four borders. The *outer surface* (fig. 311) is concavo-convex from above downwards, convex from side

Fig. 311.—Right nasal bone. Outer surface.

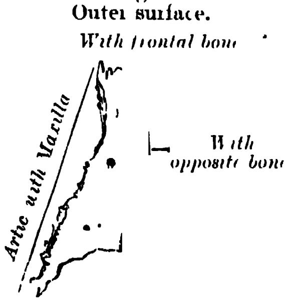


Fig. 312.—Left nasal bone. Inner surface.

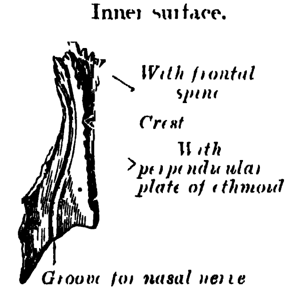


to side; it is covered by the Pyramidalis and Compressor nasi muscles, and perforated about its centre by a foramen, for the transmission of a small vein. The *inner surface* (fig. 312) is concave from side to side, and is traversed from

above downwards by a groove for the passage of a branch of the nasal nerve. The *superior border* is narrow, thick, and serrated for articulation with the nasal notch of the frontal bone. The *inferior border* is thin, and serves for the attachment of the upper lateral cartilage of the nose. It presents, about its middle, a notch which marks the termination of the groove for the nasal nerve. The *external border* is serrated, bevelled at the expense of the inner surface above, and of the outer below, to articulate with the frontal process of the maxilla. The *internal border*, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest, which forms part of the septum of the nose: this crest articulates, from above downwards, with the nasal spine of the frontal, the perpendicular plate of the ethmoid, and the septal cartilage of the nose.

Ossification.—Each bone is ossified from *one* centre, which appears about the eighth week of fœtal life in the membrane overlying the front part of the cartilaginous nasal capsule.

Articulations.—The nasal articulates with four bones: two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the maxilla.

The Maxillæ or Superior Maxillary Bones

The **Maxillæ** are the most important bones of the face from a surgical point of view, on account of the diseases to which some of their parts are liable. They are the largest bones of the face, excepting the mandible, and form, by their union, the whole of the upper jaw. Each assists in the formation of three cavities—viz. the roof of the mouth, the floor and outer wall of the nose, and the floor of the orbit; it also enters into the formation of two fossæ, the zygomatic and spheno-maxillary, and two fissures, the spheno-maxillary and pterygo-maxillary.

Each bone consists of a body and four processes—zygomatic, frontal, alveolar, and palatal.

The **body** (corpus maxillæ) is somewhat pyramidal in shape, and contains a large cavity, the *antrum of Highmore*, or *maxillary sinus*. Its surfaces are four—an anterior or facial, a posterior or zygomatic, a superior or orbital, and an internal or nasal.

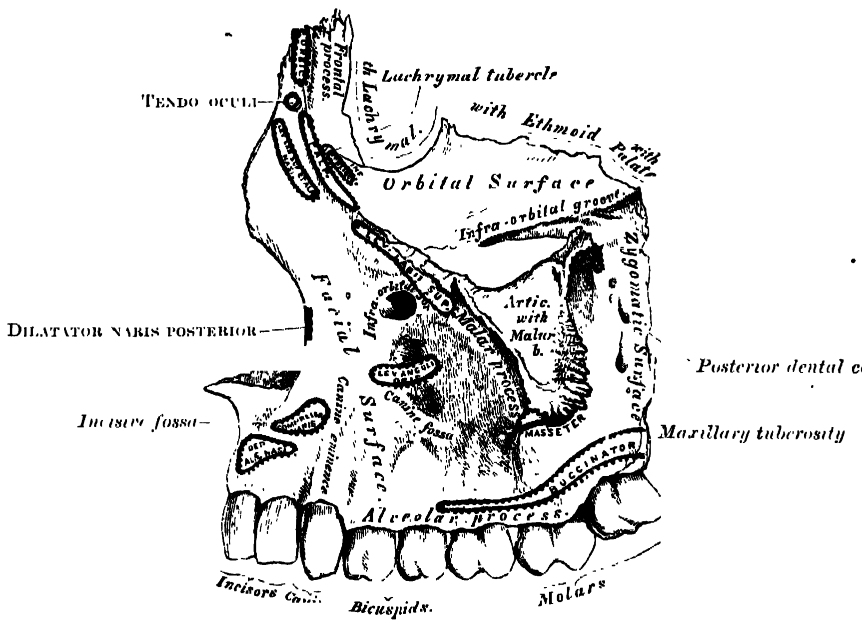
The *anterior* or *facial surface* (facies anterior) (fig. 313) is directed forwards and outwards. It presents at its lower part a series of eminences corresponding to the positions of the fangs of the teeth. Just above those of the incisor teeth is a depression, the *incisive fossa*, which gives origin to the Depressor alæ nasi; to the alveolar border below the fossa is attached a slip of the Orbicularis oris; above and a little external to it, the Compressor nasi arises. More external is another depression, the *canine fossa* (fossa canina), larger and deeper than the incisive fossa, from which it is separated by a vertical ridge, the *canine eminence*, corresponding to the socket of the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the fossa is the *infra-orbital foramen* (foramen infraorbitale), the termination of the infra-orbital canal; it transmits the infra-orbital vessels and nerve. Above the foramen is the margin of the orbit, which affords partial attachment to the Levator labii superioris. Internally, the facial surface is limited by a deep concavity, the *nasal notch* (incisura nasalis), the margin of which gives attachment to the Dilator naris posterior and terminates below in a pointed process, ~~*the anterior nasal spine*~~ (spina nasalis anterior).

The *posterior* or *zygomatic surface* (facies infratemporalis) (fig. 313) is convex, directed backwards and outwards, and forms part of the zygomatic fossa. It is separated from the facial surface by the zygomatic process and by a strong ridge, which extends upwards from the socket of the first molar tooth. It is pierced about its centre by the apertures of the *posterior dental canals* (canales alveolares). which transmit the posterior dental vessels and nerves. At the lower part of this surface is a rounded eminence, the *maxillary tuberosity* (tuber maxillare), especially prominent after the growth of the wisdom-tooth; it is rough on its inner side for articulation with the tuberosity of the palate-bone and in some cases articulates with the external pterygoid plate of the sphenoid. It gives origin to a few fibres of the Internal pterygoid. Immediately above this is a smooth surface, which forms the anterior boundary

of the spheno-maxillary fossa, and presents a groove for the second division of the fifth cranial nerve; this groove is directed outwards and slightly upwards, and becomes continuous with the infra-orbital groove on the orbital surface.

The *superior* or *orbital surface* (facies orbitalis) (fig. 313) is smooth and triangular, and forms the greater part of the floor of the orbit. It is bounded *internally* by an irregular margin which in front presents a notch, the *lachrymal notch* (incisura lacrimalis); behind this notch the margin articulates with the lachrymal, the os planum of the ethmoid and the orbital process of the palate. It is bounded *behind* by a smooth rounded edge which forms the anterior margin of the spheno-maxillary fissure, and sometimes articulates at its outer extremity with the orbital plate of the sphenoid. It is limited *in front* by part of the circumference of the orbit, which is continuous on the inner side with the frontal process, and on the outer side with the zygomatic process. Near the middle line of the posterior part of the orbital surface is a deep groove, the *infra-orbital* (sulcus infraorbitalis), for the passage of the infra-orbital vessels and nerve. The groove begins at the middle of the posterior border, where it is continuous with that near the upper edge of the posterior

FIG. 313.—Left maxilla. Outer surface.



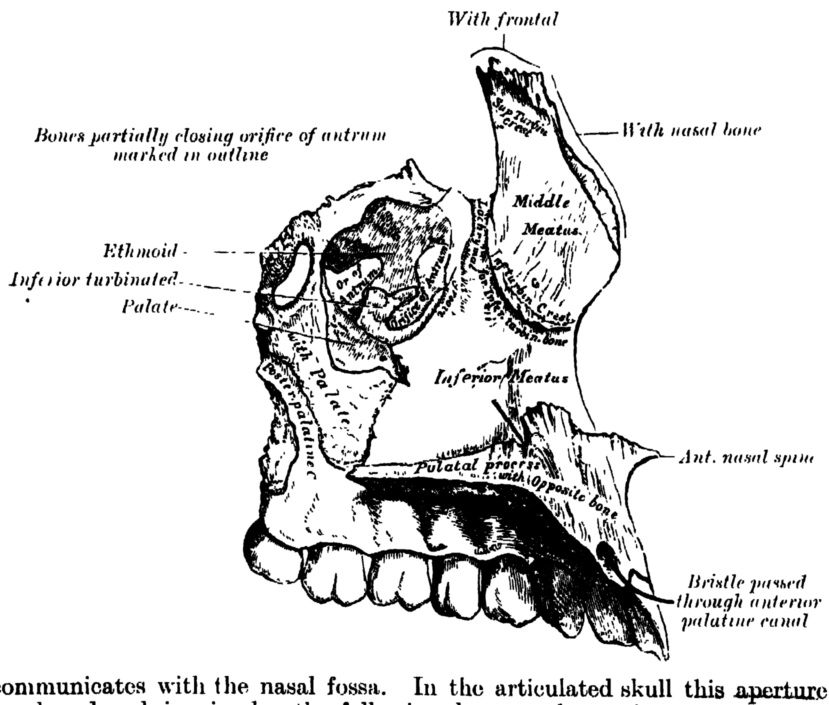
surface, and, passing forwards, ends in a canal, which subdivides into two branches. One of the canals, the *infra-orbital* (canalis infraorbitalis), opens just below the margin of the orbit; the other, which is smaller, runs downwards in the substance of the anterior wall of the antrum; it is called the *anterior dental canal*, and transmits the anterior dental vessels and nerve to the front teeth of the maxilla. From the back part of the infra-orbital canal, a second small canal is sometimes given off, which runs downwards in the outer wall of the antrum, and conveys the middle dental nerve to the bicuspid teeth; occasionally, this canal is derived from the anterior dental. At the inner and fore part of the orbital surface, just external to the lachrymal groove, is a depression, which gives origin to the Inferior oblique muscle of the eyeball.

The *internal surface* (facies nasalis) (fig. 314) presents a large, irregular opening leading into the *antrum of Highmore*. At the upper border of this aperture are some broken air-cells, which, in the articulated skull, are closed in by the ethmoid and lachrymal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal fossa, and behind it is a rough surface for articulation with the perpendicular plate of the palate bone; this surface is traversed by a groove, commencing near the

middle of the posterior border and running obliquely downwards and forwards; this groove is converted into a canal, the *posterior palatine canal* by the palate bone. In front of the opening of the antrum is a deep groove, the *lachrymal groove* (sulcus lacrimalis), which is converted into a canal (canalis nasolacrimalis) by the lachrymal and inferior turbinated bones; this canal opens into the inferior meatus of the nose and transmits the nasal duct. More anteriorly is a well-marked oblique ridge, the *inferior turbinated crest* (crista conchalis), for articulation with the inferior turbinated bone. The shallow concavity above this ridge forms part of the atrium of the middle meatus of the nose; while that below it forms part of the inferior meatus.

The **antrum of Highmore** (sinus maxillaris) is a large pyramidal cavity, hollowed out of the body of the maxilla: its *apex*, directed outwards, is formed by the zygomatic process; its *base*, directed inwards, by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. Its *inner wall*, or *base*, presents, in the disarticulated bone, a large, irregular aperture, which

FIG. 314.—Left maxilla. Inner surface.



communicates with the nasal fossa. In the articulated skull this aperture is much reduced in size by the following bones: the uncinate process of the ethmoid above, the ethmoidal process of the inferior turbinated below, the vertical plate of the palate behind, and a small part of the lachrymal above and in front. It communicates with the middle meatus of the nose, generally by two small apertures left between the above-mentioned bones. In the recent state, usually only one small opening exists, near the upper part of the cavity, sufficiently large to admit the end of a probe; the other is closed by mucous membrane. On the *posterior wall* are the *posterior dental canals*, transmitting the posterior dental vessels and nerves to the molar teeth. The *floor* is formed by the alveolar process of the jaw, and, in a cavity of average size, is on a level with the floor of the nose; where the cavity is large it reaches below this level.

Projecting into the floor of the antrum are several conical processes, corresponding to the roots of the first and second molar teeth:* in some cases the floor is perforated by the fangs of the teeth. The infra-orbital canal usually

* The number of teeth whose fangs are in relation with the floor of the antrum is variable. The antrum 'may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the *dens sapientiæ*.'—(Salter.)

projects into the cavity as a well-marked ridge which passes downwards and inwards from the roof to the anterior wall; additional ridges are sometimes seen in the posterior wall of the cavity, and are caused by the posterior dental canals. The size of the cavity varies in different skulls, and even on the two sides of the same skull. Aldren Turner (*op. cit.*) gives the following measurements as those of an average-sized antrum: vertical height opposite first molar tooth, 1½ in.; transverse breadth, 1 in.; and antero-posterior depth, 1¼ in.

Applied Anatomy.—The extreme thinness of the walls of this cavity affords an explanation of the fact that a tumour growing from the antrum and encroaching upon the adjacent parts may push up the floor of the orbit, and displace the eyeball; may project inwards into the nose; may protrude forwards on to the cheek; or may make its way backwards into the zygomatic fossa, or downwards into the mouth.

The **zygomatic** or **malar process** (processus zygomaticus) is a rough triangular eminence, situated at the angle of separation of the facial, zygomatic, and orbital surfaces. *In front* it forms part of the facial surface; *behind*, it is concave, and forms part of the zygomatic fossa; *above*, it is rough and serrated for articulation with the malar bone; while *below*, it presents a prominent arched border which marks the division between the facial and zygomatic surfaces.

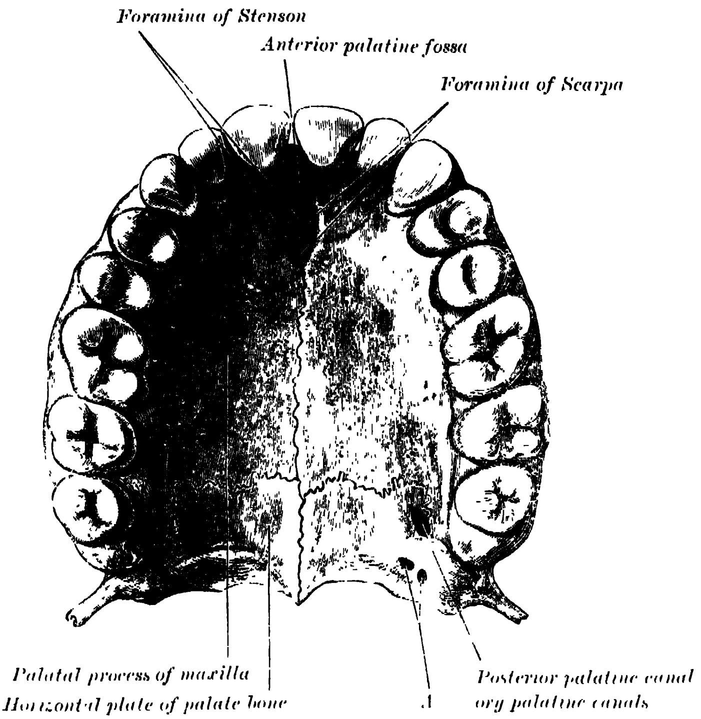
The **frontal** or **nasal process** (processus frontalis) is a strong plate, which projects upwards, inwards, and backwards, by the side of the nose, forming part of its lateral boundary. Its *external surface* is smooth, continuous with the facial aspect of the body, and gives attachment to the Levator labii superioris alæque nasi, the Orbicularis palpebrarum, and the Tendo oculi. Its *internal surface* forms part of the outer wall of the nasal fossa; at its upper part is a rough, uneven area, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is an oblique ridge, the *superior turbinated crest* (crista ethmoidalis), the posterior end of which articulates with the middle turbinated process of the ethmoid, while the anterior part is termed the *agger nasi*; the crest forms the upper limit of the atrium of the middle meatus. Its *upper border* articulates with the frontal and its *anterior* with the nasal; its *posterior border* is thick, and hollowed into a groove, which is continuous below with the *lachrymal groove* on the inner surface of the body: by the articulation of the inner margin of the groove with the anterior border of the lachrymal a corresponding groove on the lachrymal is brought into continuity, and together they form the *lachrymal fossa* for the lodgment of the lachrymal sac. The outer margin of the groove is named the *crista lacrimalis anterior*, and is continuous below with the orbital margin; at its junction with the orbital surface is a small tubercle, the *lachrymal tubercle*, which serves as a guide to the position of the lachrymal sac in the operation for fistula lacrimalis.

The **alveolar process** (processus alveolaris) is the thickest and most spongy part of the bone. It is broader behind than in front, and excavated into deep cavities for the reception of the teeth. These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and are subdivided into minor cavities by septa; those for the incisors are single, but deep and narrow. The Buccinator arises from the outer surface of this process, as far forward as the first molar tooth. When the maxillæ are articulated with each other, their alveolar processes together form the *alveolar arch*; the centre of the anterior margin of this arch is named the *alveolar point.*

The **palatal process** (processus palatinus), thick and strong, projects horizontally inwards from the inner surface of the bone. It forms a considerable part of the floor of the nose and the roof of the mouth and is much thicker in front than behind. Its *inferior surface* (fig. 315) is concave, rough and uneven, and forms, with the palatal process of the opposite bone, the anterior three-fourths of the hard palate. It is perforated by numerous foramina for the passage of the nutrient vessels; is channelled at the back part of its alveolar border by a groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the anterior or large palatine nerve from Meckel's ganglion; and presents little depressions for the lodgment

of the palatine glands. When the two maxillæ are articulated, a depression, the *anterior palatine fossa*, is seen in the middle line, immediately behind the incisor teeth. On examining the bottom of this fossa four canals are visible: two are situated laterally, and two in the middle line. The lateral canals are named the *incisor foramina* or *foramina of Stenson*; they contain the remains of the organ of Jacobson, and through each of them passes the terminal branch of the posterior palatine artery, which ascends from the mouth to the nasal fossa. The canals in the middle line are termed the *foramina of Scarpa*, and transmit the naso-palatine nerves, the left passing through the anterior, and the right through the posterior canal. On the under surface of the palatal process, a delicate linear suture, well seen in young skulls, may sometimes be noticed extending outwards and forwards from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. The small part in front of this suture constitutes the *premaxilla* or *os incisivum*, which in most vertebrates forms an independent

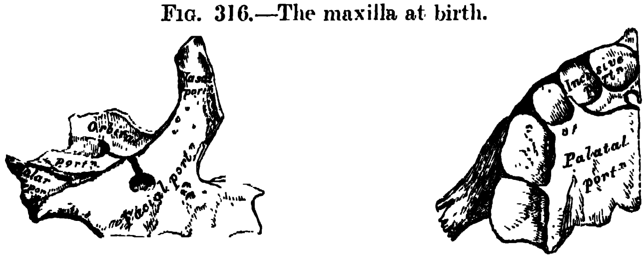
FIG. 315.—The palate and alveolar arch.



bone. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose and the anterior nasal spine, and contains the sockets of the incisor teeth. The *upper surface* of the palatal process is concave from side to side, smooth, and forms the greater part of the floor of the nasal fossa. It presents, close to its inner margin, the upper orifice of the foramen of Stenson. The *outer border* of the process is incorporated with the rest of the bone. The *inner border* is thicker in front than behind, and is raised above into a ridge, the *nasal crest* (crista nasalis), which, with the corresponding ridge of the opposite bone, forms a groove for the reception of the vomer. The front part of this ridge rises to a considerable height, and is named the *incisor crest*; it is prolonged forwards into a sharp process, which forms, together with a similar process of the opposite bone, the *anterior nasal spine* (spina nasalis anterior). The middle of the inferior border of the anterior nasal aperture at the base of the nasal spine is named the ***subnasal point***. The ***posterior border*** is serrated for articulation with the horizontal plate of the palate-bone.

Ossification.—The maxilla begins to ossify at a very early period, and ossification proceeds in it with such rapidity that it is difficult to ascertain with certainty its precise number of centres. It appears probable, however, that it is ossified from six centres, which are deposited in membrane. One, the *orbito-nasal*, forms that portion of the body of the bone which lies internal to the infra-orbital canal, including the inner part of the floor of the orbit and the outer wall of the nasal fossa; a second, the *malar* or *zygomatic*, gives origin to the portion which lies external to the infra-orbital canal, including the zygomatic process; from a third, the *palatine*, is developed the palatal process posterior to Stenson's canal together with the adjoining part of the nasal wall; a fourth, the *premaxillary*, forms the front part of the alveolus which carries the incisor teeth and corresponds to the premaxilla of the lower vertebrates;* a fifth, the *nasal*, gives rise to the frontal process and the portion above the canine tooth; and a sixth, the *infravomerine*, lies between the palatine and premaxillary centres and beneath the vomer; this centre, together with the corresponding centre of the opposite bone, separates the foramina of Stenson from each other. These various

FIG. 316.—The maxilla at birth.



ANTERIOR SURFACE INFERIOR SURFACE

centres appear about the eighth week, and by the tenth week the bone consists of two portions, one the maxilla proper, and the other the premaxilla. The suture between these two portions persists on the palate till middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisor teeth is not formed by the premaxillary bone, but by an outgrowth from the facial part of the maxilla proper. The antrum is developed at an earlier period than any of the other accessory nasal sinuses; it appears as a shallow groove on the inner surface of the bone about the fourth month of fœtal life, but does not reach its full size until after the second dentition. The sockets for the teeth are formed by the downward growth of two plates from the dental groove, and by the subsequent development of partitions jutting across from the one to the other.

Articulations.—The maxilla articulates with nine bones: two of the cranium, the frontal and ethmoid, and seven of the face—viz. the nasal, malar, lachrymal, inferior turbinated, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate, and sometimes with the external pterygoid plate of the sphenoid.

Changes produced in the Maxilla by Age

At birth the transverse and antero-posterior diameters of the bone are each greater than the vertical. The frontal process is well marked and the body of the bone consists of little more than the alveolar process, while the teeth-sockets reach almost to the floor of the orbit. The antrum of Highmore presents the appearance of a slit-like furrow on the outer wall of the nose. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone reverts in some measure to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

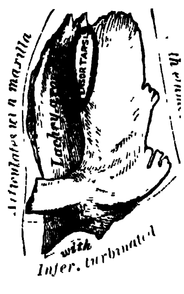
The Lachrymal Bones

The **Lachrymal Bone** (os lacrimale), the smallest and most fragile bone of the face, is situated at the front part of the inner wall of the orbit (fig. 310).

* Some anatomists believe that the premaxillary bone is ossified by two centres (see page 285).

It presents for examination two surfaces and four borders. The *external* or *orbital surface* (fig. 317) is divided by a vertical ridge, the *lachrymal crest* (crista lacrimalis posterior), into two parts. The portion in front of this crest presents a longitudinal groove (sulcus lacrimalis), the inner margin of which unites with the frontal process of the maxilla, and the lachrymal fossa is thus completed. The upper part of this fossa lodges the lachrymal sac, the lower part, the nasal duct. The portion behind the crest is smooth, and forms part of the inner wall of the orbit. The crest, with a part of the orbital surface immediately behind it, gives origin to the Tensor tarsi muscle, and terminates below in a small, hook-like projection, the *hamular process* (hamulus lacrimalis), which articulates with the lachrymal tubercle of the maxilla, and completes the upper orifice of the lachrymal canal. It sometimes exists as a separate piece, and is then called the *lesser lachrymal bone*. The *internal* or *nasal surface* presents a longitudinal furrow, corresponding to the crest on the outer surface. The area in front of this furrow forms part of the middle meatus of the nose; that behind it articulates with the ethmoid bone, and completes some of the anterior ethmoidal cells. Of the *four borders* the *anterior* is the longest, and articulates with the frontal process of the maxilla. The *posterior*, thin and uneven, articulates with the os planum of the ethmoid. The *superior*, the shortest and thickest, articulates with the internal angular process of the frontal. The *inferior* is divided by the lower edge of the vertical crest into two parts: the posterior part articulates with the orbital plate of the maxilla; the anterior is prolonged downwards as the *descending* or *turbinal process*, which articulates with the lachrymal process of the inferior turbinated bone, and assists in forming the canal for the nasal duct.

FIG. 317.—Left lachrymal bone. External surface. (Slightly enlarged.)



Ossification.—The lachrymal is ossified from a single centre, which appears about the eighth or ninth week in the membrane covering the cartilaginous nasal capsule.

Articulations.—The lachrymal articulates with four bones: two of the cranium, the frontal and ethmoid, and two of the face, the maxilla and the inferior turbinated.

THE MALAR OR ZYGOMATIC BONES

The **Malar** or **Zygomatic Bone** (os zygomaticum) is a small, quadrangular bone, situated at the upper and outer part of the face: it forms the prominence of the cheek, part of the outer wall and floor of the orbit, and parts of the temporal and zygomatic fossæ (fig. 318). It presents an external and an internal surface; four processes, the fronto-sphenoidal, orbital, maxillary, and temporal or zygomatic; and four borders.

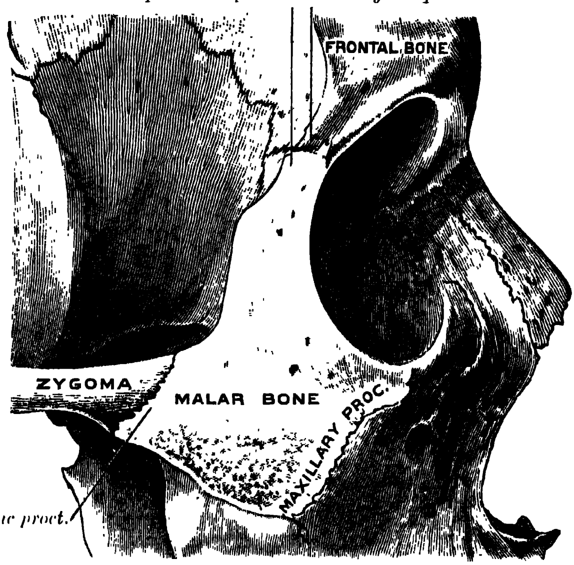
The *external surface* (facies malaris) (fig. 319) is convex and perforated near its centre by a small aperture, the *malar foramen* (foramen zygomaticofaciale), for the passage of the malar nerve and vessels. It is covered by the Orbicularis palpebrarum, and presents, below the malar foramen, a slight elevation, the *malar tubercle*, which gives origin to the Zygomatici.

The *internal surface* (facies temporalis) (fig. 320), directed backwards and inwards, is concave, presenting internally a rough, triangular area, for articulation with the maxilla, and externally a smooth, concave surface, the upper part of which forms the anterior boundary of the temporal fossa, the lower a part of the zygomatic fossa. On this surface, a little above its centre, is the aperture of a malar canal (foramen zygomaticotemporale), for the transmission of the temporal branch of the temporo-malar nerve.

The **fronto-sphenoidal process** is thick and serrated, and articulates with the external angular process of the frontal bone. To its orbital margin is attached the external tarsal ligament. The **orbital process** is a thick, strong plate, projecting backwards and inwards from the orbital margin. Its *antero-internal surface*, smooth and concave, forms, by its junction with the orbital surface of the maxilla and with the greater wing of the sphenoid, part of the floor and outer wall of the orbit. On it are seen the orifices of two

canals (foramina zygomaticoorbitalia); one of these canals opens into the temporal fossa, the other on the anterior surface of the bone; the former transmits the temporal branch, the latter the malar branch of the temporo-malar nerve. Its *postero-external surface*, smooth and convex, forms parts of

FIG. 318.—Right malar bone *in situ*



the zygomatic and temporal fossæ. Its *anterior margin*, smooth and rounded, forms part of the circumference of the orbit. Its *superior margin*, rough, and directed horizontally, articulates with the frontal bone behind the external angular process. Its *posterior margin* is serrated for articulation with the greater wing of the sphenoid and the orbital surface of the maxilla. At

FIG. 319.—Left malar bone. Outer surface.

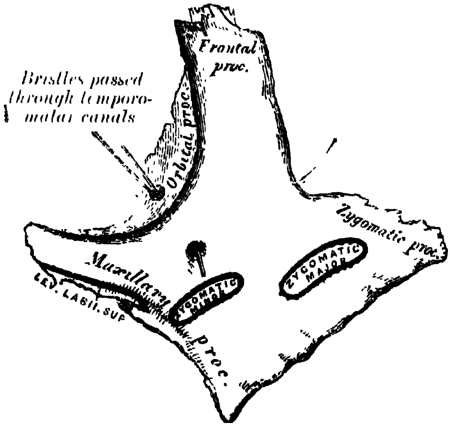


FIG. 320.—Left malar bone. Inner surface.

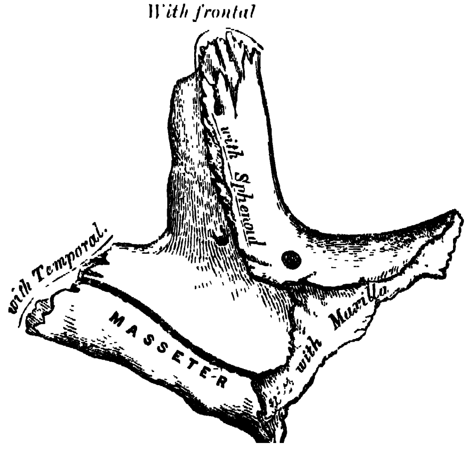


the angle of junction of the sphenoidal and maxillary portions, a short, rounded, non-articular margin is generally seen; this forms the anterior boundary of the spheno-maxillary fissure: occasionally, this non-articular margin does not exist, the fissure being completed by the junction of the maxilla and sphenoid, or by the interposition of a small Wormian bone in the angular

interval between them. The **maxillary process** is a rough, triangular surface which articulates with the maxilla. The **temporal process**, long, narrow, and serrated, articulates with the zygomatic process of the temporal.

Of the *four borders*, the *antero-superior* or *orbital* is smooth, concave, and forms a considerable part of the circumference of the orbit. The *antero-inferior* or *maxillary border* is rough, and bevelled at the expense of its inner table, to articulate with the maxilla; near the orbital margin it gives origin to the Levator labii superioris proprius. The *postero-superior* or *temporal border*, curved like an italic letter *f*, is continuous above with the commencement of the temporal ridge, and below with the upper border of the zygomatic arch. the temporal fascia is attached to it. The *postero-inferior* or *zygomatic border* affords attachment by its rough edge to the Masseter.

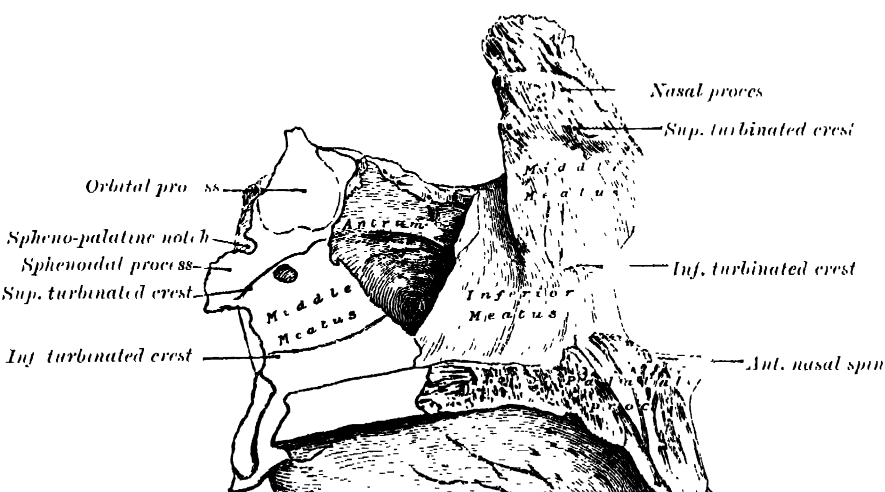
Ossification.—The malar bone ossifies generally from three centres—one for the zygomatic and two for the orbital portion; these appear about the eighth week and fuse about the fifth month of fœtal life. After birth, the bone is sometimes divided by a horizontal suture into an upper larger, and a lower smaller division. In some quadrumana the malar bone consists of two parts, an orbital and a malar.

Articulations.—The malar articulates with four bones: the frontal, sphenoid, temporal, and maxilla.

The Palate Bones

The **Palate Bone** (os palatinum) is situated at the back part of the nasal fossa between the maxilla and the pterygoid process of the sphenoid (fig. 321). It contributes to the walls of three cavities: the floor and outer wall of the nose, the roof of the mouth, and the floor of the orbit; it enters into the formation of two fossæ, the spheno-maxillary and pterygoid; and one fissure, the spheno-maxillary. The palate bone somewhat resembles the letter L, and consists of a horizontal and a vertical plate and three outstanding processes

Fig. 321.—Palate bone *in situ*.

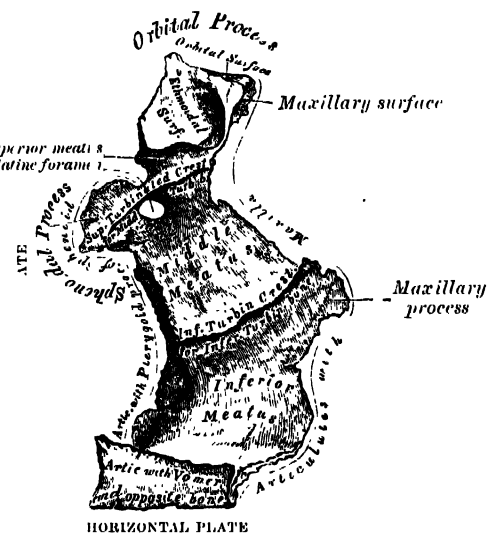


—viz. the pyramidal process or tuberosity, which is directed backwards and outwards from the junction of the plates, and the orbital and sphenoidal processes, which surmount the vertical plate, and are separated by a deep notch, the spheno-palatine notch.

The **horizontal plate** (pars horizontalis) (figs. 322 and 323) is quadrilateral, and has two surfaces and four borders. The *superior surface*, concave from side to side, forms the back part of the floor of the nose. The *inferior surface*, slightly concave and rough, forms, with the corresponding surface

of the opposite bone, the posterior fourth of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the Tensor palati. The *anterior border* is serrated, and articulates with the palatal process of the maxilla. The *posterior border* is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and, when united with the opposite bone, forms a projecting process, the *posterior nasal spine* (spina nasalis posterior) for the attachment of the Azygos uvulæ. The *external border* is united with the lower part of the perpendicular plate, and is grooved by the lower end of the posterior palatine canal. The *internal border*, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the ridge of the opposite bone, forms a crest for articulation with the posterior part of the lower edge of the vomer.

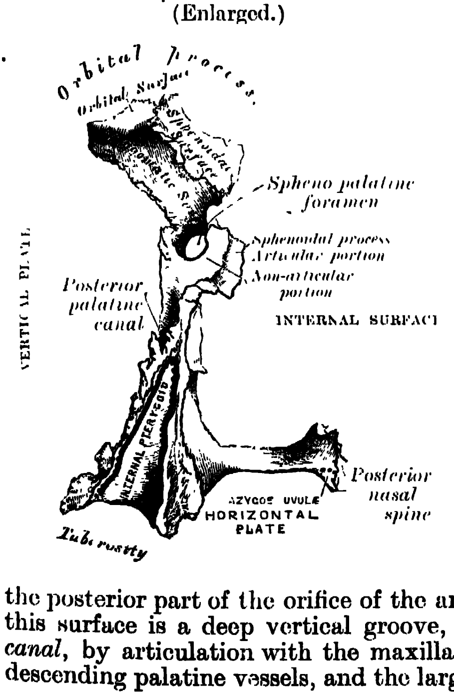
FIG. 322.—Left palate bone. Internal view. (Enlarged.)



The **vertical plate** (pars perpendicularis) (figs. 322 and 323) is thin, of an oblong form, and presents two surfaces and four borders.

The *internal surface* (facies nasalis) exhibits at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this is a well-marked horizontal ridge, the *inferior turbinated crest* (crista conchalis), for articulation with the inferior turbinated bone; still higher is a second broad, shallow depression, which forms part of the middle meatus, and is limited above by a horizontal ridge less prominent than the inferior, the *superior turbinated crest* (crista ethmoidalis), for articulation with the middle turbinated process. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the superior meatus.

FIG. 323.—Left palate bone. Posterior view. (Enlarged.)



The *external surface* (facies maxillaris) is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the maxilla; its upper and back part is smooth where it enters into the formation of the spheno-maxillary fossa; it is also smooth in front, where it covers the posterior part of the orifice of the antrum. Towards the posterior part of this surface is a deep vertical groove, converted into the *posterior palatine canal*, by articulation with the maxilla; this canal transmits the posterior or descending palatine vessels, and the large palatine nerve.

The *anterior border* is thin, irregular, and presents, opposite the inferior turbinated crest, a pointed, projecting lamina, the *maxillary process*, which is directed forwards, and closes in the lower and back part of the opening of the antrum of Highmore. The *posterior border* (fig. 323) presents a deep groove, the edges of which are serrated for articulation with the internal pterygoid plate of the sphenoid. This border is continuous above with the sphenoidal process; below it expands into the pyramidal process or tuberosity. The *superior border* supports the orbital process in front and the sphenoidal process behind. These processes are separated by the *spheno-palatine notch* (incisura sphenopalatina), which is converted into the *spheno-palatine foramen* by the under surface of the body of the sphenoid. In the articulated skull this foramen leads from the spheno-maxillary fossa into the posterior part of the superior meatus of the nose, and transmits the spheno-palatine vessels and the superior nasal and naso-palatine nerves. The *inferior border* is fused with the outer edge of the horizontal plate, and immediately in front of the tuberosity is grooved by the lower end of the posterior palatine canal.

The **tuberosity or processus pyramidalis** projects backwards and outwards from the junction of the horizontal and vertical plates, and is received into the angular interval between the lower extremities of the pterygoid plates. On its *posterior surface* is a median, grooved, triangular area, limited on either side by a rough articular furrow. The furrows articulate with the pterygoid plates, while the grooved intermediate area completes the lower part of the pterygoid fossa and gives origin to a few fibres of the Internal pterygoid. The anterior part of the *outer surface* is rough, for articulation with the tuberosity of the maxilla; its posterior part consists of a smooth triangular area which appears, in the articulated skull, between the tuberosity of the maxilla and the lower part of the external pterygoid plate, and completes the lower part of the zygomatic fossa. The *base* of the tuberosity presents, close to its union with the horizontal plate, the apertures of the *posterior* and *accessory palatine canals* (foramina palatina minora) for the transmission of the posterior and external palatine nerves.

The **orbital process** (processus orbitalis) is placed on a higher level than the sphenoidal, and is directed upwards and outwards from the front part of the vertical plate, to which it is connected by a constricted neck. It presents five surfaces, which enclose an air-cell. Of these surfaces, three are articular and two non-articular. The articular surfaces are: (1) the *anterior* or *maxillary*, directed forwards, outwards, and downwards, of an oblong form, and rough for articulation with the maxilla; (2) the *posterior* or *sphenoidal*, directed backwards, upwards, and inwards; it presents the opening of the air-cell, which usually communicates with the sphenoidal sinus; the margins of the opening are serrated for articulation with the vertical part of the sphenoidal turbinated bone; (3) the *internal* or *ethmoidal*, directed inwards, upwards, and forwards, articulates with the lateral mass of the ethmoid. In some cases, the cellular cavity above mentioned opens on this surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates with the posterior ethmoidal cells and the sphenoidal sinus. The non-articular surfaces are: (1) the *superior* or *orbital*, directed upwards and outwards, is triangular in shape, and forms the back part of the floor of the orbit; and (2) the *external* or *zygomatic*, of an oblong form, is directed outwards and downwards towards the spheno-maxillary fossa; it is separated from the orbital surface by a rounded border, which enters into the formation of the spheno-maxillary fissure.

The **sphenoidal process** (processus sphenoidalis) is a thin, compressed plate, much smaller than the orbital, and directed upwards and inwards. It presents three surfaces and two borders. The *superior surface* articulates with the root of the pterygoid process and the under surface of the sphenoidal turbinated bone, its inner border reaching as far as the ala of the vomer; it presents a groove which contributes to the formation of the pterygo-palatine canal. The *internal surface* is concave, and forms part of the outer wall of the nasal fossa. The *external surface* is divided into an articular and a non-articular portion: the former is rough, for articulation with the inner surface of the internal pterygoid plate of the sphenoid; the latter is smooth,

and forms part of the spheno-maxillary fossa. The *anterior border* forms the posterior boundary of the spheno-palatine notch. The *posterior border*, serrated at the expense of the outer table, articulates with the inner surface of the internal pterygoid plate.

The orbital and sphenoidal processes are separated from one another by the *spheno-palatine notch* (incisura sphenopalatina). Sometimes the two processes are united above, and form between them a complete foramen (fig. 322), or the notch may be crossed by one or more spicules of bone, giving rise to two or more foramina.

Ossification.—The palate bone is ossified in membrane from a single centre, which makes its appearance about the sixth or eighth week of fœtal life at the angle of junction of the two plates of the bone. From this point ossification spreads inwards to the horizontal plate, downwards into the tuberosity, and upwards into the vertical plate. Some authorities describe the bone as ossifying from four centres: one for the tuberosity and portion of the vertical plate behind the posterior palatine groove; a second for the rest of the vertical and the horizontal plates: a third for the orbital, and a fourth for the sphenoidal process. At the time of birth the height of the vertical plate is about equal to the transverse width of the horizontal plate, whereas in the adult the former measures about twice as much as the latter.

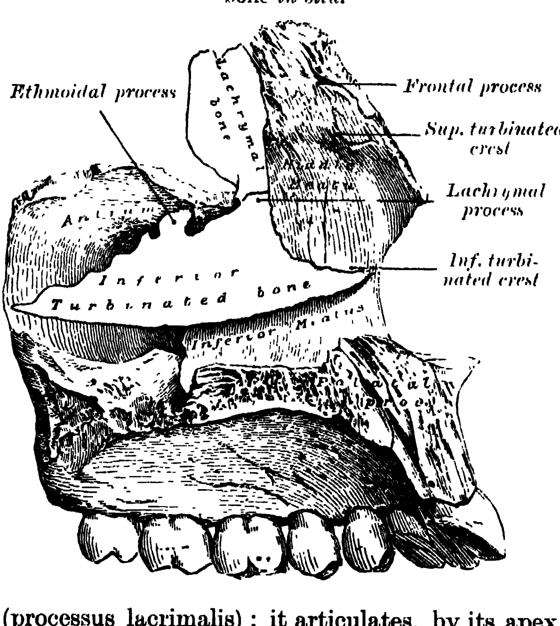
Articulations.—The palate articulates with six bones: the sphenoid, ethmoid, maxilla, inferior turbinated, vomer, and opposite palate.

The Inferior Turbinated Bones

The **Inferior Turbinated Bone** (concha nasalis inferior) extends horizontally along the outer wall of the nasal fossa (fig. 324) and consists of a lamina of spongy bone, curled upon itself like a scroll. It presents two surfaces, two borders, and two extremities.

The *internal surface* (fig. 325) is convex, perforated by numerous apertures, and traversed by longitudinal grooves for the lodgment of vessels. The *external surface* is concave (fig. 326), and forms part of the inferior meatus. Its *upper border* is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions: of these, the anterior articulates with the inferior turbinated crest of the maxilla; the posterior with the inferior turbinated crest of the palate; the middle portion presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the junction of the anterior fourth with the posterior three-fourths of the bone: it is small and pointed, and is called the *lachrymal process* (processus lacrimalis); it articulates, by its apex, with the descending or turbinal process of the lachrymal bone, and, by its margins, with the groove on the back of the frontal process of the maxilla, and thus assists in forming the canal for the nasal duct. Behind this process a broad, thin plate, the *ethmoidal process* (processus ethmoidalis) ascends to join the uncinate process of the ethmoid; from its lower border a thin lamina

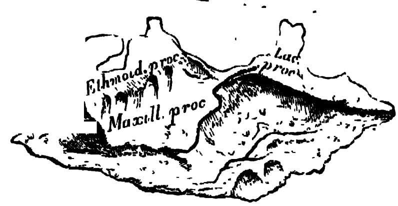
Fig. 324.—Inferior turbinated bone and lachrymal bone *in situ*.



curves downwards and outwards, hooking over the lower edge of the orifice of the antrum, which it narrows below; this lamina fixes the bone firmly to the outer wall of the nasal fossa and is called the *maxillary process* (processus maxillaris). The *inferior border* is free, thick, and cellular in structure, more especially in the middle of the bone. Both *extremities* are more or less narrow and pointed, the posterior being the more tapering.

FIG. 325.—Right inferior turbinated bone. Internal surface.

FIG. 326.—Right inferior turbinated bone. External surface.



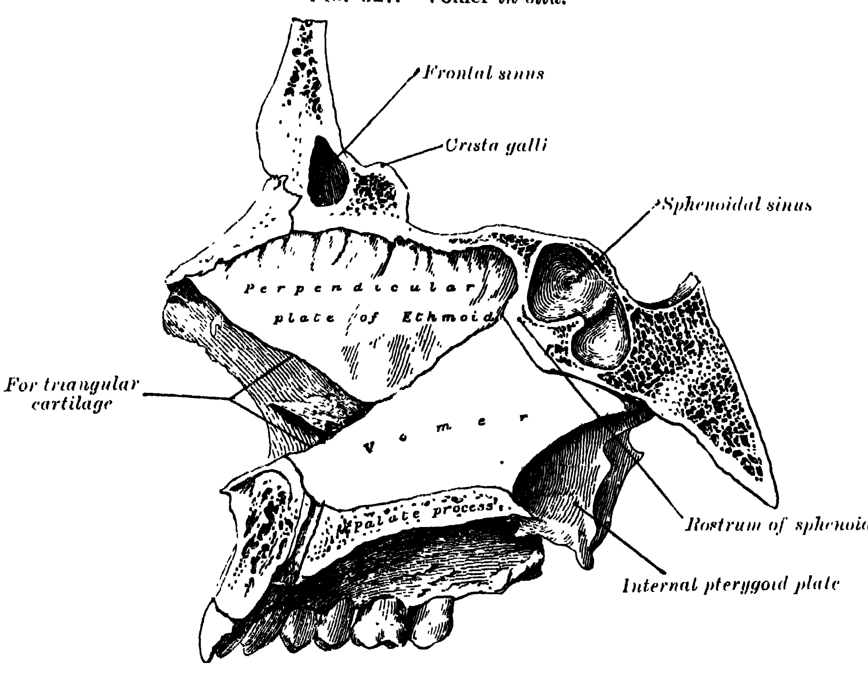
Ossification.—The inferior turbinated bone is ossified from a single centre, which appears about the fifth month of fœtal life in the outer wall of the cartilaginous nasal capsule.

Articulations.—The inferior turbinated articulates with four bones: the ethmoid, maxilla, lachrymal, and palate.

THE VOMER

The **Vomer** (vomer) is situated in the mesial plane, and forms the hinder and lower part of the septum of the nose (fig. 327). It is thin, somewhat quadrilateral in shape, and its anterior portion is frequently bent to one or

FIG. 327.—Vomer *in situ*.

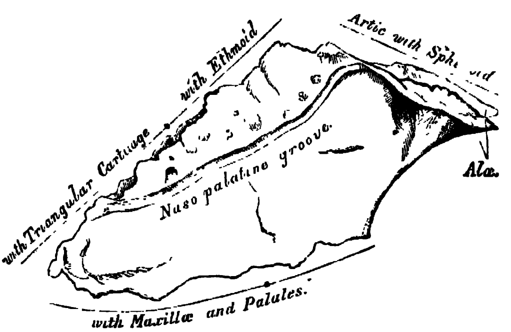


other side; it has two surfaces and four borders. The *surfaces* (fig. 328) are marked by small furrows for blood-vessels, and each presents a groove, the *naso-palatine*, which runs obliquely downwards and forwards, and transmits the naso-palatine nerve and vessels. The *superior border*, the thickest, presents a deep furrow, bounded on either side by a horizontal projecting ala of bone;

the furrow receives the rostrum of the sphenoid, while the margins of the alæ articulate with the vaginal processes of the internal pterygoid plates of the sphenoid behind, and with the sphenoidal processes of the palate bones in front. The *inferior border* articulates with the crest formed by the maxillæ and palate bones. The *anterior border* is the longest and slopes downwards and forwards. Its upper half is fused with the perpendicular plate of the ethmoid; its lower half is grooved for the inferior margin of the septal cartilage of the nose. The *posterior border* is free, concave, and separates the nasal fossæ behind. It is thick and bifid above, thin below.

Ossification.—At an early period the septum of the nose consists of a plate of cartilage, the *ethmo-vomerine cartilage*. The postero-superior part of this cartilage is ossified to form the perpendicular plate of the ethmoid; its antero-inferior portion persists as the septal cartilage, whilst the vomer is ossified in the membrane covering its postero-inferior part. Two ossific centres, one on either side of the middle line, appear about the eighth week of fœtal life in this part of the membrane, and hence the vomer consists primarily of two lamellæ. About the third month these unite below, and thus a deep groove is formed in which the cartilage is lodged. As growth proceeds, the union of the lamellæ extends upwards and forwards, and at the same time the intervening plate of cartilage undergoes absorption. By the age of puberty the lamellæ are united to form a mesial plate, but evidence of the bilaminar origin of the bone is seen in the everted alæ of its upper border and the groove on its anterior margin.

Fig. 328.—The vomer.



Articulations.—The vomer articulates with six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the two maxillæ and the two palate bones; it also articulates with the cartilage of the nasal septum.

Applied Anatomy.—The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, little, if any, submucous connective tissue intervening. Hence polypi are rarely found growing from this surface, though they frequently grow from the outer walls of the nasal fossæ, where the submucous tissue is abundant.

The Mandible or Inferior Maxilla

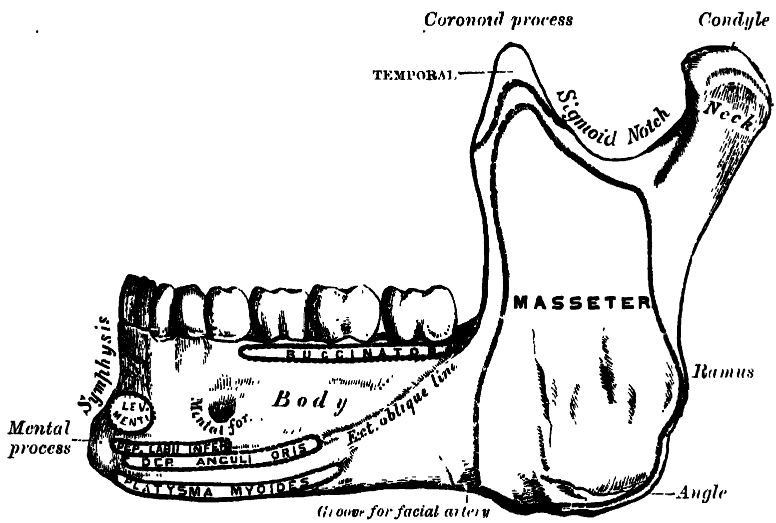
The **Mandible** (mandibula), the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the *body*, and two perpendicular portions, the *rami*, which join the back part of the body nearly at right angles.

The **body** (corpus mandibulæ) is curved somewhat like a horseshoe, and has two surfaces and two borders. The **external surface** (fig. 329) is marked in the median line by a faint ridge, indicating the *symphysis* or line of junction of the two pieces of which the bone is composed at an early period of life. This ridge divides below and encloses a triangular eminence, the *mental protuberance* (protuberantia mentalis), the base of which is depressed in the centre but raised on either side to form the *mental tubercle* (tuberculum mentale). On either side of the symphysis, just below the incisor teeth, is a depression, the *incisive fossa*, which gives origin to the Levator menti and a small portion of the Orbicularis oris. Below the second bicuspid tooth, on either side, midway between the upper and lower borders of the body, is the *mental foramen*, for the passage of the mental vessels and nerve. Running backwards and upwards from each mental tubercle is a faint ridge, the *external oblique line* (linea obliqua), which is continuous with the anterior border of the

ramus: it affords attachment to the Depressor labii inferioris and Depressor anguli oris; the Platysma is attached below it.

The *internal surface* (fig. 330) is concave from side to side, and presents, near the lower part of the symphysis, a pair of laterally placed tubercles, termed the *genial* or *mental spines* (spinæ mentales), which give origin to the Genio-hyo-glossi. Immediately below these is a second pair of spines, or more frequently a median ridge or impression, for the origin of the Genio-hyoid muscles. In some cases the mental spines are fused to form a single eminence, in others they are absent and their position is indicated merely by an irregularity of the surface. Above the mental spines a median foramen and furrow are sometimes seen; they mark the line of union of the halves of the bone. Below the mental spines, on either side of the middle line, is an oval depression for the attachment of the anterior belly of the Digastric. Extending upwards and backwards on either side from the lower part of the symphysis is the *internal oblique line* or *mylo-hyoid ridge* (linea mylo-hyoidea) which gives origin to the Mylo-hyoid; at its posterior end, near the alveolar margin, it gives origin to a small part of the Superior constrictor muscle of the pharynx, and attachment to the pterygo-mandibular ligament. Above the anterior part of this ridge is a smooth triangular area against

FIG. 329.—Mandible. Outer surface. Side view.



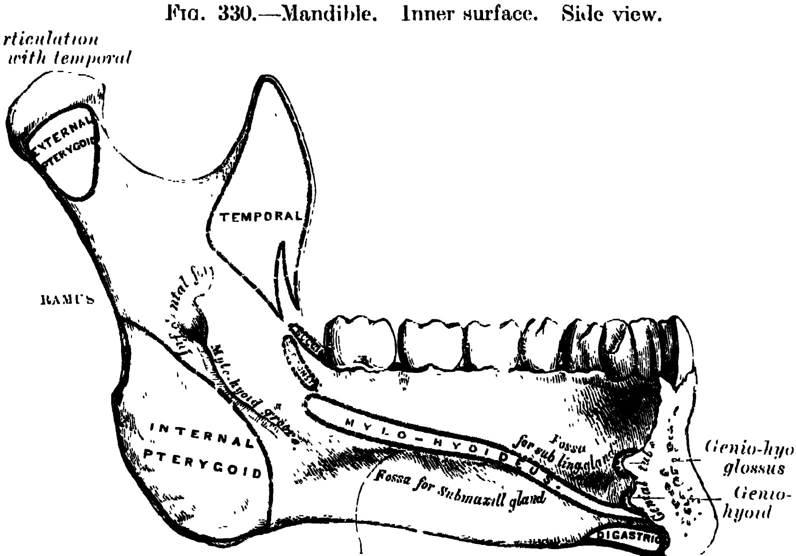
which the sublingual gland rests, and below the hinder part of the ridge is an oval fossa for the submaxillary gland.

The *superior* or *alveolar border*, wider behind than in front, is hollowed into cavities, for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To its outer lip, on either side, the Buccinator is attached as far forward as the first molar tooth. The *inferior border* is rounded, longer than the superior, and thicker in front than behind; at the point where it joins the lower border of the ramus a shallow groove, for the facial artery, may be present.

The **perpendicular portion,** or **ramus** (ramus mandibulæ) is quadrilateral in shape, and presents for examination two surfaces, four borders, and two processes. The *external surface* (fig. 329) is flat and marked by oblique ridges at its lower part; it gives attachment throughout nearly the whole of its extent to the Masseter. The *internal surface* (fig. 330) presents about its centre the oblique *aperture of the inferior dental canal* (foramen mandibulare), for the passage of the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the *lingula mandibulæ*, which gives attachment to the spheno-mandibular ligament; at its lower and back part is a notch from which the *mylo-hyoid groove* runs obliquely downwards and forwards, and lodges the

mylo-hyoid vessels and nerve. Behind this groove is a rough surface, for the insertion of the Internal pterygoid. The *inferior dental canal* (canalis mandibulæ) runs obliquely downwards and forwards in the substance of the ramus, and then horizontally forwards in the body, where it is placed under the alveoli, and communicates with them by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward to be lost in the cancellous tissue beneath the incisor teeth. The canal in the posterior two-thirds of the bone is situated nearer the internal surface of the mandible; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli. The *lower border* of the ramus is thick, straight, and continuous with the inferior border of the body of the bone. At its junction with the posterior border is the *angle* (angulus mandibulæ), which may be either inverted or everted, and is marked by rough, oblique ridges on each side, for the attachment of the Masseter externally, and the Internal pterygoid internally; the stylo-mandibular

FIG. 330.—Mandible. Inner surface. Side view.



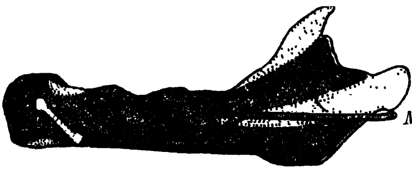
ligament is attached to the angle between these muscles. The *anterior border* is thin above, thicker below, and continuous with the external oblique line. The *posterior border* is thick, smooth, rounded, and covered by the parotid gland. The *upper border* is thin, and presents two processes, separated by a deep concavity, the *sigmoid notch*. Of these processes, the anterior is the *coronoid*, the posterior the *condylar*.

The **coronoid process** (processus coronoideus) is a thin, triangular eminence, which varies in shape and size. Its *anterior border* is convex and is continuous below with the anterior border of the ramus; its *posterior border* is concave and forms the anterior boundary of the sigmoid notch. Its *external surface* is smooth, and affords insertion to the Temporal and Masseter muscles. Its *internal surface* gives insertion to the Temporal muscle, and presents a ridge which begins near the apex of the process and runs downwards and forwards to the inner side of the last molar tooth. Between this ridge and the anterior border is a grooved triangular area, the upper part of which gives attachment to the Temporal, the lower part to some fibres of the Buccinator.

The **condylar process** (processus condyloideus) is thicker than the coronoid, and consists of two portions: the *condyle*, and the constricted portion

which supports it, the *neck*. The *condyle* presents an articular surface which articulates with the glenoid cavity of the temporal bone ; it is convex from before backwards, and from side to side, and extends farther on the posterior than on the anterior aspect. Its long axis is directed inwards and slightly backwards, and if prolonged to the middle line will meet that of the opposite condyle near the anterior margin of the foramen magnum. At the outer extremity of the condyle is a small tubercle for the attachment of the external lateral ligament of the temporo-mandibular joint. The *neck* (collum mandibulæ) is flattened from before backwards, and strengthened by ridges which descend from the fore part and sides of the condyle. Its posterior surface is convex ; its anterior presents a depression for the attachment of the External pterygoid muscle.

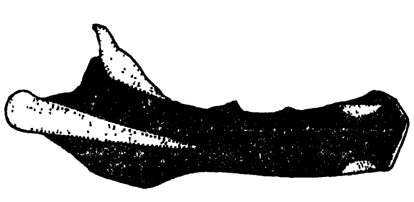
FIG. 331.—Scheme showing ossification of the mandible, inner side (Low). The membrane bone is coloured red. The greater part of Meckel's cartilage is coloured blue. The upturned, stippled portion near the symphysis represents the part of Meckel's cartilage which is surrounded and invaded by the membrane bone. The accessory nuclei of cartilage in the condyle, coronoid process, alveolar border and body are indicated by stippled areas.



The *sigmoid notch*, separating the two processes, is a deep semilunar depression, and is crossed by the masseteric vessels and nerve.

Ossification.—The mandible is ossified in the fibrous membrane covering the outer surfaces of Meckel's cartilages. These cartilages form the cartilaginous bar of the mandibular arch (see p. 108), and are two in number, a right and a left. Their proximal or cranial ends are connected with the periotic capsules, and their distal extremities are joined to one another at the symphysis by mesodermal tissue. They can be seen on the inner aspect of the mandible of a five-months fœtus (fig. 331), where they run forwards immediately below the condyles and then, bending downwards, lie in a groove near the lower border of the bone ; in front of the canine tooth they incline upwards and inwards to the symphysis. From the proximal end of each cartilage the malleus and incus, two of the bones of the middle ear, are developed ; the next succeeding portion, as far as the lingula, is replaced by fibrous tissue, which persists to form the spheno-mandibular ligament. Between the lingula and the canine tooth the cartilage disappears, whilst the portion of it which lies below and behind the incisor teeth becomes ossified and incorporated with this part of the mandible.

FIG. 332.—Scheme showing ossification of mandible from the outer side (Low). Membrane bone coloured red. Accessory nuclei of cartilage stippled.



Ossification takes place in the membrane covering the outer surface of Meckel's cartilage (fig. 332), and each half of the bone is formed from a single centre which appears, near the mental foramen, about the sixth week of fœtal life—i.e. earlier than in any other bone except the clavicle. By the tenth week the portion of Meckel's cartilage which lies below and behind the incisor teeth is surrounded and invaded by the membrane-bone. Somewhat later, accessory nuclei of cartilage make their appearance—viz. a wedge-shaped nucleus in the condyle, a small one in the coronoid process, and smaller ones in the front part of both alveolar walls and along the front of the lower border of the bone. These accessory nuclei possess no separate ossific centres, but ossification extends into them from the adjacent membrane-bone and they undergo absorption. The inner alveolar border, usually described as arising from a separate ossific centre (*splenial centre*), is formed in the human mandible by an ingrowth from the main mass of the bone. At birth the

SIDE VIEW OF THE MANDIBLE AT DIFFERENT PERIODS OF LIFE

FIG. 333.—At birth.

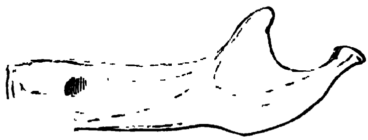


FIG. 334.—In childhood.

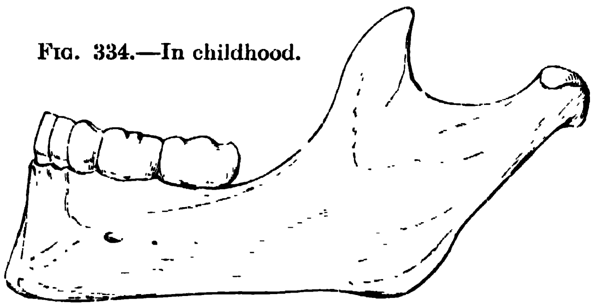

FIG. 335.—In the adult.

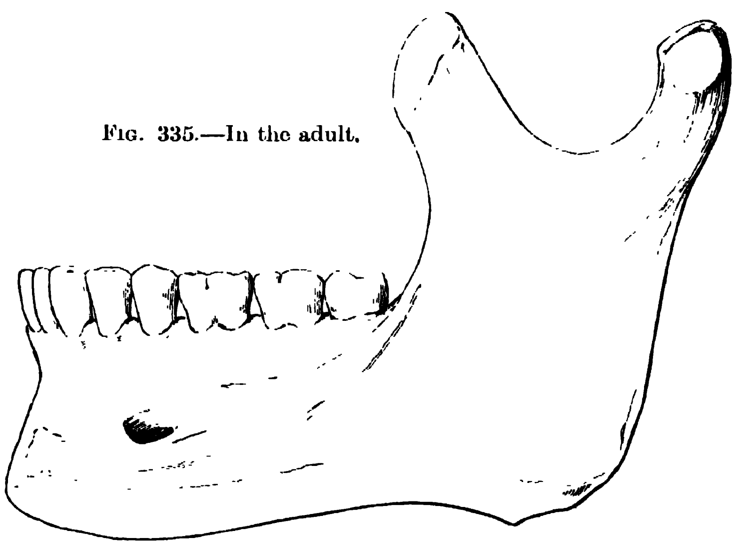

FIG. 336.—In old age.

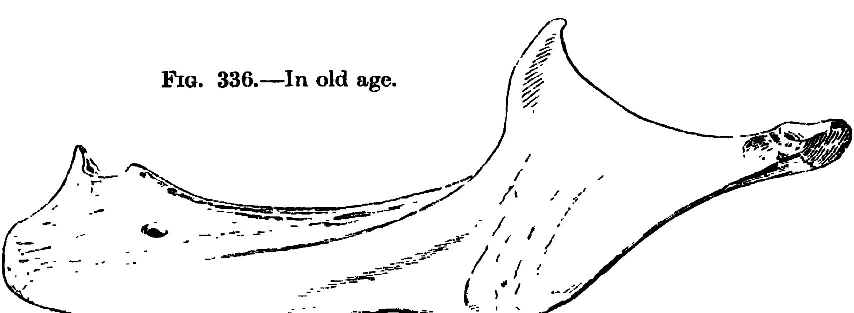


bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

The above description of the ossification of the mandible is based on the researches of Low* and Fawcett,† and differs somewhat from that usually given.

Articulations.—The mandible articulates with the two temporal bones.

Changes produced in the Mandible by Age

At birth (fig. 333), the body of the bone is a mere shell, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned off from one another. The dental canal is of large size, and runs near the lower border of the bone: the mental foramen opens beneath the socket of the first molar tooth. The angle is obtuse (175°), and the condylar portion is nearly in line with the body. The coronoid process is of comparatively large size, and projects above the level of the condyle.

After birth (fig. 334), the two segments of the bone become joined at the symphysis, from below upwards, in the first year; but a trace of separation may be visible in the beginning of the second year, near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body increases owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal, after the second dentition, is situated just above the level of the mylo-hyoid ridge; and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth; about the fourth year it is 140°.

In the adult (fig. 335), the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower borders of the bone, and the dental canal runs nearly parallel with the mylo-hyoid line. The ramus is almost vertical in direction, the angle measuring from 110° to 120°.

In old age (fig. 336), the bone becomes greatly reduced in size, for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains; consequently, the chief part of the bone is below the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The ramus is oblique in direction, the angle measures about 140°, and the neck of the condyle is more or less bent backwards.

Hyoid Bone

The **Hyoid Bone** (os hyoideum) is named from its resemblance to the Greek upsilon; it is also called the *os linguæ*, because it supports the tongue, and gives attachment to several of its muscles. It is a bony arch, shaped like a horseshoe, and consists of five segments, a body, two greater cornua, and two lesser cornua. It is suspended from the tips of the styloid processes of the temporal bones by the stylo-hyoid ligaments.

The **body** (*basi-hyal*) or central part of the bone is of a quadrilateral form. Its *anterior surface* (fig. 337) is convex and directed forwards and upwards; it presents a median and a transverse ridge which subdivide it into four areas, two on either side of the middle line. At the point of intersection of these ridges is an elevation named the *tubercle*. The anterior surface gives attachment to the Genio-hyoid in the greater part of its extent; above, to the Genio-hyo-glossus; below, to the Mylo-hyoid, Stylo-hyoid, and aponeurosis of the Digastric (suprahyoid aponeurosis); and externally to a part of the Hyo-glossus. The *posterior surface* is smooth, concave, directed backwards and downwards, and separated from the epiglottis by the thyro-hyoid membrane and a quantity of loose areolar tissue; a bursa intervenes between it and the thyro-hyoid membrane. The *superior border* is rounded, and gives attachment to the thyro-hyoid membrane and parts of the Genio-hyo-glossus and Chondro-glossus. The *inferior border* gives attachment, in front, to the Sterno-hyoid; behind to the Omo-hyoid, and at its junction with the great cornu to part of the Thyro-

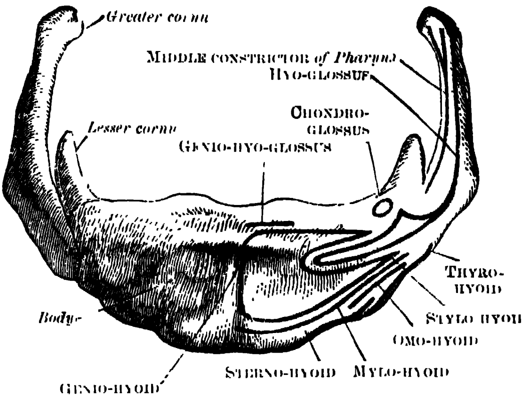
* 'The Development of the Lower Jaw in Man,' by Alexander Low, M.A., M.B. (*Proceedings of the Anatomical and Anthropological Society of the University of Aberdeen*, 1905).

† 'Ossification of the Lower Jaw in Man,' by Professor Fawcett (*Journal of the American Medical Association*, September 2, 1905).

hyoid. It also gives attachment to the Levator glandulæ thyroideæ, when this muscle is present. In early life the *lateral surfaces* are connected to the greater cornua by synchondroses; after middle life usually by bony union.

The **greater cornua** (*thyro-hyals*) project backwards from the lateral surfaces of the body; they are flattened from above downwards and diminish in size from before backwards; each terminates in a tubercle for the attachment of the lateral thyro-hyoid ligament. The outer surface gives attachment to the Hyo-glossus; the upper border to the Middle constrictor of the pharynx, and the lower to part of the Thyro-hyoid.

Fig. 337.—Hyoid bone. Anterior surface (enlarged).



The **lesser cornua** (*cerato-hyals*) are two small, conical eminences, attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments.* The smaller cornua are connected to the body of the bone by distinct diarthrodial joints, which usually persist throughout life, but occasionally become ankylosed.

Ossification.—The hyoid is ossified from *six* centres; two for the body, and one for each cornu. Ossification commences in the body about the eighth month, in the greater cornua towards the end of fœtal life, and in the lesser cornua during the first or second year after birth.

Surface Form.—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated on a level with the angle of the jaw. This process of bone is best perceived by making pressure on one cornu and so pushing the bone over to the opposite side, when the cornu of that side will be distinctly felt immediately beneath the skin. It is an important landmark in ligature of the lingual artery.

Applied Anatomy.—The hyoid bone is occasionally fractured, generally from direct violence, as in hanging, forcible grasping of the throat in garotting or throttling, or by a blow. The fracture generally occurs about the junction of the greater cornu with the body of the bone, but sometimes takes place through the latter. Since the muscles of the tongue have important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

EXTERIOR OF THE SKULL

The skull as a whole may be viewed from different points, and the views so obtained are termed the *normæ* of the skull; thus, it may be examined from above (norma verticalis), from below (norma basalis), from the side (norma lateralis), from behind (norma occipitalis), or from the front (norma frontalis).

The Skull from Above (norma verticalis)

When viewed from above the outline presented varies greatly in different skulls; in some it is more or less oval, in others more nearly circular. The surface is traversed by three sutures, viz.: (1) the *coronal*, nearly transverse in direction, between the frontal and parietals; (2) the *sagittal*, mesially placed, and deeply serrated in its anterior two-thirds, uniting the parietal bones; and (3) the upper part of the *lambdoid*, between the parietals and occipital. The point of junction of the sagittal and coronal sutures is named the *bregma*,

* These ligaments in many animals are distinct bones, and in man may undergo partial ossification.

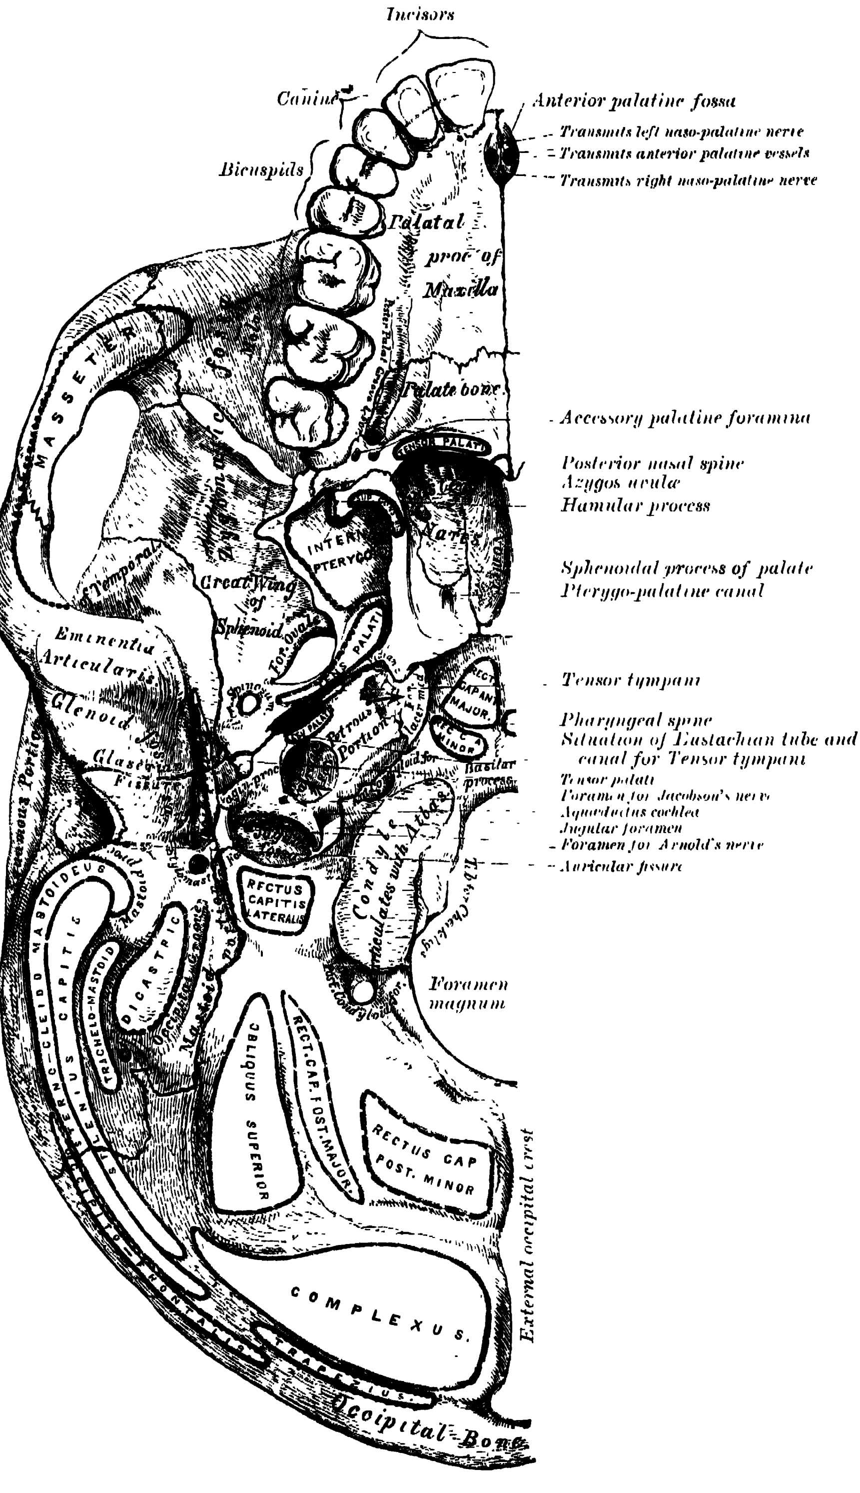
that of the sagittal and lambdoid sutures, the *lambda*; these points indicate respectively the positions of the anterior and posterior fontanelles in the fœtal skull. On either side of the sagittal suture are the *parietal eminence* and *parietal foramen*—the latter, however, is frequently absent on one or both sides. The skull is often somewhat flattened in the neighbourhood of the parietal foramina, and the term *obelion* is applied to that point of the sagittal suture which is on a level with the foramina. In front is the *glabella*, and on its lateral aspects are the *superciliary ridges*, and above these the *frontal eminences*. Immediately above the glabella may be seen the remains of the *inter-frontal suture*; in a small percentage of skulls this suture persists and extends along the mesial plane to the bregma. Passing backwards and upwards from the external angular processes of the frontal bone are the *temporal lines*, which mark the upper limits of the temporal fossæ. The zygomatic arches may or may not be seen projecting beyond the anterior portions of these lines.

The Skull from Below (norma basalis)

The inferior surface of the base of the skull exclusive of the mandible (fig. 338) is bounded in front by the incisor teeth in the maxillæ; behind, by the superior curved lines of the occipital; and laterally by the alveolar arch, the lower border of the malar, the zygoma, and an imaginary line, extending from the zygoma to the mastoid process and extremity of the superior curved line of the *occipital*. It is formed by the palatal processes of the maxillæ and palate bones, the vomer, the pterygoid processes, the under surfaces of the greater wings, spinous processes, and part of the body of the sphenoid, the under surfaces of the squamous, mastoid, and petrous portions of the temporals, and the under surface of the occipital bone. The anterior part or hard palate is raised above the level of the rest of the surface (when the skull is turned over for the purpose of examination), and is bounded in front and laterally by the alveolar arch containing the sixteen teeth of the maxillæ. Immediately behind the incisor teeth is the *anterior palatine fossa*. At the bottom of this fossa four apertures may usually be seen: two placed laterally, the *foramina of Stenson*, open above, into the floor of the nose, and transmit the anterior branches of the posterior palatine vessels, and two in the median line, the *foramina of Scarpa*, the anterior transmitting the left, and the posterior the right naso-palatine nerve. The vault of the hard palate is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and traversed by a crucial suture formed by the junction of the four bones of which it is composed. In the young skull a suture may be seen passing outwards and forwards on either side from the anterior palatine fossa to the interval between the lateral incisor and canine teeth, and marking off the premaxillary portion of the bone. At each posterior angle of the hard palate is the *posterior palatine foramen*, for the transmission of the posterior palatine vessels and large descending palatine nerve; and running forwards and inwards from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the *tuberosity of the palate-bone*, perforated by one or more *accessory posterior palatine canals*, and marked by the commencement of a ridge, which runs transversely inwards, and serves for the attachment of the tendinous expansion of the Tensor palati. Projecting backwards from the centre of the posterior border of the hard palate is the *posterior nasal spine*, for the attachment of the Azygos uvulæ. Behind and above the hard palate are the posterior apertures of the nares (*choanæ*), measuring about an inch in their vertical and half an inch in their transverse diameters. They are separated from one another by the vomer, and each is bounded above by the body of the sphenoid, below by the horizontal plate of the palate-bone, and laterally by the internal pterygoid plate of the sphenoid. At the base of the vomer may be seen the expanded alæ of this bone, receiving between them the rostrum of the sphenoid. Near the lateral margins of the alæ of the vomer, at the root of the pterygoid processes, are the *pterygo-palatine canals*. The pterygoid process, which bounds the posterior nares on either side, presents near its base the *pterygoid* or *Vidian canal*, for the Vidian nerve and artery. Each process consists of two plates, separated behind by the pterygoid fossa, which lodges the Internal pterygoid and Tensor palati. The internal plate is

long and narrow, presenting on the outer side of its base the *scaphoid fossa*, for the origin of the Tensor palati, and at its lower extremity the *hamular process*, around which the tendon of this muscle turns. The external pterygoid plate is

FIG. 338.—Base of skull. Inferior surface.



broad; its outer surface forms the inner boundary of the zygomatic fossa, and affords attachment to the External pterygoid.

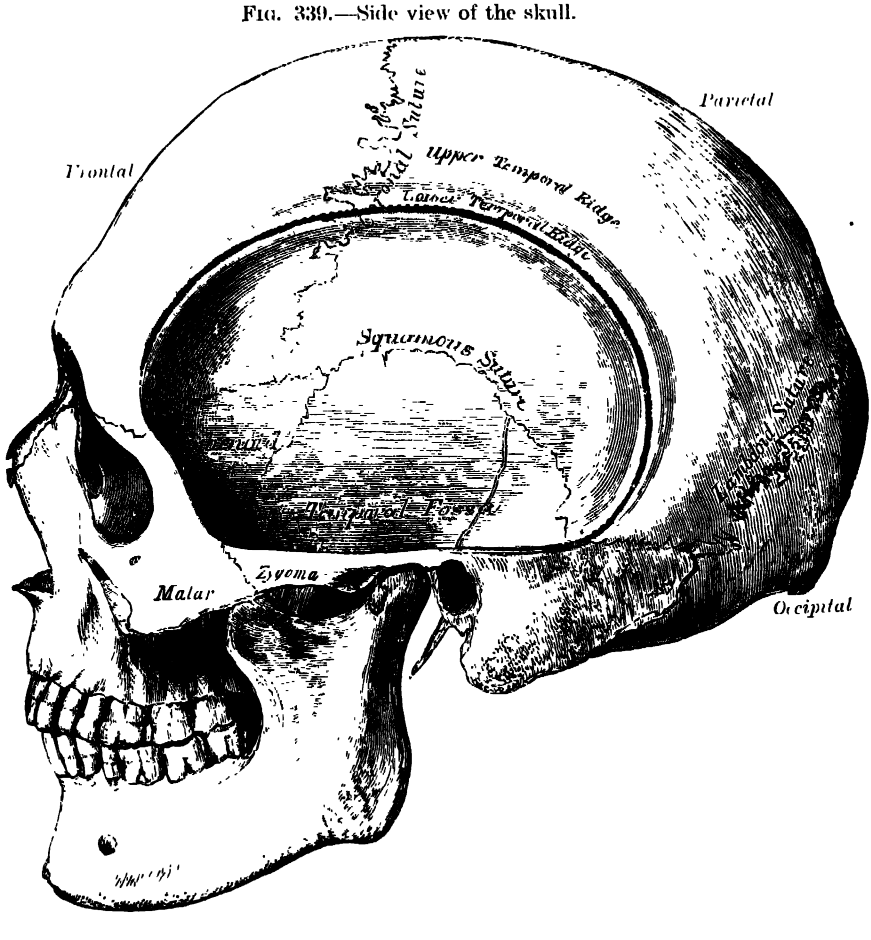
Behind the nasal fossæ in the middle line is the basilar portion of the occipital bone, presenting near its centre the *pharyngeal tubercle* for the attachment of the fibrous raphe of the pharynx, with depressions on either side for the insertions of the Recti capitis antici major and minor. At the base of the external pterygoid plate is the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small superficial petrosal nerve; behind this, the *foramen spinosum* which transmits the middle meningeal artery and veins, and the prominent spinous process of the sphenoid, which gives attachment to the spheno-mandibular ligament and the Tensor palati. External to the spinous process is the *glenoid fossa*, divided into two parts by the *Glaserian fissure*; the anterior portion, concave, smooth, bounded in front by the *eminentia articularis*, serves for the articulation of the condyle of the lower jaw; the posterior portion, rough and bounded behind by the tympanic plate, is occupied by a part of the parotid gland. Emerging from between the laminæ of the vaginal process of the tympanic plate is the *styloid process*; and at the base of this process is the *stylo-mastoid foramen*, for the exit of the facial nerve, and entrance of the stylo-mastoid artery. External to the stylo-mastoid foramen, between the tympanic plate and the mastoid process, is the *auricular fissure*, for the auricular branch of the pneumogastric. Upon the inner side of the mastoid process is the *digastric fossa*, and a little more internally, the *occipital groove* for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the *foramen lacerum medium*, bounded in front by the greater wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and internally by the body of the sphenoid and basilar portion of the occipital bone; it presents in front the posterior orifice of the *Vidian canal*; behind, the aperture of the *carotid canal*. The basilar surface of this opening is filled up in the recent state by a fibro-cartilaginous plate, across the upper or cerebral surface of which the internal carotid artery passes. External to this aperture is a groove, the *sulcus tubæ auditivæ*, between the petrous part of the temporal and the greater wing of the sphenoid. This sulcus is directed outwards and backwards from the root of the internal pterygoid plate and lodges the cartilaginous part of the Eustachian tube; it is continuous behind with the canal in the temporal bone which forms the bony part of the same tube. At the bottom of this sulcus is a narrow cleft, the *fissura petro-squamosa*, which is occupied, in the recent condition, by a plate of cartilage, the bones bounding the fissure being united by a synchondrosis. Behind this suture is the under surface of the petrous portion of the temporal bone, presenting, near its apex, the quadrilateral rough surface, part of which affords attachment to the Levator palati muscle; to the outer side of this surface is the orifice of the carotid canal, and to its inner side, the depression leading to the *aquæductus cochleæ*, the former transmitting the internal carotid artery and the carotid plexus of the sympathetic, the latter serving for the passage of a vein from the cochlea. Behind the carotid canal is a large aperture, the *jugular foramen*, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and is partly subdivided into three compartments. The anterior compartment transmits the inferior petrosal sinus; the middle, the glosso-pharyngeal, pneumogastric, and spinal accessory nerves; the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries. On the ridge of bone dividing the carotid canal from the jugular foramen is the small foramen for Jacobson's nerve (tympanic branch of the glosso-pharyngeal); and on the wall of the jugular foramen, near the root of the styloid process, is the small aperture for Arnold's nerve (auricular branch of the pneumogastric). Extending forwards from the jugular foramen to the foramen lacerum medium is the *fissura petro-occipitalis*, which is occupied, in the recent state, by a plate of cartilage. Behind the basilar portion of the occipital bone is the *foramen magnum*, bounded laterally by the occipital condyles which are rough internally for the attachment of the check or odontoid ligaments. External to each condyle is the *jugular process*, which gives attachment to the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament. The foramen

magnum transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. The mid-points on the anterior and posterior margins of the foramen magnum are respectively termed the *basion* and the *opisthion*. In front of each condyle is the *anterior condyloid foramen*, for the passage of the hypoglossal nerve and a meningeal artery. Behind each condyle is the *fossa condyloidea*, perforated on one or both sides by the posterior condyloid foramen, for the transmission of a vein from the lateral sinus. Behind the foramen magnum is the *external occipital crest*, terminating above at the *external occipital protuberance*, while on either side are the *superior* and *inferior curved lines*; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles which are enumerated on page 215.

THE SKULL IN PROFILE (norma lateralis)

When viewed from the side (fig. 339) the skull is seen to consist of the cranium above and behind, and of the face below and in front. The cranium is somewhat ovoid in shape, but its contour varies in different cases and depends largely on the length and height of the skull and on the degree of prominence of the superciliary ridges and frontal eminences. Entering into its formation

FIG. 339.—Side view of the skull.



are to be seen the frontal, the parietal, the occipital, the temporal, and the greater wing of the sphenoid. These bones are joined to one another and to the malar by the following sutures: the *zygomatico-temporal* between the zygomatic process of the temporal and the temporal process of the malar; the *fronto-malar* uniting the malar with the external angular process of the frontal;

the sutures surrounding the great wing of the sphenoid, viz. : the *spheno-malar* in front, the *spheno-frontal* and *spheno-parietal* above, and the *spheno-squamosal* behind. The spheno-parietal suture varies in length in different skulls, and is absent in those cases where the frontal articulates with the squamous part of the temporal. The point corresponding with the posterior end of the spheno-parietal suture is named the *pterion* ; it is situated about an inch and a quarter behind, and a little above the level of the external angular process of the frontal bone.

The *squamous suture* arches backwards from the pterion and connects the squamous part of the temporal with the lower border of the parietal: this suture is continuous behind with the short, nearly horizontal *parieto-mastoid suture*, which unites the mastoid process of the temporal with the region of the postero-inferior angle of the parietal. Extending from above downwards and forwards across the cranium are the *coronal* and *lambdoid sutures*; the former connects the parietal with the frontal, the latter, the parietal with the occipital. The lambdoid suture is continuous below with the *occipito-mastoid suture* between the occipital and the mastoid portion of the temporal. In or near this suture is the *mastoid foramen*, for the transmission of an emissary vein. The point of meeting of the parieto-mastoid, occipito-mastoid, and lambdoid sutures is known as the *asterion*. Immediately above the orbital margin is the *superciliary ridge*, and, at a higher level, the *frontal eminence*. Near the centre of the parietal bone is the *parietal eminence*. Posteriorly is the *external occipital protuberance*, from which the superior curved line may be followed forwards to the mastoid process. Arching across the side of the cranium are the *temporal lines* or ridges, which mark the upper limit of the temporal fossa.

The **temporal fossa** is bounded above and behind by the temporal lines, which extend from the external angular process of the frontal bone upwards and backwards across the frontal and parietal bones, and then curve downwards and forwards to become continuous with the supra-mastoid crest and the posterior root of the zygoma. The point where the upper temporal line cuts the coronal suture is named the *stephanion*. The temporal fossa is bounded in front by the frontal and malar bones, and opening on the back of the latter is a foramen which transmits the temporal branch of the temporo-malar nerve. Externally the fossa is limited by the zygomatic arch, formed by the malar and temporal bones ; below, it is separated from the zygomatic fossa by the *infra-temporal crest* on the greater wing of the sphenoid, and by a ridge, continuous with this crest, which is carried backwards across the squamous part of the temporal to the anterior root of the zygoma. In front and below, the fossa communicates with the orbital cavity through the *spheno-maxillary fissure*. The floor of the fossa is deeply concave in front and convex behind, and is formed by the malar, frontal, parietal, sphenoid, and temporal bones. It is traversed by vascular furrows : one, usually well marked, runs upwards above and in front of the external auditory meatus, and lodges the middle temporal artery. Two others, frequently indistinct, may be observed on the anterior part of the floor, and are for the anterior and posterior deep temporal arteries. The temporal fossa contains the Temporal muscle and its vessels and nerves, together with the temporal branch of the temporo-malar nerve.

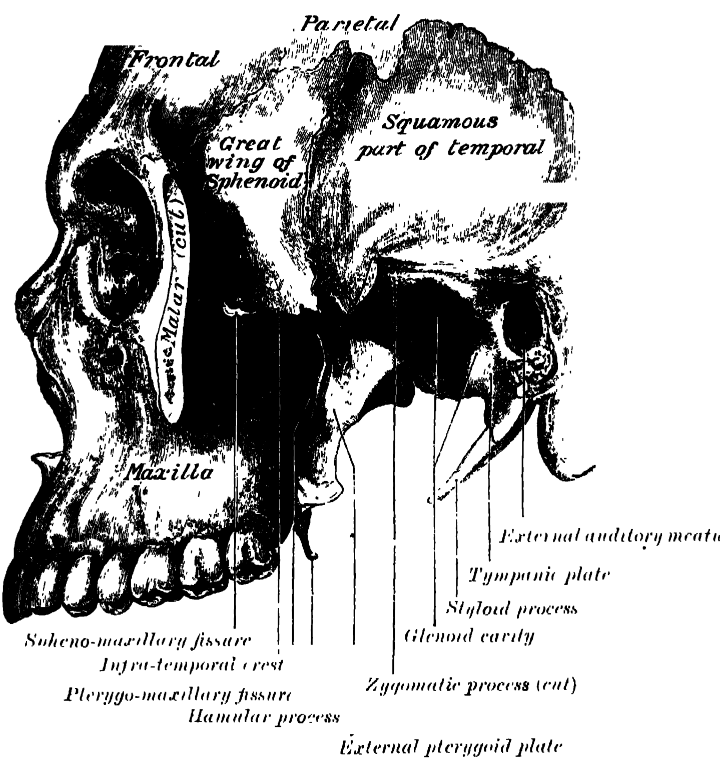
The *zygomatic arch* is formed by the zygomatic process of the temporal and the temporal process of the malar, the two being united by an oblique suture ; the tendon of the Temporal muscle passes under the arch to gain insertion into the coronoid process of the mandible. The zygomatic process of the temporal arises by two roots, an anterior, directed inwards in front of the glenoid cavity, where it expands to form the eminentia articularis, and a posterior, which runs backwards above the external auditory meatus and is continuous with the supra-mastoid crest. The upper border of the arch gives attachment to the temporal fascia ; its lower border and inner surface give origin to the Masseter.

Below the posterior root of the zygoma is the elliptical orifice of the *external auditory meatus*, bounded in front, below, and behind by the tympanic plate; to the outer margin of this plate the cartilaginous part of the external auditory meatus is attached. The small triangular area between the posterior root of the zygoma and the postero-superior part of the

orifice is termed the *supra-meatal triangle*, on the anterior border of which a small spinous process, the *supra-meatal spine*, is sometimes seen. Between the tympanic plate and the eminentia articularis is the *glenoid cavity*, divided into two parts by the Glaserian fissure. The anterior and larger part of the cavity articulates with the condyle of the mandible and is limited behind by the post-glenoid process: the posterior part lodges a portion of the parotid gland. The styloid process extends downwards and forwards for a variable distance from the lower part of the tympanic plate, and gives attachment to the Stylo-glossus, Stylo-hyoid, and Stylo-pharyngeus, and to the stylo-hyoid and stylo-mandibular ligaments. Projecting downwards behind the external auditory meatus is the mastoid process, to the outer surface of which the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid are attached.

The **zygomatic or infra-temporal fossa** (fig. 340) is an irregularly shaped cavity, situated below and on the inner side of the zygoma. It is bounded,

FIG. 340.—Left zygomatic fossa.



in front, by the zygomatic surface of the maxilla and the ridge which descends from its malar process; behind, by the eminentia articularis of the temporal and the spine of the sphenoid; above, by the greater wing of the sphenoid below the infra-temporal crest, and by the under surface of the squamous temporal; below, by the alveolar border of the maxilla; internally, by the external pterygoid plate. It contains the lower part of the Temporal muscle, the External and Internal pterygoids, together with the internal maxillary vessels and inferior maxillary nerve and their branches. The *foramen ovale* and *foramen spinosum* open on its roof, and the *posterior dental canals* on its anterior wall. At its upper and inner part may be observed two fissures, which together form a T-shaped fissure, the horizontal limb being named the spheno-maxillary, and the vertical one the pterygo-maxillary fissure.

The *spheno-maxillary fissure* (fissura orbitalis inferior), horizontal in direction, opens into the outer and back part of the orbit. It is bounded above by the lower border of the orbital surface of the greater wing of the sphenoid;

below, by the external border of the orbital surface of the maxilla and the orbital process of the palate bone; externally, by a small part of the malar bone *: internally, it joins at right angles with the pterygo-maxillary fissure. Through the spheno-maxillary fissure the orbit communicates with the temporal, zygomatic, and spheno-maxillary fossæ; the fissure transmits the superior maxillary nerve and its temporo-malar branch, the infra-orbital vessels, the ascending branches from Meckel's ganglion, and a vein which connects the ophthalmic vein with the pterygoid venous plexus.

The *pterygo-maxillary fissure* is vertical, and descends at right angles from the inner extremity of the preceding; it is a triangular interval, formed by the divergence of the maxilla from the pterygoid process of the sphenoid. It connects the spheno-maxillary fossa with the zygomatic fossa, and transmits the terminal part of the internal maxillary artery.

The **spheno-maxillary fossa** (fossa pterygo-palatina) is a small, triangular space situated at the angle of junction of the spheno-maxillary and pterygo-maxillary fissures, and placed beneath the apex of the orbit. It is bounded above by the under surface of the body of the sphenoid and by the orbital process of the palate bone; in front, by the zygomatic surface of the maxilla: behind, by the base of the pterygoid process and lower part of the anterior surface of the greater wing of the sphenoid; internally, by the vertical plate of the palate bone with its orbital and sphenoidal processes. This fossa communicates with the orbit by the spheno-maxillary fissure, with the nasal cavity by the spheno-palatine foramen, and with the zygomatic fossa by the pterygo-maxillary fissure. Five foramina open into it. Of these, three are on the posterior wall, viz.: the *foramen rotundum*, the *Vidian canal*, and the *pterygo-palatine canal*, from without downwards and inwards. On the inner wall is the *spheno-palatine foramen*, and below is the superior orifice of the *posterior palatine canal*. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

The Skull from Behind (norma occipitalis)

When viewed from behind the cranium presents a more or less circular outline. In the middle line is the posterior part of the *sagittal suture* connecting the parietal bones; extending downwards and outwards from the hinder end of the sagittal suture is the deeply serrated *lambdoid suture* joining the parietals to the occipital and continuous below with the parieto-mastoid and occipito-mastoid sutures; it frequently contains one or more Wormian bones. Near the middle of the squama occipitalis is the external occipital protuberance or *inion*, and extending outwards from it on either side is the *superior curved line* (linea nuchæ superior), and above this the faintly marked *linea suprema*. The part of the squama above the inion and lineæ supremæ is named the planum occipitale, and is covered by the Occipito-frontalis muscle: the part below is termed the planum nuchale, and is divided by a mesial ridge which runs downwards and forwards from the inion to the foramen magnum; this ridge gives attachment to the ligamentum nuchæ. The muscles attached to the planum nuchale are enumerated on page 215. Below and in front are the mastoid processes, convex externally and grooved internally by the digastric fossæ. In or near the occipito-mastoid suture is the *mastoid foramen* for the passage of the mastoid emissary vein.

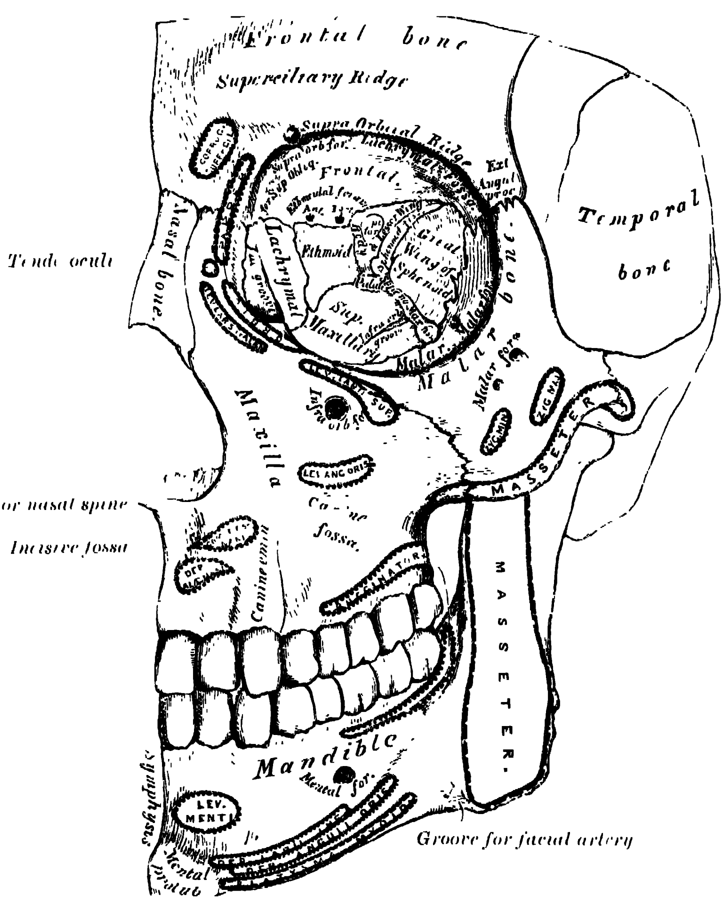
The Skull from the Front (norma frontalis)

When viewed from the front (fig. 341) the skull exhibits a somewhat oval outline, limited above by the frontal bone, below by the body of the mandible, and laterally by the malar bones and the mandibular rami. The upper part, formed by the vertical plate of the frontal, is smooth and convex; the lower part, made up of the bones of the face, is irregular, and is excavated laterally by the orbital cavities, and presents in the middle line the anterior nasal aperture leading to the cavity of the nose, and below this the transverse slit between the upper and lower dental arcades. Above, the *frontal eminences*

* Occasionally the superior maxillary bone and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from it.

stand out more or less prominently, and beneath these are the *superciliary ridges*, joined to one another in the middle by the *glabella*. On and above the glabella a trace of the *interfrontal suture* sometimes persists; beneath it is the fronto-nasal suture, the mid-point of which is termed the *nasion*. Behind and below the fronto-nasal suture the internal angular process of the frontal articulates with the lachrymal and with the frontal process of the maxilla. Arching between the internal and external angular processes of the frontal is the upper part of the margin of the orbit, thin and prominent in its outer two-thirds, rounded in its inner third, and presenting, at the junction of these two portions, the *supra-orbital notch* or *foramen* for the supra-orbital nerve and vessels. The external angular process articulates with the malar, and from it the temporal line extends upwards and backwards. Below the

FIG. 341.—Anterior region of the skull.



fronto-nasal suture is the bridge of the nose, convex from side to side, concavo-convex from above downwards, and formed by the two nasal bones supported in the middle line by the perpendicular plate of the ethmoid, and laterally by the frontal processes of the maxillæ which are prolonged upwards between the nasal and lachrymal bones and form the lower and inner part of the circumference of each orbit. Below the nasal bones and between the maxillæ is the anterior aperture of the nose, pyriform in shape, with the narrow end directed upwards. Laterally this opening is bounded by sharp margins, to which the lateral cartilages of the nose are attached; below, the margins are thicker and curve inwards and forwards to end in the *anterior nasal spine*. On looking into the nasal cavity, the bony septum which separates the nasal fossæ presents, in front, a large triangular deficiency; this, in the recent

state, is filled up by the septal cartilage. On the lateral wall of each nasal fossa the anterior part of the inferior turbinated bone is visible. Below and external to the anterior nasal aperture are the facial surfaces of the maxillæ, each perforated, near the lower margin of the orbit, by the *infra-orbital foramen* for the passage of the infra-orbital nerve and vessels. Below and internal to this foramen is the canine eminence separating the incisive from the canine fossa. Beneath these fossæ are the alveolar processes of the maxillæ containing the upper teeth, which overlap the teeth of the mandible in front. The malar bone on either side forms the prominence of the cheek, the lower and outer portion of the orbital cavity, and the anterior part of the zygomatic arch. It articulates internally with the maxilla, behind with the zygomatic process of the temporal, and above with the greater wing of the sphenoid and the external angular process of the frontal; it is perforated by the *malar foramen* for the passage of the malar branch of the temporo-malar nerve. On the body of the mandible is a median ridge, indicating the position of the symphysis; this ridge divides below to enclose the mental protuberance, the lateral angles of which constitute the mental tubercles. Below the incisor teeth is the incisive fossa, and beneath the second bicuspid tooth the *mental foramen* which transmits the mental nerve and vessels. Passing upwards from the mental tubercle is the *external oblique line*, which is continuous behind with the anterior border of the ramus. The posterior border of the ramus runs downwards and forwards from the condyle to the angle, which is frequently more or less everted.

The **orbits** (fig. 341) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forwards and outwards, and their apices backwards and inwards, so that their long axes, if continued backwards, would meet over the body of the sphenoid bone. Each presents for examination a roof, a floor, an inner and an outer wall, a base, and an apex.

The *roof* is concave, directed downwards, and slightly forwards, and formed in front by the orbital plate of the frontal; behind by the lesser wing of the sphenoid. It presents internally the depression for the attachment of the cartilaginous pulley of the Superior oblique; externally, the *lachrymal fossa* for the lachrymal gland; and posteriorly, the suture between the frontal and the lesser wing of the sphenoid.

The *floor* is directed upwards and outwards, and is of less extent than the roof; it is formed chiefly by the orbital surface of the maxilla; in front, and externally, to a small extent, by the orbital process of the malar, and behind and internally, by the orbital process of the palate. At its inner angle is the upper opening of the naso-lachrymal canal, immediately to the outer side of which is a depression for the origin of the Inferior oblique muscle of the eyeball. On its outer part is the suture between the maxilla and malar, and at its posterior part that between the maxilla and the orbital process of the palate. Running forwards near the middle of the floor is the *infra-orbital groove*, terminating in front in the infra-orbital canal and transmitting the infra-orbital nerve and vessels.

The *inner wall* is nearly vertical, and is formed from before backwards by the frontal process of the maxilla, the lachrymal, the os planum of the ethmoid, and a small part of the body of the sphenoid in front of the optic foramen. Sometimes the sphenoidal turbinated bone appears in this wall (see footnote, page 236). It exhibits three vertical sutures—viz.: one between the frontal process of the maxilla and the lachrymal, another between the lachrymal and ethmoid, and a third between the ethmoid and sphenoid. In front is seen the *lachrymal groove*, which lodges the lachrymal sac, and behind the groove is the *lachrymal crest*, from which the Tensor tarsi arises. At the junction of the inner wall and the roof is the suture which joins the frontal bone to the frontal process of the maxilla, the lachrymal, and the ethmoid. The point of junction between the anterior border of the lachrymal and the frontal is named the *dacryon*. In the suture between the frontal and the os planum of the ethmoid are the *anterior* and *posterior ethmoidal foramina*, the former transmitting the nasal nerve and anterior ethmoidal vessels, the latter the posterior ethmoidal vessels.

The *outer wall*, directed inwards and forwards, is formed by the orbital process of the malar and the orbital surface of the greater wing of the sphenoid;

these are united by a vertical suture which terminates below at the front end of the spheno-maxillary fissure. On the orbital process of the malar are the orifices of one or two canals which transmit the temporal and malar branches of the temporo-malar nerve. Between the roof and the outer wall, near the apex of the orbit, is the *sphenoidal fissure*. Through this fissure the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves enter the orbital cavity, also some filaments from the cavernous plexus of the sympathetic and the orbital branches of the middle meningeal artery. Passing backwards through the fissure are the ophthalmic vein and the recurrent branch from the lachrymal artery to the dura mater. The outer wall and the floor are separated posteriorly by the *spheno-maxillary fissure* which transmits the superior maxillary nerve and its temporo-malar branch, the infra-orbital vessels, and the ascending branches from Meckel's ganglion.

The *base* of the orbit, quadrilateral in shape, is formed above by the supra-orbital arch of the frontal bone, in which is the *supra-orbital notch* or *foramen* for the passage of the supra-orbital vessels and nerve; below by the malar and maxilla, united by the *malo-maxillary suture*; externally by the malar and the external angular process of the frontal joined by the *fronto-malar suture*; internally by the internal angular process of the frontal and the frontal process of the maxilla, the *fronto-maxillary suture* intervening.

The *apex*, situated at the back of the orbit, corresponds to the optic foramen,* a short, circular canal, which transmits the optic nerve and ophthalmic artery.

It will thus be seen that there are *nine* openings communicating with each orbit—viz.: the optic foramen, sphenoidal fissure, spheno-maxillary fissure, supra-orbital foramen, infra-orbital canal, anterior and posterior ethmoidal foramina, malar foramen, and the canal for the nasal duct.

INTERIOR OF THE SKULL

In order to study the interior of the skull the skull-cap should be removed by a saw-cut carried round the cranium about the level of the frontal eminences and the upper limits of the squamous sutures, cutting the occipital bone about an inch above the external protuberance.

Inner Surface of the Skull-cap

The inner surface of the skull-cap is concave and presents depressions for the convolutions of the cerebrum, together with numerous furrows for the lodgment of branches of the meningeal arteries. Along the middle line is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind; it lodges the superior longitudinal sinus, and its margins afford attachment to the falx cerebri. On either side of it are several depressions for the Pacchionian bodies, and at its back part, the openings of the *parietal foramina* when these are present. It is crossed, in front, by the *coronal suture*, and behind by the *lambdoid*, whilst the *sagittal* lies in the mesial plane between the parietal bones.

Upper Surface of the Base of the Skull

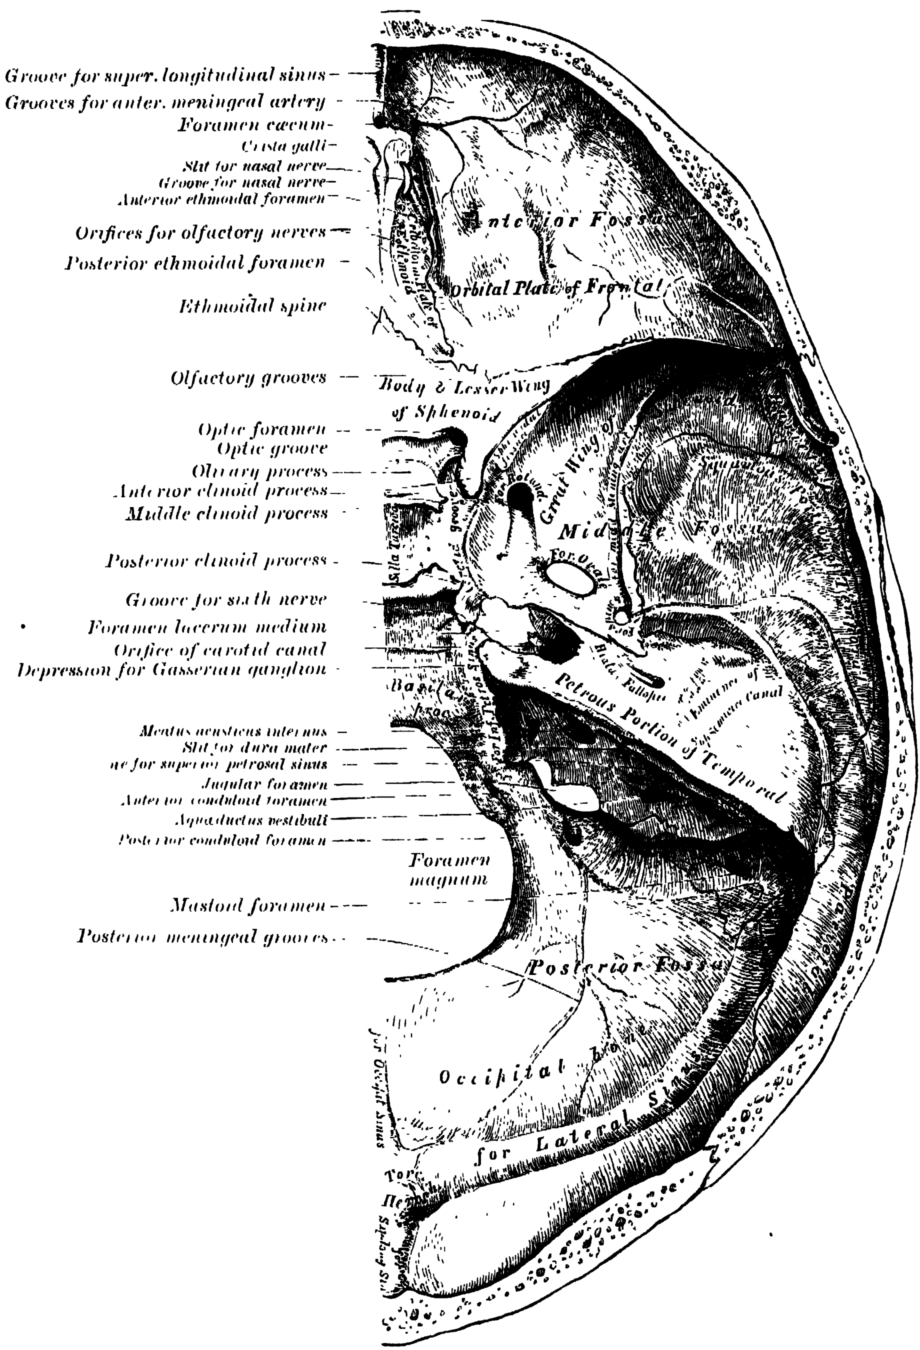
The upper surface of the base of the skull or floor of the cranial cavity (fig. 342) presents three fossæ, called the *anterior*, *middle*, and *posterior cranial fossæ*.

Anterior fossa.—The floor of the anterior fossa is formed by the orbital plates of the frontal, the cribriform plate of the ethmoid, and the lesser wings and front part of the body of the sphenoid; it is limited behind by the posterior borders of the lesser wings of the sphenoid and by the anterior margin

* Some anatomists describe the apex of the orbit as corresponding with the inner end of the sphenoidal fissure. It seems better, however, to adopt the statement in the text, since the muscles of the eyeball take origin around the optic foramen, and diverge from it to the globe of the eye.

of the optic groove. It is traversed by three sutures, the *fronto-ethmoidal*, *spheno-ethmoidal* and *spheno-frontal*. Its lateral portions roof in the orbital cavities and support the frontal lobes of the cerebrum; they are convex

FIG. 342.—Base of the skull. Upper surface.



and marked by depressions for the brain convolutions, and grooves for branches of the meningeal arteries. The central portion corresponds with the roof of the nose, and is markedly depressed on either side of the crista galli. It presents, in and near the median line, from before backwards, the commence-

ment of the *frontal crest* for the attachment of the falx cerebri; the *foramen cæcum*, between the frontal bone and the crista galli of the ethmoid, which usually transmits a small vein from the nose to the superior longitudinal sinus; behind the foramen cæcum, the *crista galli*, the free margin of which affords attachment to the falx cerebri; on either side of the crista galli, the *olfactory groove* formed by the cribriform plate, which supports the olfactory bulb, and presents foramina for the transmission of the olfactory nerves to the nose, and in front a slit-like opening for the nasal branch of the ophthalmic division of the fifth nerve. On the outer side of each olfactory groove are the internal openings of the *anterior* and *posterior ethmoidal foramina*; the anterior, situated about the middle of the outer margin of the olfactory groove, transmits the anterior ethmoidal vessels and the nasal nerve; the nerve runs in a groove along the outer edge of the cribriform plate to the slit-like opening above mentioned; the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits a meningeal branch from the posterior ethmoidal artery. Farther back in the middle line is the *ethmoidal spine*, bounded behind by a slight elevation separating two shallow longitudinal grooves which support the olfactory lobes. Behind this is the anterior margin of the optic groove, running outwards on either side to the upper margin of the optic foramen.

The **middle fossa**, deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in front by the posterior margins of the lesser wings of the sphenoid, the anterior clinoid processes, and the ridge forming the anterior margin of the optic groove; behind, by the superior borders of the petrous portions of the temporals, and the dorsum sellæ, externally by the squamous portions of the temporals, antero-inferior angles of the parietals, and greater wings of the sphenoid. It is traversed by four sutures, the *squamous*, *spheno-parietal*, *spheno-squamosal*, and *spheno-petrosal*.

The middle part of the fossa presents, in front, the *optic groove* and *olivary eminence*; the optic groove terminates on either side at the *optic foramen*, which transmits the optic nerve and ophthalmic artery to the orbital cavity. Behind the optic foramen the *anterior clinoid process* is directed backwards and inwards and gives attachment to the tentorium cerebelli. Behind the olivary eminence is a deep depression, the *sella turcica*, which lodges the pituitary body and presents on its anterior wall, the *middle clinoid processes*. The sella turcica is bounded posteriorly by a quadrilateral plate of bone, the *dorsum sellæ*, the upper angles of which are surmounted by the *posterior clinoid processes*: these afford attachment to the tentorium cerebelli, and below each is a notch for the sixth nerve. On either side of the sella turcica is the *carotid groove*, which is broad, shallow, and curved somewhat like the italic letter *f*. It begins behind at the foramen lacerum medium, and ends on the inner side of the anterior clinoid process, where it is sometimes converted into a foramen (carotico-clinoid) by the union of the anterior with the middle clinoid process; posteriorly, it is bounded on the outer side by the *lingula*. This groove lodges the cavernous sinus and the internal carotid artery, the latter being surrounded by a plexus of sympathetic nerves.

The lateral parts of the middle fossa are of considerable depth, and support the temporal lobes of the brain. They are marked by depressions for the brain convolutions and traversed by furrows for the anterior and posterior branches of the middle meningeal artery. These furrows begin near the foramen spinosum, and the anterior runs forwards and upwards to the antero-inferior angle of the parietal, where it is sometimes converted into a bony canal; the posterior runs backwards and outwards across the squamous portion of the temporal and passes on to the parietal near the middle of its lower border. The following apertures are also to be seen. In front is the *sphenoidal fissure*, bounded above by the lesser wing, below, by the greater wing, and internally, by the body of the sphenoid; it is usually completed externally by the orbital plate of the frontal bone. It transmits to the orbital cavity the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, some filaments from the cavernous plexus of the sympathetic, and the orbital branch of the middle meningeal artery; and from the orbital cavity a recurrent branch from the lachrymal artery to the dura mater, and the

ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the *foramen rotundum*, for the passage of the second division of the fifth nerve; still more posteriorly is the *foramen Vesalii*, which varies in size in different individuals, and is often absent; when present, it opens below at the outer side of the scaphoid fossa, and transmits a small vein. Behind and external to the latter opening is the *foramen ovale*, which transmits the third division of the fifth nerve, the small meningeal artery, and the small superficial petrosal nerve.* On the outer side of the foramen ovale is the *foramen spinosum*, for the passage of the middle meningeal artery and veins, and a recurrent branch from the inferior maxillary nerve. On the inner side of the foramen ovale is the *foramen lacerum medium*; in the recent state the lower part of this aperture is filled up by a layer of fibro-cartilage, while its upper and inner parts transmit the internal carotid artery surrounded by a plexus of sympathetic nerves. The Vidian nerve and a meningeal branch from the ascending pharyngeal artery pierce the layer of fibro-cartilage. On the anterior surface of the petrous portion of the temporal bone are seen, from without inwards, the eminence caused by the projection of the superior semicircular canal; in front and a little to the outer side of this a depression corresponding to the roof of the tympanic cavity; the groove leading to the *hiatus Fallopii*, for the transmission of the great superficial petrosal nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the small superficial petrosal nerve; and, near the apex of the bone, the depression for the Gasserian ganglion and the orifice of the carotid canal.

The **posterior fossa** is the largest and deepest of the three. It is formed by the dorsum sellæ and clivus of the sphenoid, the occipital, the petrous and mastoid portions of the temporals, and the postero-inferior angles of the parietal bones; it is crossed by two sutures, the *occipito-mastoid* and the *parieto-mastoid*, and lodges the cerebellum, pons Varolii, and medulla oblongata. It is separated from the middle fossa in and near the median line by the dorsum sellæ, and on either side by the superior border of the petrous portion of the temporal bone. This border gives attachment to the tentorium cerebelli, is grooved for the superior petrosal sinus, and presents at its inner extremity a notch upon which the fifth nerve rests. The fossa is limited behind by the grooves for the lateral sinuses. In its centre is the *foramen magnum*, on either side of which is a rough tubercle for the attachment of the lateral odontoid or check ligaments; a little above this tubercle is the *anterior condyloid foramen*, which transmits the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum the basilar process of the occipital and the posterior part of the body of the sphenoid form a grooved surface which supports the medulla oblongata and pons Varolii; in the young skull these bones are joined by a synchondrosis. This grooved surface is separated on either side from the petrous portion of the temporal by the *petro-occipital fissure*, which is occupied in the recent state by a plate of cartilage. This fissure is continuous behind with the jugular foramen, and its margins are grooved for the inferior petrosal sinus. The *jugular foramen* is situated between the lateral portion of the occipital and the petrous part of the temporal. The anterior portion of this foramen transmits the inferior petrosal sinus; the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and the middle, the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. Above the jugular foramen is the *internal auditory meatus*, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the aquæductus vestibuli, which lodges the ductus endolymphaticus; while between these, and near the superior border of the petrous portion, is a small triangular depression, the remains of the fossa subarcuata, which lodges a process of the dura mater and occasionally transmits a small vein. Behind the foramen magnum are the *inferior occipital fossæ*, which support the hemispheres of the cerebellum, separated from one another by the *internal occipital crest*, which serves for the attachment of the falx cerebelli, and lodges the occipital sinus. The posterior fossæ are surmounted by the deep transverse grooves for the *lateral sinuses*. Each of

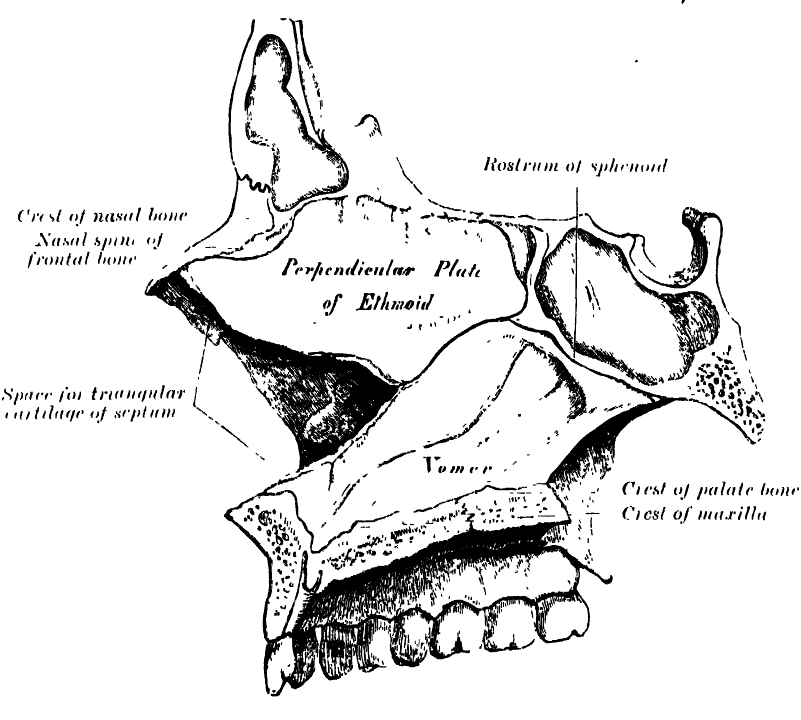
* See footnote, page 234.

these channels, in its passage to the jugular foramen, grooves the occipital, the postero-inferior angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and terminates at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal, the orifice of the *mastoid foramen* may be seen; and, just previous to its termination, the *posterior condyloid foramen* opens into it; neither foramen is constant.

THE NASAL FOSSÆ

The **nasal fossæ** are two irregular cavities, situated one on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They open on the face through the pear-shaped *anterior nasal aperture*, and communicate behind with the nasal part of the pharynx by the *posterior nares* or *choanæ*. They are much narrower above than below, and in the middle than at their anterior or posterior openings: their depth, which is considerable, is greatest in the middle. They communicate with the frontal, ethmoidal, sphenoidal, and maxillary sinuses. Each fossa is bounded by a roof, a floor, an inner and an outer wall.

FIG. 343.—Inner wall of left nasal fossa.



The *roof* (figs. 343 and 344) is horizontal in its central part, but slopes downwards in front and behind; it is formed in front by the nasal bones and nasal spine of the frontal; in the middle, by the cribriform plate of the ethmoid; and behind, by the body of the sphenoid, the sphenoidal turbinated bones, the ala of the vomer and the sphenoidal process of the palate-bone. The cribriform plate of the ethmoid presents the foramina for the olfactory nerves; on the posterior part of the roof is the opening into the sphenoidal sinus.

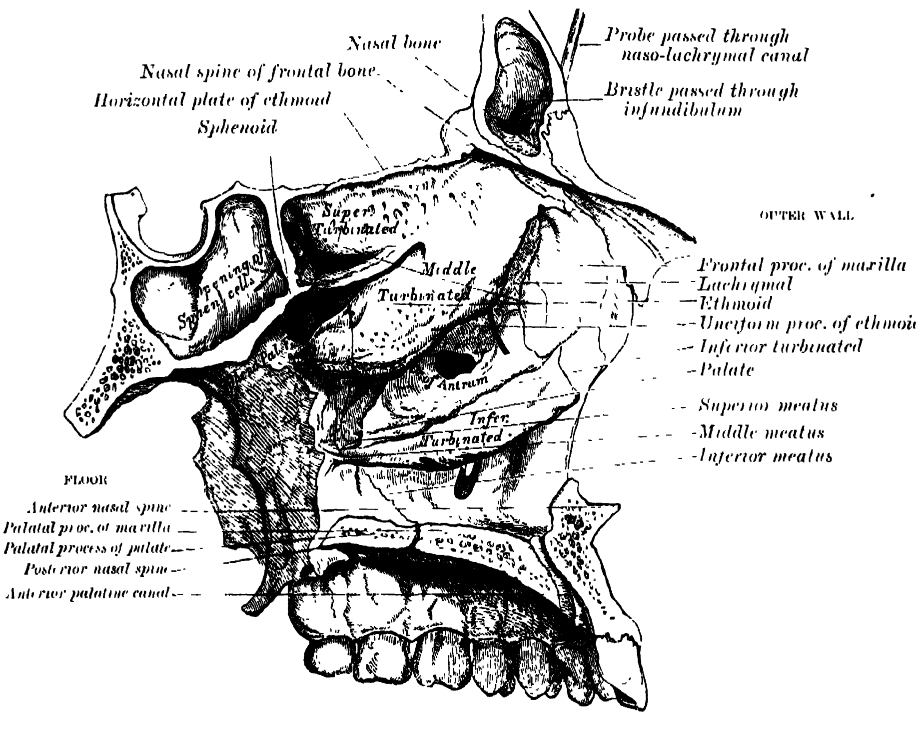
The *floor* is flattened from before backwards and concave from side to side. It is formed by the palatal processes of the maxilla and palate; near its anterior extremity is the opening of the incisor foramen.

The *inner wall*, or septum nasi (fig. 343), is frequently deflected to one or other side. It is formed, in front, by the crest of the nasal bones and nasal

spine of the frontal; in the middle, by the perpendicular plate of the ethmoid; behind, by the vomer and rostrum of the sphenoid; below, by the crest of the maxillæ and palate bones. It presents, in front, a large, triangular notch, which receives the septal cartilage of the nose; and behind, the free edge of the vomer. Its surface is marked by numerous furrows for vessels and nerves and by the groove for the naso-palatine nerve, and is traversed by sutures connecting the bones of which it is formed.

The *outer wall* (fig. 344) is formed, in front, by the frontal process of the maxilla and by the lachrymal bone; in the middle, by the ethmoid, maxilla and inferior turbinated bones; behind, by the vertical plate of the palate-bone, and the internal pterygoid plate of the sphenoid. This surface presents three irregular longitudinal passages, termed the superior, middle, and inferior meatuses of the nose. The *superior meatus*, the smallest of the three, occupies the middle third of the outer wall. It lies between the superior and middle turbinated processes of the ethmoid; the *spheno-palatine* foramen opens into

FIG. 344.—Roof, floor, and outer wall of left nasal fossa.



it behind, and the *posterior ethmoidal cells* in front. The sphenoidal sinus opens into a recess, the *spheno-ethmoidal recess*, which is placed above and behind the superior turbinated process. The *middle meatus* is situated between the middle turbinated process and the inferior turbinated bone, and extends from the anterior to the posterior end of the latter. It presents in front the orifice of the *infundibulum*, by which the middle meatus communicates with the frontal sinus and anterior ethmoidal cells. The infundibulum leads downwards into a curved groove, the *hiatus semilunaris*, in the posterior part of which is seen the orifice of the antrum of Highmore. In a considerable percentage of skulls the antral orifice is duplicated, the second opening being usually situated behind the hiatus. Above the hiatus semilunaris is a smooth convex surface—the *bulla ethmoidalis*—on which the middle ethmoidal cells open. The *inferior meatus*, the largest of the three, is the space between the inferior turbinated bone and the floor of the nasal fossa. It extends almost the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower *orifice of the canal for the nasal duct.*

The *anterior nasal aperture* is a heart-shaped or pyriform opening, whose long axis is vertical, and narrow extremity upwards. This opening in the recent state is much contracted by the cartilages of the nose. It is bounded above by the inferior borders of the nasal bones; laterally by the thin, sharp margins which separate the facial from the nasal surfaces of the maxillæ; and below by the same borders, where they slope inwards to join each other at the anterior nasal spine.

The *posterior nares* or *choanæ* are each bounded above by the under surface of the body of the sphenoid and ala of the vomer; below, by the posterior border of the horizontal plate of the palate-bone; externally, by the inner surface of the internal pterygoid plate; they are separated from each other by the posterior border of the vomer.

Differences in the Skull due to Age

At birth the skull as a whole is large in proportion to the other parts of the skeleton, but its facial portion is small, and equals only about one-eighth of the bulk of the cranium as compared with one-half in the adult. The frontal and parietal eminences are prominent, and the greatest width of the skull is at the level of the latter; on the other hand, the glabella, superciliary ridges; and mastoid processes are not developed. Ossification of the skull-bones is not completed, and many of them—e.g. the occipital, temporals, sphenoid, frontal, and mandible—consist of more than one piece. Unossified membranous intervals, termed *fontanelles*, are seen at the angles of the parietal bones; these fontanelles are six in number: two, an anterior and a posterior, are situated in the middle line, and two, an antero-lateral and a postero-lateral, are placed on either side.

The *anterior* or *bregmatic fontanelle* (fig. 345) is the largest, and is situated at the junction of the sagittal, coronal, and interfrontal sutures; it is lozenge-shaped, and measures about an inch and a half in its antero-posterior and an inch in its trans-

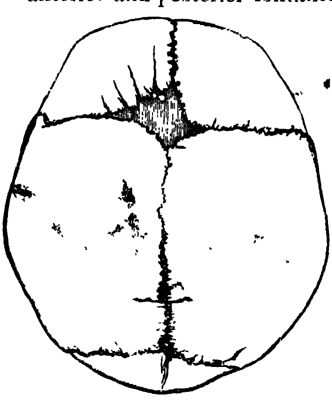


Fig. 345.—Skull at birth, showing the anterior and posterior fontanelles.

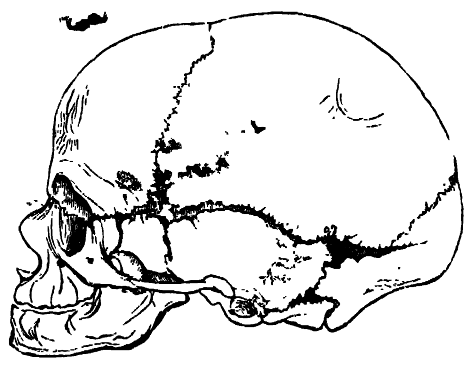

Fig. 346.—The lateral fontanelles.

verse diameter. The *posterior fontanelle* is triangular in form and is situated at the junction of the sagittal and lambdoid sutures. The *lateral fontanelles* (fig. 346) are small, irregular in shape, and correspond respectively with the antero-inferior and postero-inferior angles of the parietal bones. An additional fontanelle is sometimes seen in the sagittal suture at the region of the obelion. The fontanelles are usually closed by the growth and extension of the bones which surround them, but sometimes they are the sites of separate ossific centres which develop into Wormian bones. The posterior and lateral fontanelles are obliterated within a month or two after birth, but the anterior is not completely closed until the first half of the second year; sometimes it remains open beyond the second year, a condition which is usually due to malnutrition in rickets. A knowledge of the shape and position of the fontanelles is of service to the accoucheur in enabling him to determine which part of the fœtal head is presenting during parturition.

The small size of the face at birth is mainly accounted for by the rudimentary condition of the jaws, the non-eruption of the teeth, and the small size of the

maxillary air-sinuses and nasal cavities. At birth the nasal cavities lie almost entirely between the orbits, and the lower border of the anterior nasal aperture is only a little below the level of the orbital floor. With the eruption of the milk-teeth there is an enlargement of the face and jaws, and these changes are still more marked after the second dentition.

The skull grows rapidly from birth to the seventh year, by which time the foramen magnum and petrous parts of the temporals have reached their full size and the orbital cavities are only a little smaller than those of the adult. Growth is slow from the seventh year until the approach of puberty, when a second period of activity takes place: this consists of an increase in all directions, but it is especially marked in the frontal and facial regions, where it is associated with the development of the air-sinuses.

Obliteration of the sutures of the vault of the skull takes place as age advances. This process may commence between the ages of thirty and forty, and is first seen on the inner surface, and some ten years later on the outer surface of the skull. The dates given are, however, only approximate, as it is impossible to state with anything like accuracy the time at which the sutures are closed. Obliteration usually occurs first in the posterior part of the sagittal suture, next in the coronal, and then in the lambdoid.

In old age the skull generally becomes thinner and lighter, but in a small proportion of cases it increases in thickness and weight, owing to a hypertrophy of the inner table. The most striking feature of the old skull is the diminution in the size of the jaws consequent on the loss of the teeth and the absorption of the alveolar processes. This is associated with a marked reduction in the vertical measurement of the face and with an alteration in the angles of the mandible.

Sexual Differences in the Skull

Until the age of puberty there is little difference between the skull of the female and that of the male. The skull of an adult female is as a rule lighter and smaller, and its cranial capacity about 10 per cent. less, than that of the male. Its walls are thinner and its muscular ridges less strongly marked; the glabella, superciliary ridges, and mastoid processes are less prominent, and the corresponding air-sinuses are small or rudimentary. The upper margin of the orbit is sharp, the forehead vertical, the frontal and parietal eminences prominent, and the vault somewhat flattened. The contour of the face is more rounded, the facial bones are smoother, and the jaws and their contained teeth smaller. From what has been said it will be seen that more of the infantile characteristics are retained in the skull of the adult female than in that of the adult male. A well-marked male or female skull can easily be recognised as such, but in some cases the respective characteristics are so indistinct that the determination of the sex may be difficult or impossible.

Craniology

Skulls vary in size and shape, and the term *craniology* is applied to the study of these variations. The size of a skull constitutes a good index of the development of the brain which it contained, and is most conveniently arrived at by ascertaining the *capacity* of the cranial cavity. This is accomplished by filling the cavity with shot and measuring the contents in a graduated vessel. Skulls may be classified according to their capacities as follows:

1. *Microcephalic*, with a capacity of less than 1350 cubic centimetres—e.g. those of native Australians and Andaman Islanders.
2. *Mesocephalic*, with a capacity of from 1350 c.cm. to 1450 c.cm.—e.g. those of African negroes and Chinese.
3. *Megacephalic*, with a capacity of over 1450 c.cm.—e.g. those of Europeans, Japanese, and Eskimos.

In comparing the shape of one skull with that of another it is necessary to adopt some definite position in which the skull should be placed during the process of examination. It should be so placed that a line carried through the lower margin of the orbit and upper margin of the external auditory meatus is in the horizontal plane. The normæ of one skull can then be compared with those of another, and the differences in contour and surface-form noted. Further, it is necessary that the various linear measurements used to determine the shape of the

skull should be made between definite and easily localised points on its surface. The principal points have already been mentioned in the descriptions of the individual skull-bones, but are here tabulated for convenience of reference. They may be divided into two groups: (1) those in the mesial plane, and (2) those on either side of it.

The points in the mesial plane are the:

Mental point. The most prominent point of the chin.

Alveolar point or *prosthion.* The central point of the anterior margin of the upper alveolar arch.

Sub-nasal point. The middle of the lower border of the anterior nasal aperture, at the base of the nasal spine.

Nasion. The central point of the fronto-nasal suture.

Glabella. The point in the middle line at the level of the superciliary ridges.

Ophryon. The point in the middle line at the level where the temporal lines most nearly approach each other.

Bregma. The meeting point of the coronal and sagittal sutures.

Obelion. A point in the sagittal suture on a level with the parietal foramina.

Lambda. The point of junction of the sagittal and lambdoid sutures.

Occipital point. The point in the middle line of the occipital bone farthest from the glabella.

Inion. The external occipital protuberance.

Opisthion. The mid-point of the posterior margin of the foramen magnum.

Basion. The mid-point of the anterior margin of the foramen magnum.

The points on either side of the mesial plane are the:

Gonion. The outer margin of the angle of the mandible.

Dacryon. The point of union of the antero-superior angle of the lachrymal with the frontal bone and the frontal process of the maxilla.

Stephanion. The point where the temporal line intersects the coronal suture.

Pterion. The point where the greater wing of the sphenoid joins the antero-inferior angle of the parietal.

Auricular point. The centre of the orifice of the external auditory meatus.

Asterion. The point of meeting of the lambdoid, masto-occipital, and masto parietal sutures.

The *horizontal circumference* of the cranium is measured in a plane passing through the glabella (Turner) or the ophryon (Flower) in front, and the occipital point behind; it averages about twenty inches (50 cm.) in the female and twenty-one inches (52·5 cm.) in the male.

The *occipito-frontal* or *longitudinal arc* is measured from the nasion over the middle line of the vertex to the opisthion; while the *basi-nasal length* is the distance between the basion and the nasion. These two measurements, plus the antero-posterior diameter of the foramen magnum, represent the *vertical circumference* of the cranium.

The *length* is measured from the glabella to the occipital point, while the *breadth* or greatest transverse diameter is usually found near the external auditory meatus. The proportion of breadth to length $\left(\frac{\text{breadth} \times 100}{\text{length}}\right)$ is termed the *cephalic index* or *index of breadth.*

The *height* is usually measured from the basion to the bregma, and the proportion of height to length $\left(\frac{\text{height} \times 100}{\text{length}}\right)$ constitutes the *vertical* or *height index.*

In studying the face the principal points to be noticed are the proportion of its length and breadth, the shape of the orbits and of the anterior nasal aperture, and the degree of projection of the jaws.

The *length of the face* may be measured from the ophryon or nasion to the chin, or, if the mandible be wanting, to the alveolar point; while its *width* is represented by the distance between the zygomatic arches. By comparing the length with the width of the face, skulls may be divided into two groups: *dolichofacial* or *leptoprosope* (long-faced) and *brachyfacial* or *chamoprosope* (short-faced).

The *orbital index* signifies the proportion which the orbital height bears to the orbital width, thus:

$$\frac{\text{orbital height} \times 100}{\text{orbital width}}.$$

The *nasal index* expresses the proportion which the width of the anterior nasal aperture bears to the height of the nose, the latter being measured from the nasion to the lower margin of the nasal aperture, thus:

$$\frac{\text{nasal width} \times 100}{\text{nasal height}}.$$

The degree of projection of the jaws is determined by the *gnathic* or *alveolar index*, which represents the proportion between the basi-alveolar and basi-nasal lengths, thus:

$$\frac{\text{basi-alveolar length} \times 100}{\text{basi-nasal length}}.$$

The following table, modified from that given by Duckworth,* illustrates how these different indices may be utilised in the classification of skulls:

INDEX	CLASSIFICATION	NOMENCLATURE	EXAMPLES
1. Cephalic .	Below 75 . . .	Dolichocephalic .	Kaffirs and Native Australians
	Between 75 and 80	Mesaticephalic .	Europeans and Chinese
	Above 80 . . .	Brachycephalic .	Mongolians and Andamans
2. Orbital .	Below 84 . . .	Microseme . .	Tasmanians and Native Australians
	Between 84 and 89	Mesoseme .	Europeans
	Above 89 . . .	Megaseme. . .	Chinese and Polynesians
3. Nasal . .	Below 48 . . .	Leptorhine . .	Europeans
	Between 48 and 53	Mesorhine. . .	Japanese and Chinese
	Above 53 . . .	Platyrhine . .	Negroes and Native Australians
4. Gnathic .	Below 98 . . .	Orthognathous .	Europeans
	Between 98 and 103	Mesognathous .	Chinese and Japanese
	Above 103 . . .	Prognathous . .	Native Australians

Surface Form.—The various bony prominences or landmarks which are easily felt and recognised in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follows:

1. Supra-orbital arch
2. Internal angular process.
3. External angular process.
4. Zygomatic arch.
5. Mastoid process.
6. External occipital protuberance.
7. Superior curved line of occipital bone.
8. Parietal eminence.
9. Temporal ridge.
10. Frontal eminence.
11. Superciliary ridge.
12. Nasal bone.
13. Lower margin of orbit.
14. Mandible.

1. The *supra-orbital arch* can be felt throughout its entire extent, covered by the eyebrow. It forms the upper boundary of the circumference of the orbit and separates the face from the forehead. It terminates internally at the root of the nose, in the *internal angular process* which articulates with the lachrymal bone and frontal process of the maxilla, and externally in the *external angular process* which articulates with the malar bone. At the junction of the inner and middle thirds of the arch, a slight interruption in the outline may sometimes be felt; this is the *supra-orbital notch.* When the notch

* *Morphology and Anthropology*, by W. L. H. Duckworth, M.A., Cambridge University Press.

is converted into a foramen, the interruption does not exist. A line carried from this notch or foramen downwards over the face, to the second bicuspid tooth of the mandible, passes over the infra-orbital and the mental foramina, and thus constitutes a guide to the points of exit of the three largest cutaneous branches of the fifth cranial nerve. In the less civilised races, as the forehead recedes backwards, the supra-orbital arch becomes more prominent and approaches more to the condition seen in the monkey tribe, in which the supra-orbital arches are very largely developed and acquire additional prominence from the oblique direction of the frontal bone. 2. The *internal angular process* can scarcely be felt. Its position is indicated by the angle formed by the supra-orbital arch with the frontal process of the maxilla and the lachrymal bone at the inner side of the orbit. Between the internal angular processes is a broad surface, which assists in forming the root of the nose, and immediately above this an expanded, smooth, somewhat triangular area, the *glabella*, situated between and connecting the superciliary ridges. 3. The *external angular process* is much more strongly marked than the internal, and can be plainly felt. It is formed by the junction of the supra-orbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does not articulate with the malar, and therefore this lateral support to the bones of the face is not present. 4. The *zygomatic arch* can be felt throughout its entire length, and is formed by the malar bone and the zygomatic process of the temporal bone. Its anterior part is broad, and constitutes the prominence of th cheek; its posterior part is narrow, and terminates just in front and a little above the tragus of the external ear. Its upper border may be traced backwards, as the posterior root, above the tragus and the external auditory meatus to join the posterior part of the lower temporal ridge, forming the *supramastoid crest*. A spot in this line, immediately in front of the upper border of the tragus and between it and the condyle of the mandible, is known as the *pre-auricular point*. This is an important landmark, since the temporal vessels and the auriculo-temporal nerve cross it, and two inches vertically above it is the lower end of the fissure of Rolando. The lower border of the zygomatic arch is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the latter, which somewhat obscures its outline. 5. Behind the ear the *mastoid portion of the temporal bone* can be plainly felt, terminating below in a nipple-shaped process. Its anterior border lies immediately behind the concha, and its apex is about on a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood. 6. The *external occipital protuberance* (*inion*) can be felt at the level where the skin of the neck joins that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. 7. Running outwards on either side from the external occipital protuberance is an arched ridge of bone, the *superior curved line*, which gives attachment to some of the muscles which keep the head erect on the vertebral column. Below this line the surface of bone is obscured by the overlying muscles, except in the middle, where the external occipital crest can generally be felt at the bottom of the nuchal furrow. Above it, the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital, the parietal, and the frontal bones themselves; in bald persons, even the lines of junction of the bones (especially that of the occipital and parietals at the lambdoid suture) may be defined as slight depressions, caused by the thickening of the borders of the bones. 8. Near the line of the greatest transverse diameter of the head are the *parietal eminences*, one on either side of the middle line; they denote the points where ossification of the parietal bones began. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms a dome, so that the force of the blow is diffused over the bone in every direction. 9. At the side of the head is the *temporal ridge*. Commencing at the external angular process, it may be felt as a curved ridge, passing upwards on the frontal bone, and then curving backwards, separating the forehead from the temporal fossa. It may then be traced, in a curved direction, over the parietal bone, where, though less marked, it can generally be recognised. Finally, the ridge curves downwards and forwards, and terminates in the posterior root of the zygoma. 10. The *frontal eminences* vary in prominence in different individuals, and are frequently unsymmetrical. Their prominence depends more upon the general shape of the bone than upon the size of the eminences themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright, and the frontal eminences stand out in bolder relief. Thus they may be considered as affording, to a certain extent, an indication of the development of the frontal lobes of the brain, and of the mental powers of the individual. 11. Below the frontal eminences are the *superciliary ridges*, which denote the position of the frontal sinuses, and vary in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. The degree of prominence of the superciliary ridges is not, however, necessarily dependent on the size of the frontal sinuses, for large sinuses may be present in cases where there is but little elevation of the ridges,

and, on the other hand, strongly marked ridges may be associated with small air-sinuses. They commence on either side of the glabella, and here present a rounded form, which gradually fades away at their outer ends. 12. The *nasal bones* form the prominence of the nose. They vary much in size and shape, and to them is due the varieties in the contour of this organ and much of the character of the face. 13. The *lower margin of the orbit*, formed by the maxilla and malar bone, can be felt throughout its entire length. It is continuous internally with the frontal process of the maxilla, and at their point of junction is a little tubercle, which serves as a guide to the position of the lachrymal sac, which is situated above and behind it. 14. The outline of the *mandible* can be felt throughout its entire length. Just in front of the tragus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened, this prominence of bone advances out of the glenoid fossa on to the eminentia articularis, and recedes when the mouth is closed. From the condyle the posterior border of the ramus can be followed down to the angle, and from the angle to the symphysis menti the lower rounded border of the body of the bone is plainly to be felt. At the point of junction of the two halves of the bone is a well-marked triangular eminence, the *mental process*, which forms the prominence of the chin.

Applied Anatomy.—Occasionally a protrusion of the brain or its membranes may take place through one of the sutures, owing to non-closure. When the protrusion consists of membranes only, and is filled with cerebro-spinal fluid, it is called a *meningocele*; when it consists of brain as well as membranes, it is termed an *encephalocele*. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place between the centres of ossification of the tabular portion of the occipital bone (see page 217). They generally occur through the upper part of the vertical fissure, which is the last to ossify, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions are met with in other situations, as in the sagittal, lambdoid, and other sutures, or through abnormal gaps and deficiencies at the sides or base of the skull.

The chief function of the skull is to protect the brain from any form of violence to which it may be subjected. We find, therefore, that those portions of the skull which are most exposed to external violence are thicker than those which are shielded from injury by overlying muscles. Thus, the skull-cap is thick and dense, whereas the squamous portion of the temporal bone, being protected by the Temporal muscle, and the inferior occipital fossæ, being shielded by the muscles at the back of the neck, are thin and fragile. Fracture of the skull is further prevented by its elasticity, its rounded shape, and its construction of a number of secondary elastic arches, each made up of a single bone. The manner in which vibrations are transmitted through the bones of the skull is also of importance as regards its protective mechanism, at all events as far as the base is concerned. In the vault, the bones being of a fairly equal thickness and density, vibrations are transmitted in a uniform manner in all directions, but in the base, owing to the varying thickness and density of the bones, this is not so; and therefore in this situation there are special buttresses which serve to carry the vibrations in certain definite directions. At the front of the skull, on either side, is the ridge which separates the anterior from the middle fossa of the base; and behind, the ridge or buttress which separates the middle from the posterior fossa; and if any violence is applied to the vault, the vibrations would be carried along these buttresses to the sella turcica, where they meet. This part has been termed the 'centre of resistance,' and here there is a special protective mechanism to guard the brain. The subarachnoid space is dilated, and the increased quantity of cerebro-spinal fluid acts as a water-cushion to shield the brain from injury. In like manner, when violence is applied to the base of the skull, as in falls upon the feet, the vibrations are carried backwards through the occipital crest, and forwards through the basilar process and body of the sphenoid to the vault of the skull.

Fractures of the skull are best considered as affecting either the vault or the base. Fractures of the vault may, and generally do, involve the whole thickness of the bone; but sometimes the inner table only may be fractured, and portions of it driven inwards. As a rule, in fractures of the skull, the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inwards becomes broken up, and is more diffused by the time it reaches the inner table; the bone being in the form of an arch bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch, i.e. the outer table, and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be simple fissures, or may be starred and comminuted, and the fragments may be depressed or elevated. Cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture, a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if the fracture is also depressed, a fissure circumscribes the radiating lines, enclosing a portion of the skull. If this area is circular it is termed a 'pond' fracture, and would in all probability have been caused by a round instrument, as a life preserver or hammer; if

elliptical in shape it is termed a 'gutter' fracture, and would owe its shape to the instrument which had produced it, as a poker. Fracture of the outer table alone only occurs in the region of the frontal sinuses where the two tables are completely separated.

Fractures of the base of the skull may be produced by *indirect* or *direct* violence. I. In cases of the former class the violence is applied to the vertex or some part of the cranial convexity, as when a person falls from a height on to his head and a fracture of the base results. The mechanism of this form of fracture was formerly explained by the doctrine of *contre-coup*, i.e. that the force was transmitted from one side of the skull to the other; but this idea is now completely exploded, and there are at the present day two theories as to mode of causation of these fractures. (*a*) According to Aran's theory of *irradiation* all fractures of the base are produced by a fissure, which starts from the point of injury and radiates to the base. There can be little doubt that many cases of fracture of the base, especially of the middle fossæ, are caused in this way, but it is insufficient to explain all, since instances have been met with of fracture of the base of the skull in which there has been no fracture of the vault. (*b*) To explain these cases, another theory, known as the *compression* or *bursting* theory, has been suggested. If a hollow, elastic sphere is compressed from above downwards, it will bulge laterally, and, if the compression is sufficient, it will eventually burst in the situation where it bulges. Now, the skull is an elastic sphere, and when compression is applied to it, its diameter will be reduced along the line of greatest pressure and will therefore be increased in other directions, and may increase to such an extent that bursting occurs. In a hollow elastic sphere of uniform thickness, the bulging and subsequent bursting take place at the equatorial line midway between the two points of compression; but the skull is not of uniform thickness, and therefore the bulging and subsequent bursting take place at the weakest part.

II. Direct violence applied to the base of the skull may cause fracture in several different ways: by the impact of the vertebral column against the condyles of the occipital bone, in falls on the buttocks or feet; by the condyle of the lower jaw being driven against the glenoid fossa, in blows or falls on the chin; by the thrusting of a pointed instrument through the orbit or nose; by gunshot wounds through the mouth; and by a fall or a stab on the back of the head.

In the majority of cases of fracture of the base, the fracture is compound. In the anterior fossa, if the fissure extend across the cribriform plate, the nasal mucous membrane is usually torn and the fracture rendered compound into the nose. In the middle fossa, the fracture usually opens up the tympanic cavity, and if the membrana tympani be torn, the fracture is compound, *via* the external auditory meatus. Continued bleeding from the nose or ear is one of the most constant symptoms in these cases.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighbourhood of the parietal eminence, it runs downwards through the parietal and the squamous portion of the temporal and across the petrous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa, to the foramen lacerum medium of the other side, and may indeed travel round the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise: thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn and thus permit of the escape of the cerebro-spinal fluid should there be a communication between the internal ear and the tympanum together with rupture of the membrana tympani, as is frequently the case: again, if the fissure pass across the pituitary fossa and the muco-periosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the result of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forwards, appears as a subconjunctival ecchymosis. If the roof of the nasal fossa be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebro-spinal fluid from the nose, should the dura mater and arachnoid have been torn. In fractures of the posterior fossa, extravasation of blood may appear at the nape of the neck, beneath the muscles attached to the superior curved line of the occipital bone.

Diseases of the Skull.—An inflammatory condition affecting the bones and the pericranium together is generally caused by septic infection either of a scalp wound, exposing and bruising the bone, or of a compound fracture, and is termed *septic osteomyelitis*. Occasionally it may occur independently of injury, and then follows the same course, and is due to the same causes, as acute infective osteomyelitis in the long bones.

The most common chronic disease of the skull is due to syphilis. In *acquired syphilis* the disease usually occurs as *nodes*, which arise most commonly in the pericranium, but may also arise in the diploë, or more rarely on the inner surface of the skull. The formation of *gummata* under the periosteum generally leads to *caries*, which may be either limited if the gumma is localised, or widespread if the gumma is diffuse. The caries is often complicated by *necrosis*, for a condition of sclerosis is frequently set up in the surrounding bone, and the vessels in the Haversian canals become compressed and the vitality of the bone is interfered with; hence we often find a central necrosing area surrounded by a zone of caries. Large carious sequestra may be thrown off after prolonged suppuration, leaving considerable areas of the dura mater exposed. A common result of syphilitic disease of the skull is the production of large hard masses of bones on its surface, which give it a tuberculated appearance; in other cases, the skull presents a curious worm-eaten appearance; this is due to the fact that the osteogenetic powers of the pericranium are small and the formation of bone on the surface slight. In *hereditary syphilis*, in addition to the formation of gummata, which are usually of the subperiosteal variety, atrophic or hypertrophic changes may take place. In the atrophic cases the bone becomes abnormally thin, or even perforated, generally where there is pressure, as from the pillow or nurse's arm. Hence they are usually met with in the parietal bones or vertical plate of the occiput. This condition is known as craniotabes, and may also occur as a consequence of rickets; it gives rise to a peculiar sensation known as that of 'egg-shell crackling' when the affected bones, reduced to a membranous or parchment-like consistency, are palpated. In the hypertrophic cases, a deposit of porous bone takes place around the anterior fontanelle in the parietal and frontal bones; these deposits are separated by the coronal and sagittal sutures, and give to the skull an appearance like a 'hot cross bun.' They are known as *Parrot's nodes*, and such a skull has received the name of the 'hot cross bun' skull.

The most common tumours of the skull are the osteomata and the sarcomata. The osteoma is generally the ivory exostosis, though cases of spongy exostosis do occur. Sarcomata of the skull may arise either from the pericranium or the diploe, but it is usually impossible to distinguish clinically between the two. Carcinoma, if it occurs in the skull, is always secondary to cancer in some other part of the body.

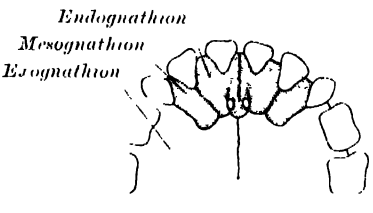
Hypertrophic changes occur in the skull in ostitis deformans, acromegaly, leontiasis ossea, and in rickets. In these latter cases the skull becomes enlarged from the formation of periosteal outgrowths of soft pumice-like osteoid tissue on the outer side of the skull. These deposits are very rich in blood-vessels, and occur between the ridges of the cranial bones and their centres of ossification, and are symmetrically arranged—often about the anterior fontanelle. The anterior fontanelle itself, instead of closing between the 18th and 24th months, as it normally does, remains patent in rickets until the third or even the sixth year. The general shape of the skull alters. The forehead is high and square, with prominent frontal eminences, and the head tends to be cubical or box-shaped, whereas in hydrocephalus it is rather globular; the enlargement of the head in rickets appears to be greater than it really is because the development of the facial bones is retarded. The base of the nose may appear sunken, from retarded development of the basis cranii. In marked cases of rickets these changes in the shape of the skull are permanent. In congenital hydrocephalus, or enlargement of the head due to the presence of excess of fluid in the ventricles of the brain, the cranium becomes globular, and its bones are thin and atrophic. Often they are widely separated, the intervening fontanelles being much enlarged and partially filled in by numerous Wormian bones; the atrophy of the cranium and brain may be so extreme that the light of a candle may be plainly visible through the whole thickness of the enlarged head.

The head may be abnormally small (microcephalus) with premature ossification of its sutures, a condition usually associated with idiocy. Linear craniotomy, or the excision of a strip of bone on either side of the median line, has been proposed as an operation likely to improve the patient's mental development by allowing room for the growth and expansion of the brain. Unfortunately in these cases the brain always shows imperfect or prematurely arrested development, so that the operation is foredoomed to failure; in addition, premature ossification of the sutures is not invariably present in microcephalus.

The mastoid antrum, situated in the mastoid portion of the temporal bone, is sometimes the seat of suppuration as a result of infection extending backwards from the tympanic cavity. In such cases, the surgeon has to open the antrum in order to give exit to the pus. This he does by introducing his gouge in the suprameatal triangle (see page 224). A line is drawn horizontally through the upper border of the bony external auditory meatus, and a second vertically through the posterior wall of the meatus, and the gouge is applied in the angle where these two lines intersect each other; if the instrument be introduced at a higher level it will open the cavity of the skull. It is to be carried in the direction of the external auditory canal—inwards, forwards, and a little upwards—for the distance of from 1 to 1½ cm., when the antrum will be reached. In some cases of middle-ear trouble, septic thrombosis of the lateral sinus takes place, and it becomes necessary to trephine and explore the sinus.

In connection with the bones of the face a common malformation is *cleft palate*. The cleft usually starts posteriorly, and in its most elementary form may consist simply of a bifid uvula; or the cleft may extend through the soft palate; or the posterior part or the whole of the hard palate may be involved, the cleft extending as far forwards as the anterior palatine canal. In the severest forms, the cleft extends through the alveolus and passes between the premaxillary bone and the rest of the upper jaw; that is to say, between the lateral incisor and canine teeth. In some instances, the cleft has been noticed to pass outwards between the central and lateral incisor teeth; and this has induced some anatomists to believe that the premaxillary bone is developed from two centres (fig. 347) and not from one, as was stated in the description of the bone. The mesial segment, bearing a central incisor, is called an *endognathion*; the lateral segment, bearing the lateral incisor, is called a *mesognathion*; and the rest of the maxilla is termed the *exognathion*. The cleft may affect one or both sides; if the latter, the central part is frequently displaced forwards and remains united to the septum of the nose, the deficiency in the alveolus being complicated with a cleft in the lip (hare-lip). On examining a cleft palate in which the alveolus is not implicated, the cleft will generally appear to be in the mesial line, but occasionally is unilateral and in some cases bilateral. To understand this it must be borne in mind that three processes are concerned in the formation of the palate—the two palatal processes of the maxillæ, which grow in horizontally and unite in the middle line; and the ethmo-vomerine process, which grows downwards from the base of the skull and fronto-nasal process to unite with the palatal process in the mesial line. In those cases where the palatal processes fail to unite with each other and with the mesial process, the cleft of the palate is median; where one palatal process unites with the mesial septum, the other failing to do so, the cleft in the palate is unilateral. The right process is the one which usually joins, and the cleft is therefore on the left side. In some cases where the palatal processes fail to meet in the middle, the ethmo-vomerine process grows downwards into the cleft and thus produces a bilateral cleft. Occasionally there may be a hole in the middle line of the hard palate, the anterior part of the hard and the soft palate being perfect, but this is rare, because, as a rule, the union of the various processes progresses from before backwards, and therefore the posterior part of the palate is more frequently defective than the anterior.

Fig. 347.—The premaxilla and its sutures (after Albrecht)



The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the mandible, and of these, the latter is by far the most frequently fractured of all the bones of the face. Fracture of the *nasal* bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backwards or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The *malar* bone is probably never broken alone—that is to say, without fracture of some of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs from direct violence, as is usually the case, the fragments may be displaced inwards. Fractures of the *maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the *mandible* is in the neighbourhood of the canine tooth, as at this spot the bone is weakened by the deep socket for the fang of this tooth; it is next most frequently fractured at the angle; then at the symphysis; and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gum. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighbourhood of the symphysis to the hyoid bone.

The maxilla and the mandible are frequently the seat of necrosis; but the disease more often affects the lower than the upper jaw. It may be the result of periostitis from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it sometimes occurs in children after attacks of the exanthematous fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in the manufacture of matches. In the vast majority of cases, however, it is of dental origin.

Tumours originate in the jaw-bones not infrequently, and may be either innocent or malignant. In the maxilla cysts may occur in the antrum; or in either jaw in connection with the teeth; those connected with the roots of fully developed teeth are known as dental cysts; those connected with unerupted teeth, dentigerous cysts. Malignant tumours show a marked degree of malignancy when occurring in the maxilla.

The maxilla sometimes requires removal for tumours or other conditions. In order to remove it, the patient should be placed in the recumbent position, in a good light, with

the head and shoulders just raised. The central incisor tooth on the affected side is then extracted. One incision is begun just below the inner canthus of the eye and passes along the side of the nose, round the ala, and down the middle line of the upper lip into the mouth. A second incision is made from the commencement of the first, along the lower border of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outwards, so as to expose the bone. The periosteum attached along the lower margin of the orbit is now to be incised, and with the handle of the scalpel the periosteum covering the floor of the orbit is to be raised from the bone; for in all cases it is essential that this fibrous layer should not be removed. The mouth is now widely opened with a gag, and the mucous membrane covering the hard palate incised down to the bone in the middle line, and the soft palate separated from the hard. The surgeon now proceeds to divide the connections of the bone with the other bones of the face, having first separated the ala of the nose from its bony attachment. They are (1) the junction with the malar bone, the line of section being carried into the spheno-maxillary fissure; (2) the frontal process of the maxilla; a small portion of its upper extremity, connected with the nasal bone in front, the lachrymal bone behind, and the frontal bone above, being left; (3) the connection with opposite maxilla and with the palate bone in the roof of the mouth. The bone is now firmly grasped with lion-forceps; and by means of a rocking movement upwards and downwards, the remaining attachments of the orbital plate with the ethmoid, and of the back of the bone with the palate, are broken through. Occasionally, in removing the upper jaw, it will be found that the orbital plate can be saved, and this should always be done if possible. A horizontal saw-cut is to be made just below the infra-orbital foramen, and the bone cut through in this situation.

THE EXTREMITIES

The extremities, or limbs, are long, jointed appendages of the body, each of which is connected to the trunk by one end, and is free in the rest of its extent. They are *four* in number: an *upper* or *thoracic pair*, connected with the thorax and subservient mainly to prehension; and a *lower pair*, connected with the vertebral column, intended for support and locomotion. Both pairs of limbs are constructed after one common type, but certain differences are observed between the upper and lower pairs, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk are named respectively the shoulder and pelvic girdles. The *shoulder girdle* (cingulum extremitatis superioris) is formed by the scapulæ and clavicles, and is imperfect in front and behind. In front, however, it is completed by the upper end of the sternum, with which the inner extremities of the clavicles articulate. Behind, it is widely imperfect, the scapulæ being connected to the trunk by muscles only. The *pelvic girdle* (cingulum extremitatis inferioris) is formed by the innominate bones, which articulate with each other in front, at the symphysis pubis. It is imperfect behind, but the gap is filled in by the upper part of the sacrum. The pelvic girdle therefore presents, with the sacrum, a complete ring, massive and comparatively rigid, in marked contrast to the lightness and mobility of the shoulder girdle.

BONES OF THE UPPER EXTREMITY

The Clavicle

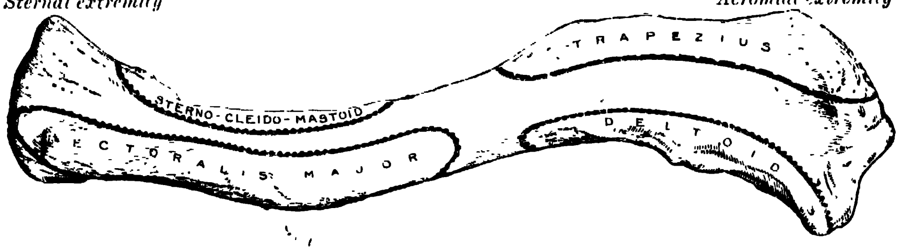
The **Clavicle** (clavicula), or collar-bone (figs. 348 and 349), forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates by its inner extremity with the upper end of the sternum, and by its outer with the acromion process of the scapula.* It presents a double curvature, the convexity being directed forwards at the sternal end, and the concavity at the scapular end. Its outer third is flattened from above downwards, whilst its

* The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore-limbs are used only for progression, but is present for the most part in animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating with either the scapula or sternum.

inner portion, consisting of the inner two-thirds, is of a rounded or prismatic form.

The **outer third** presents two surfaces, an upper and a lower; and two borders, an anterior and a posterior. The *upper surface* is flat, rough, and marked by impressions for the attachments of the Deltoid in front, and the Trapezius behind; between these two impressions a small portion of the bone is subcutaneous. The *under surface* is flat. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the *conoid tubercle*; this, in the natural position of the bone,

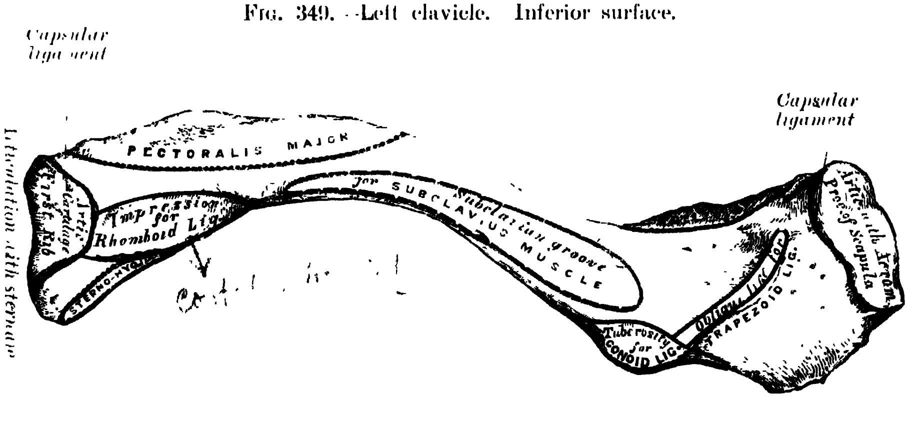
FIG. 348.—Left clavicle. Superior surface.



surmounts the coracoid process of the scapula, and gives attachment to the conoid ligament. From this tubercle an oblique ridge, the *oblique* or *trapezoid ridge*, passes forwards and outwards, and affords attachment to the trapezoid ligament. The *anterior border* is concave, thin, and rough, and gives attachment to the Deltoid; it frequently presents, at its inner part, a tubercle, the *deltoid tubercle*. The *posterior border* is convex, rough, thicker than the anterior, and gives attachment to the Trapezius.

The **inner two-thirds** constitute the prismatic portion of the bone, which is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces. The *anterior border* is continuous with the anterior margin of the flat portion. Its outer portion is smooth, and

FIG. 349.—Left clavicle. Inferior surface.



corresponds to the interval between the attachment of the Pectoralis major and Deltoid; its inner part forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The *superior border* is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. Smooth and rounded externally, it becomes rough towards the inner third for the attachment of the Sterno-mastoid, and terminates at the upper angle of the sternal extremity. The *posterior* or *subclavian border* separates the posterior from the inferior surface, and extends from the conoid tubercle to the rhomboid impression; it forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia which envelops the Omo-hyoid.

The *anterior surface* is included between the superior and anterior borders. Its outer part looks upwards, and is continuous with the superior surface of the flattened portion; it is smooth, convex, and nearly subcutaneous, being covered only by the Platysma. Its inner portion is divided by a narrow subcutaneous area into two parts: a lower, elliptical in form, and directed forwards, for the attachment of the Pectoralis major; and an upper, for the attachment of the Sterno-cleido-mastoid. The *posterior* or *cervical surface* is smooth, and looks backwards towards the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; internally, by the margin of the sternal extremity; and externally, by the conoid tubercle. It is concave from within outwards, and is in relation, by its lower part, with the suprascapular vessels. This surface, at the junction of the inner and outer curves, is also in close relation with the brachial plexus of nerves and the subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sterno-hyoid; and presents, near the middle, a foramen, directed obliquely outwards, which transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior and another on the inferior surface. The *inferior* or *subclavian surface* is bounded, in front, by the anterior border; behind, by the subclavian border. It is narrow internally, but gradually increases in width externally, and is continuous with the under surface of the flat portion. On its inner part is a broad rough surface, the *rhomboid impression* (tuberositas costalis), rather more than an inch in length, for the attachment of the costo-clavicular or rhomboid ligament. The rest of this surface is occupied by a groove, broad and smooth externally, narrow and more uneven internally, which gives attachment to the Subclavius; the costo-coracoid membrane, which splits to enclose the muscle, is attached to the margins of the groove. Not infrequently this groove is subdivided longitudinally by a line which gives attachment to the intermuscular septum of the Subclavius.

The **inner** or **sternal extremity** (extremitas sternalis) of the clavicle is triangular in form, directed inwards, and a little downwards and forwards; it presents an articular facet, concave from before backwards, convex from above downwards, which articulates with the manubrium sterni through the intervention of an interarticular fibro-cartilage. The lower part of the facet is carried outwards on the inferior surface of the bone as a small semi-oval area which articulates with the cartilage of the first rib. The circumference of the articular surface is rough, for the attachment of numerous ligaments; the upper angle gives attachment to the interarticular fibro-cartilage.

The **outer** or **acromial extremity** (extremitas acromialis), directed outwards and forwards, presents a small, flattened, oval facet (facies articularis acromialis) which looks obliquely downwards, for articulation with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromio-clavicular ligaments.

In the female, the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In those persons who perform considerable manual labour it becomes thicker and more curved, and its ridges for muscular attachment are prominently marked.

Structure.—The clavicle consists of cancellous tissue, invested in a compact layer, which is much thicker in the middle than at the extremities of the bone.

Ossification.—The clavicle begins to ossify before any other bone in the body; it is ossified from two centres—viz. a primary centre for the shaft and outer end, which appears during the fifth or sixth week of fœtal life, and a secondary centre for the sternal end, which makes its appearance about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Surface Form.—The clavicle can be felt throughout its entire length. At the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Sterno-mastoid a V-shaped notch, the *presternal notch*. Passing outwards, the shaft of the bone can be defined immediately under the skin, with its convexity forwards in the *inner two-thirds*; the surface is partially obscured above and below by the attachments of the Sterno-mastoid and Pectoralis major. In the outer third it is concave forwards, and terminates externally in a somewhat enlarged extremity which articulates with the acromion process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the

arm is lying quietly by the side, though in well-developed subjects it may incline a little upwards at its outer end. Its direction, however, varies with the varying movements of the shoulder-joint. The clavicle inclines backwards, so that its outer or acromial extremity is on a plane posterior to its sternal end. This causes the shoulder to be thrown backwards away from the thorax.

Applied Anatomy.—The clavicle is very frequently fractured. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk, acting as a buttress to keep the point of the shoulder away from the thorax. It is, moreover, slender, and is very superficial. It may be broken by direct or indirect violence. The most common cause is, however, indirect violence, as the result of force applied to the hand or shoulder, and the bone then gives way at the junction of its outer with its inner two-thirds, that is to say, at the junction of the two curves, for this is its weakest part. The fracture is generally oblique, and the displacement of the outer fragment is downwards, forwards, and inwards. The deformity is mainly due to the weight of the arm acting upon the fragment when the buttress-like action of the bone is gone, assisted by the muscles which pass from the thorax to the upper extremity. The inner fragment, as a rule, is little displaced. Beneath the bone the main vessels of the upper limb and the great nerve-cords of the brachial plexus lie on the first rib and are liable to be wounded in fracture, especially in fracture from direct violence, when the force of the blow drives the broken ends inwards. Fortunately the Subclavius intervenes between these structures and the clavicle, and often protects them from injury.

The clavicle is occasionally the seat of sarcomatous tumours, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inwards. The removal of the outer part is comparatively easy, but resection of the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.

Great deformity of the clavicle may be met with in rickets, the natural curvatures of the bone being exaggerated until it takes on an S-shape.

The Scapula

The **Scapula** or shoulder blade forms the posterior part of the shoulder girdle. It is a flat, triangular bone, and presents for examination two surfaces, three borders, and three angles.

The *ventral surface* (facies costalis) (fig. 350) presents a broad concavity, the *fossa subscapularis.* The inner two-thirds of the fossa are marked by several oblique ridges, which are directed outwards and upwards; the outer third is smooth. The oblique ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis. The outer third of the fossa is covered by the fibres of this muscle. The subscapular fossa is separated from the internal border by smooth triangular areas at the superior and inferior angles, and in the interval between these by a narrow ridge which is often deficient. These triangular areas and the intervening ridge afford attachment to the Serratus magnus. The subscapular fossa presents a transverse depression at its upper part, where the bone appears to be bent on itself along a line at right angles to and passing through the centre of the glenoid cavity, forming a considerable angle, called the *subscapular angle*; this gives greater strength to the body of the bone by its arched form, while the summit of the arch serves to support the spine and acromion process.

The *dorsal surface* (facies dorsalis) (fig. 351) is arched from above downwards, and is alternately concave and convex from side to side. It is subdivided unequally into two parts by the *spine*; the portion above the spine is called the *supraspinous fossa*, and that below it the *infraspinous fossa.*

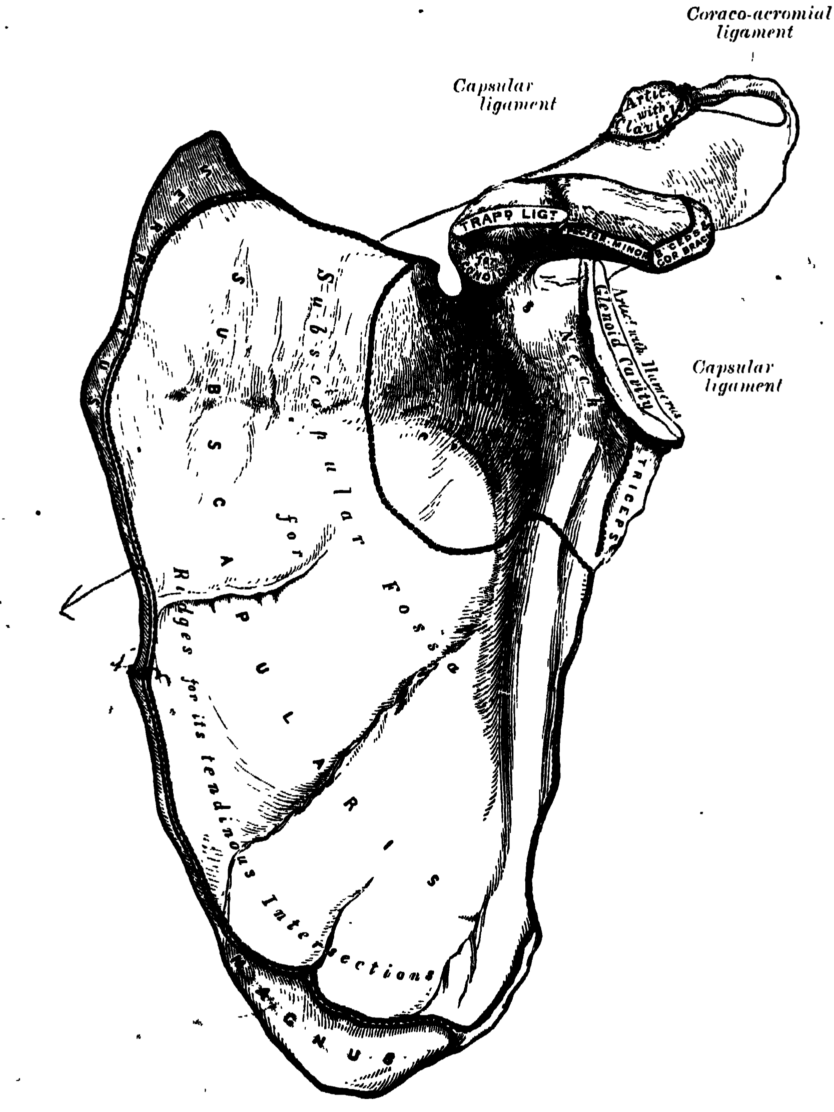
The *supraspinous fossa* (fossa supraspinata), the smaller of the two, is concave, smooth, and broader at the vertebral than at the humeral extremity. It affords attachment by its inner two-thirds to the Supraspinatus.

The *infraspinous fossa* (fossa infraspinata) is much larger than the preceding; towards its vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, while near the axillary border is a deep groove which runs from the upper towards the lower part. The inner two-thirds of the fossa affords attachment to the Infraspinatus; the outer third is covered by this muscle.

The dorsal surface is marked near the axillary border by an elevated ridge, which runs from the lower part of the glenoid cavity, downwards and backwards to the vertebral border, about an inch above the inferior angle.

The ridge serves for the attachment of a strong aponeurosis, which separates the Infraspinatus from the two Teres muscles. The surface of bone between the ridge and the axillary border is narrow in the upper two-thirds of its extent, and is crossed near its centre by a groove for the passage of the dorsalis scapulæ vessels; it affords attachment to the Teres minor. Its lower third presents a broader, somewhat triangular surface, which gives origin to the Teres major, and over which the Latissimus dorsi glides; frequently the

Fig. 350.—Left scapula. Anterior surface.

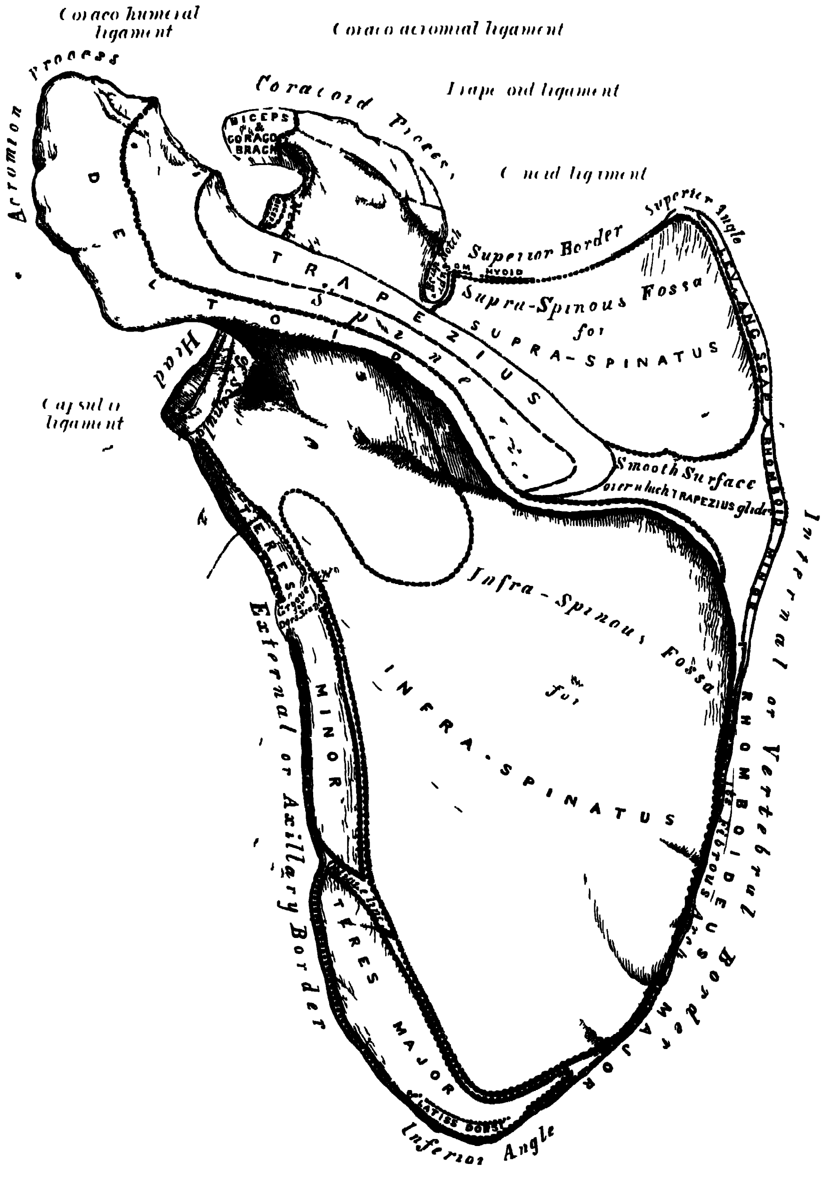


latter muscle takes origin by a few fibres from this part. The broad and narrow portions of bone above alluded to are separated by an oblique line, which runs from the axillary border, downwards and backwards, to meet the elevated ridge: to it is attached the aponeurosis which separates the Teres muscles from each other.

The **spine** (spina scapulæ) is a prominent plate of bone, which crosses obliquely the inner four-fifths of the dorsal surface of the scapula at its upper part, and separates the supra- from the infra-spinous fossa. It begins at the

vertebral border by a smooth, triangular area over which the tendon of insertion of the lower part of the Trapezius glides, and, gradually becoming more elevated as it passes outwards, ends in the acromion process, which overhangs the shoulder-joint. The spine is triangular, and flattened from above downwards, its apex being directed inwards, its base outwards It presents two surfaces and three borders. Its *superior surface* is concave, it assists in

FIG. 351 — Left scapula. Posterior surface.



forming the supraspinous fossa, and affords attachment to part of the Supraspinatus. Its *inferior surface* forms part of the infraspinous fossa, gives origin to a portion of the Infraspinatus, and presents near its centre the orifice of a nutrient canal. Of the three borders, the *anterior* is attached to the dorsum of the bone; the *posterior*, or *crest of the spine*, is broad, and presents two lips and an intervening rough interval. The Trapezius is attached to the

superior lip, and a rough tubercle is generally seen on that portion of the spine which receives the tendon of insertion of the lower part of this muscle. The Deltoid is attached to the whole length of the inferior lip. The interval between the lips is subcutaneous and partly covered by the tendinous fibres of these muscles. The *external border*, or *base*, the shortest of the three, is slightly concave; its edge, thick and round, is continuous above with the under surface of the acromion process, below with the neck of the scapula. It forms the inner boundary of a notch, the *great scapular notch*, which serves to connect the supra- and infra-spinous fossæ.

The **acromion process** (acromion) forms the summit of the shoulder, and is a large, somewhat triangular or oblong process, flattened from behind forwards, directed at first a little outwards, and then curving forwards and upwards, so as to overhang the glenoid cavity. Its *upper surface*, directed upwards, backwards, and outwards, is convex, rough, and gives attachment to some fibres of the Deltoid, and in the rest of its extent is subcutaneous. Its *under surface* is smooth and concave. Its *outer border* is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its *inner border*, shorter than the outer, is concave, gives attachment to a portion of the Trapezius, and presents about its centre a small, oval surface (facies articularis acromii) for articulation with the acromial end of the clavicle. Its *apex*, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coraco-acromial ligament.

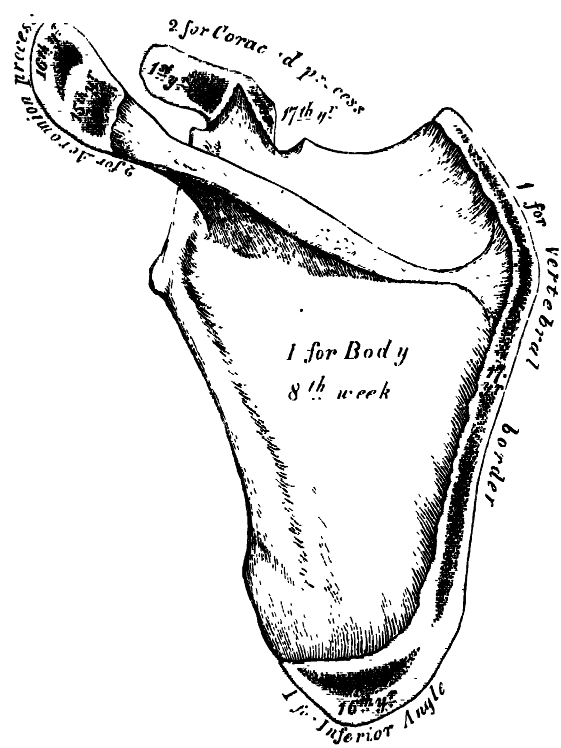
Of the three *borders* of the scapula, the *superior* (margo superior) is the shortest and thinnest; it is concave, and extends from the superior angle to the base of the coracoid process. At its outer part is a deep, semicircular notch, the *suprascapular notch* (incisura scapulæ), formed partly by the base of the coracoid process. This notch is converted into a foramen by the transverse ligament, and serves for the passage of the suprascapular nerve; sometimes the ligament is ossified. The adjacent margin of the superior border affords attachment to the Omo-hyoid. The *external* or *axillary border* (margo axillaris) is the thickest of the three. It begins above at the lower margin of the glenoid cavity, and inclines obliquely downwards and backwards to the inferior angle. Immediately below the glenoid cavity is a rough impression, the *infraglenoid tubercle* (tuberositas infraglenoidalis) about an inch in length, which affords attachment to the long head of the Triceps. In front of this is a longitudinal groove, which extends as far as the lower third of this border, and affords origin to part of the Subscapularis. The inferior third, which is thin and sharp, serves for the attachment of a few fibres of the Teres major behind, and of the Subscapularis in front. The *internal* or *vertebral border* (margo vertebralis), also named the *base*, is the longest of the three, and extends from the superior to the inferior angle. It is arched, intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outwards, so as to form an obtuse angle with the part below. This border presents an anterior and a posterior lip, and an intermediate narrow area. The *anterior lip* affords attachment to the Serratus magnus; the *posterior lip*, to the Supraspinatus above the spine, the Infraspinatus below; the area between the two lips, to the Levator anguli scapulæ above the triangular surface at the commencement of the spine, to the Rhomboideus minor on the edge of that surface, and to the Rhomboideus major; this last is attached by means of a fibrous arch, connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the border.

Of the three *angles*, the *superior* (angulus medialis), formed by the junction of the superior and internal borders, is thin, smooth, rounded, inclined somewhat outwards, and gives attachment to a few fibres of the Levator anguli scapulæ. The *inferior angle* (angulus inferior), thick and rough, is formed by the union of the vertebral and axillary borders, its outer surface affording attachment to the Teres major and frequently to a few fibres of the Latissimus dorsi. The *external angle* (angulus lateralis) is the thickest part of the bone, and forms what is called the head of the scapula. The *head* presents a shallow, pyriform, articular surface, the *glenoid cavity* (cavitas glenoidalis), directed outwards and forwards. It is broader below than above and its vertical diameter is the longest. At its apex is a slight elevation, the *supraglenoid tubercle*

(tuberositas supraglenoidalis), to which the long tendon of the Biceps is attached. The surface is covered with cartilage in the recent state; and its margins, slightly raised, give attachment to a fibro-cartilaginous structure, the *glenoid ligament*, which deepens the cavity. The *neck* of the scapula (collum scapulæ) is the slightly depressed surface which surrounds the head; it is more distinct behind where it forms part of the great scapular notch, than in front, and below than above.

The **coracoid process** (processus coracoideus) is a thick curved process attached by a broad base to the upper part of the neck of the scapula; it is directed at first upwards and inwards; then, becoming smaller, it changes its direction, and passes forwards and outwards. The ascending portion, flattened from before backwards, presents in front a smooth concave surface, over which the Subscapularis passes. The horizontal portion is flattened from above downwards; its upper surface is convex and irregular, and gives attachment

FIG. 352.—Plan of ossification of the scapula. From seven centres.



to the Pectoralis minor; its under surface is smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coraco-acromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and Coraco-brachialis and gives attachment to the costo-coracoid ligament. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forwards and outwards, on to the upper surface of the horizontal portion, is an elevated ridge for the attachment of the trapezoid ligament.

Structure.—The head, processes, and the thickened parts of the bone, contain cancellous tissue; the rest of the bone consists of a thin layer of compact tissue. The central part of the supraspinous fossa and the upper part of the infraspinous fossa, but especially the former, are usually so thin as to be semi-transparent; occasionally the bone is found wanting in this situation, and the adjacent muscles are separated only by fibrous tissue.

Ossification (fig. 352).—The scapula is ossified from *seven* or more centres: one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle.

Ossification of the body begins about the second month of fœtal life, by the formation of an irregular quadrilateral plate of bone, immediately behind the glenoid cavity. This plate extends so as to form the chief part of the bone, the spine growing up from its posterior surface about the third month. At birth, a large part of the scapula is osseous, but the glenoid cavity, the coracoid and acromion processes, the posterior border, and inferior angle are cartilaginous. From the fifteenth to the eighteenth month after birth, ossification takes place in the middle of the coracoid process, which as a rule becomes joined with the rest of the bone about the fifteenth year. Between the fourteenth and twentieth years, ossification of the remaining parts takes place in quick succession, and usually in the following order; first, in the root of the coracoid process, in the form of a broad scale; secondly, near the base of the acromion process; thirdly, in the inferior angle and contiguous part of the posterior border; fourthly, near the extremity of the acromion; fifthly, in the posterior border. The base of the acromion process is formed by an outward extension of the spine; the two separate nuclei of the process unite, and then join with the extension from the spine. The upper third of the glenoid cavity is ossified from a separate centre (subcoracoid), which makes its appearance between the tenth and eleventh years and joins between sixteen and eighteen. Further, an epiphysial plate appears for the lower part of the glenoid cavity, while the tip of the coracoid process frequently presents a separate nucleus. These various epiphyses are joined to the bone by the twenty-fifth year. Failure of bony union between the acromion process and spine sometimes occurs, the junction being effected by fibrous tissue, or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union, it is probable that the detached segment was never united to the rest of the bone.

Articulations.—The scapula articulates with the humerus and clavicle.

Surface Form.—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromio-clavicular joint by running the finger along it, the position of the joint being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backwards to the spine. The place of junction is denoted by a prominence, which is sometimes called the acromial angle. The spine can be felt as a distinct ridge, marked on the surface as an oblique depression, which becomes less and less distinct and ends a little external to the spinous processes of the vertebræ. Its termination is indicated by a slight dimple in the skin, on a level with the interval between the third and fourth thoracic spines. Below this point the vertebral border of the scapula may be traced, running downwards and outwards to the inferior angle of the bone, which can be recognised, although covered by the Latissimus dorsi. From this angle the axillary border can usually be traced through its thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid process may be felt about an inch below the junction of the middle and outer third of the clavicle. It is covered by the anterior border of the Deltoid, and lies a little to the outer side of a slight depression, corresponding to the interval between the Pectoralis major and Deltoid. When the arm is hanging by the side, the upper angle of the scapula corresponds to the upper border of the second rib or the interval between the first and second thoracic spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth thoracic spines.

Applied Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased, and the elasticity of the ribs on which it rests. Fracture of the neck is also uncommon. The most frequent course of the fracture is from the suprascapular notch to the infraglenoid tubercle, and it derives its principal interest from its simulation of a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. The acromion process is more frequently broken than any other part of the bone, and fibrous union is very liable to occur in this situation.

The presence of 'winged scapulæ' (scapulæ alatæ) described in thin persons of feeble muscular development in whom the lower angles of the blade-bones project unduly, is due partly to abnormal roundness of the thoracic wall ('barrel-shaped chest,' page 213),

and partly to weakness and flaccidity of the Latissimus dorsi and Serratus magnus. The shoulders are held low in these subjects, and the clavicles slope downwards and forwards, carrying with them the scapulæ, which fit ill to the posterior wall of the chest and so tend to project from it.

Tumours of various kinds grow from the scapula. Of the innocent form probably the osteomata are the most common. When an osteoma grows from the venter of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. Sarcomatous tumours sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T-shaped incision, and the flaps being reflected, the removal is commenced from the posterior or vertebral border, so that the subscapular vessels which lie along the axillary border are amongst the last structures divided, and can be at once secured.

The Humerus

The **Humerus** (figs. 353 and 354) is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

The **upper extremity** consists of a large rounded *head* joined to the shaft by a constricted portion called the *neck*, and two eminences, the *greater* and *lesser tuberosities*.

The **head** (caput humeri), nearly hemispherical in form,* is directed upwards, inwards, and a little backwards, and articulates with the glenoid cavity of the scapula. The circumference of its articular surface is slightly constricted, and is termed the *anatomical neck*, in contradistinction to the constriction which exists below the tuberosities. The latter is called the *surgical neck* (collum chirurgicum), since it is frequently the seat of fracture. Fracture of the anatomical neck does sometimes, though rarely, occur.

The *anatomical neck* (collum anatomicum) is obliquely directed, forming an obtuse angle with the shaft. It is most distinctly marked in the lower half of its circumference; in the upper half it is represented by a narrow groove separating the head from the tuberosities. Its circumference affords attachment to the capsular ligament, and is perforated by numerous vascular foramina.

The **greater tuberosity** (tuberculum majus) is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat impressions, separated by two slight ridges: the highest impression gives insertion to the Supraspinatus; the middle to the Infraspinatus; the lowest one, and the shaft of the bone below it, to the Teres minor. The outer surface of the greater tuberosity is convex, rough, and continuous with the outer surface of the shaft.

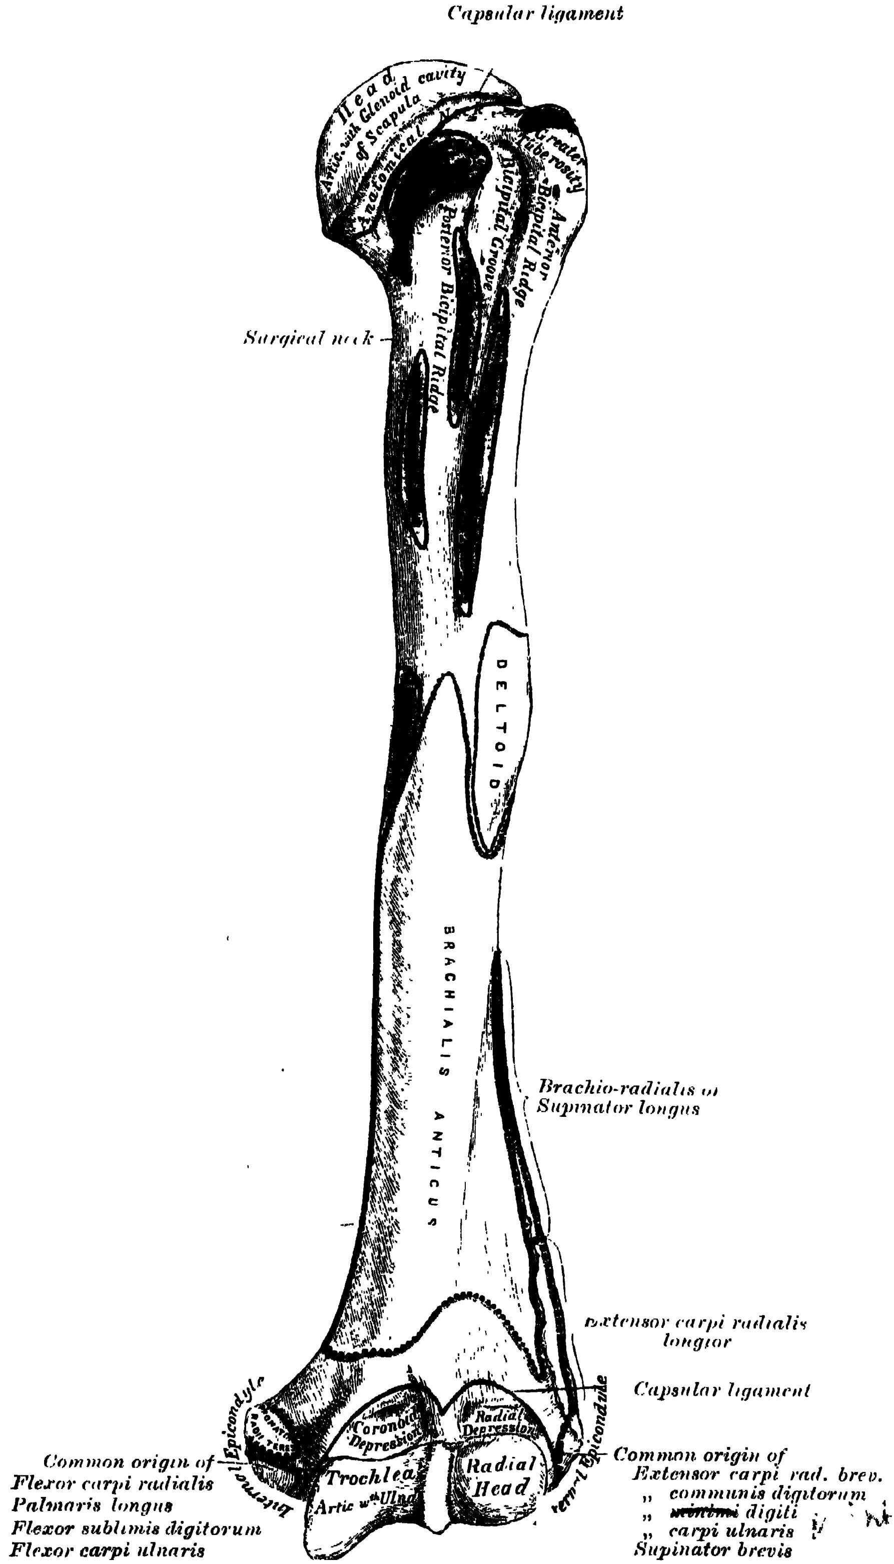
The **lesser tuberosity** (tuberculum minus), although smaller, is more prominent than the greater: it is situated in front, and is directed inwards and forwards. Above and in front it presents an impression for the insertion of the tendon of the Subscapularis.

The tuberosities are separated from each other by a deep groove, the *bicipital groove* (sulcus intertubercularis) which lodges the long tendon of the Biceps, ~~and transmits a branch of the~~ anterior circumflex artery to the shoulder-joint. It begins above between the two tuberosities, runs obliquely downwards and a little inwards, and ends near the junction of the upper with the middle third of the bone. In the recent state its upper part is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder-joint; its lower portion gives insertion to the tendon of the Latissimus dorsi. It is deep and narrow above, and becomes shallow and a little broader as it descends. Its lips are called, respectively, the anterior and posterior *bicipital ridges* (cristæ tuberculi majoris et minoris), and form the upper parts of the anterior and internal borders of the shaft of the bone.

The **shaft** (corpus humeri) is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

* Though the head is nearly hemispherical in form, its margin, as Humphry has shown, is by no means a true circle. Its greatest diameter is, from the top of the bicipital groove in a direction downwards, inwards, and backwards. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upwards, outwards, and forwards.

Fig. 353.—Left humerus. Anterior view.

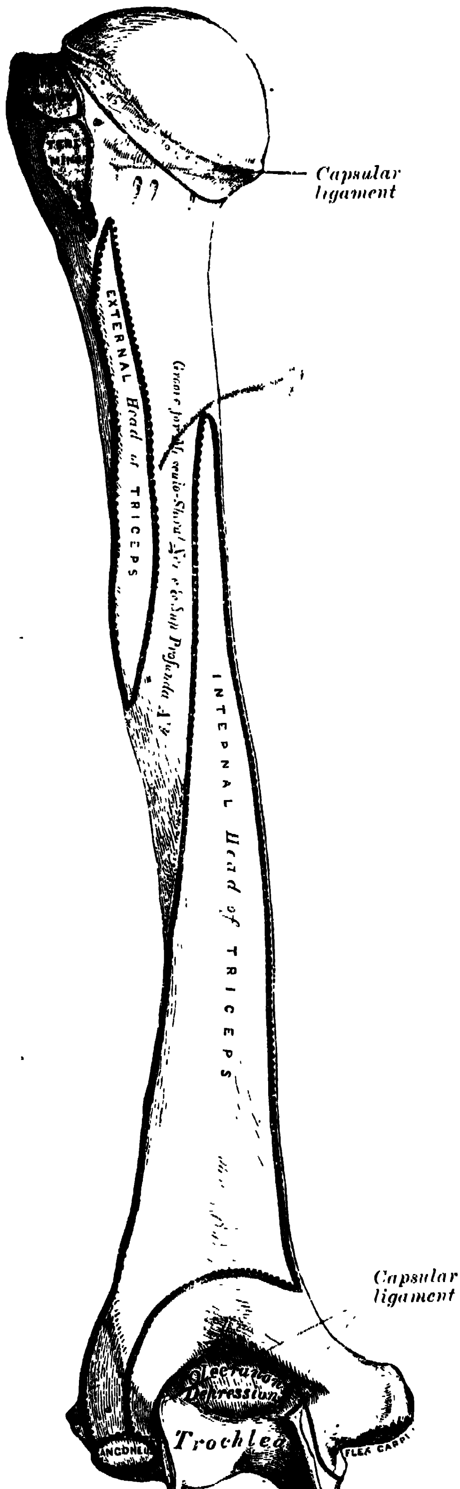


The *anterior border* (margo anterior) runs from the front of the greater tuberosity above to the coronoid fossa below, separating the internal from the external surface. Its upper part is very prominent and rough, and forms the outer lip of the bicipital groove ; it is sometimes called the *anterior bicipital* or *pectoral ridge*, and serves for the insertion of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the rough deltoid impression ; below, it is smooth and rounded, affording attachment to the Brachialis anticus.

The *external border* (margo lateralis) runs from the back part of the greater tuberosity to the external epicondyle, and separates the external from the posterior surface. Its upper half is rounded and indistinctly marked, serving for the attachment of the lower part of the insertion of the Teres minor, and below this giving origin to the external head of the Triceps muscle; its centre is traversed by a broad, but shallow oblique depression, the *musculo-spiral groove* (sulcus radialis). Its lower part forms a prominent, rough margin, a little curved from behind forwards, the *external supracondylar ridge*, which presents an anterior lip for the origin of the Brachioradialis above, and Extensor carpi radialis longior below, a posterior lip for the Triceps, and an intermediate space for the attachment of the external intermuscular septum.

The *internal border* (margo medialis) extends from the lesser tuberosity to the internal epicondyle. Its upper third consists of a prominent ridge, the *posterior bicipital ridge*, which gives insertion to the tendon of the Teres major. About its centre is a slight impression for the insertion of the Coraco-brachialis, and just below this is the entrance of the nutrient canal, directed downwards ; sometimes there is a second nutrient canal situated at the commencement of the musculo-spiral groove. The inferior third of this border is raised into a slight ridge, the *internal supracondylar ridge*, which becomes very prominent below ; it presents an anterior lip for the

Fig. 354.—Left humerus. Posterior view.



origins of the Brachialis anticus and Pronator teres, a posterior lip for the internal head of the Triceps, and an intermediate space for the attachment of the internal intermuscular septum.

The *external surface* (facies anterior lateralis) is directed outwards above, where it is smooth, rounded, and covered by the Deltoid; forwards and outwards below, where it is slightly concave from above downwards, and gives origin to part of the Brachialis anticus muscle. About the middle of this surface is a rough, triangular elevation (tuberositas deltoidea) for the insertion of the Deltoid; below this is the *musculo-spiral groove*, directed obliquely from behind, forwards, and downwards, and transmitting the musculo-spiral nerve and superior profunda artery.

The *internal surface* (facies anterior medialis), less extensive than the external, is directed inwards above, forwards and inwards below; its upper part is narrow, and forms the floor of the bicipital groove which gives insertion to the tendon of the Latissimus dorsi; its middle part is slightly rough for the attachment of some of the fibres of the tendon of insertion of the Coraco-brachialis; its lower part is smooth, concave from above downwards, and gives origin to the Brachialis anticus.*

The *posterior surface* (facies posterior) appears somewhat twisted, so that its upper part is directed a little inwards, its lower part backwards and a little outwards. Nearly the whole of this surface is covered by the external and internal heads of the Triceps, the former arising from its upper and outer part, the latter from its inner and back part, the two heads being separated by the musculospiral groove.

The **lower extremity** is flattened from before backwards, and curved slightly forwards; it terminates below in a broad, articular surface, which is divided into two parts by a slight ridge. Projecting on either side are the external and internal epicondyles. The *articular surface* extends a little lower than the epicondyles, and is curved slightly forwards; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, named the *capitellum*, or *radial head* of the humerus (capitulum humeri); it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is a slight depression, the *fossa radialis*, which receives the anterior border of the head of the radius, when the forearm is flexed. The inner portion of the articular surface, the *trochlea humeri*, presents a deep depression between two well-marked borders. The trochlea is convex from before backwards, concave from side to side, and occupies the anterior, lower, and posterior parts of the extremity. The external border, less prominent than the internal, separates it from the groove which articulates with the margin of the head of the radius. The internal border is thicker, of greater length, and consequently more prominent, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna; it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forwards, and from without inwards. Above the front part of the trochlear surface is a small depression, the *fossa coronoidea*, which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlea is a deep triangular depression, the *olecranon fossa* (fossa olecrani), in which

* A small, hook-shaped process of bone, the *supracondylar process*, varying from $\frac{1}{10}$ to $\frac{3}{4}$ of an inch in length, is not infrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal epicondyle. It is curved downwards, forwards, and inwards, and its pointed extremity is connected to the internal border, just above the inner epicondyle, by a ligament or fibrous band, which gives origin to a portion of the Pronator teres; through the arch completed by this fibrous band the median nerve and brachial artery pass, when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial. A well-marked groove is usually found behind the process, in which the nerve and artery are lodged. This arch is the homologue of the supracondyloid foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region.

the summit of the olecranon process is received in extension of the forearm. These fossæ are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated, forming the supratrochlear foramen; their margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and the fossæ are lined, in the recent state, by the synovial membrane of this articulation. The *external epicondyle* (epicondylus lateralis) is a small, tubercular eminence, less prominent than the internal, curved a little forwards, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the Extensor and Supinator muscles. The *internal epicondyle* (epicondylus medialis), larger, more prominent, and therefore more liable to fracture than the external, is directed a little backwards; it gives attachment to the internal lateral ligament of the elbow-joint, to the Pronator teres, and to a tendon common to the origin of some of the Flexor muscles of the forearm. The ulnar nerve runs in a groove (sulcus n. ulnaris) on the back of the internal epicondyle. These epicondyles are directly continuous above with the external and internal supracondylar ridges.

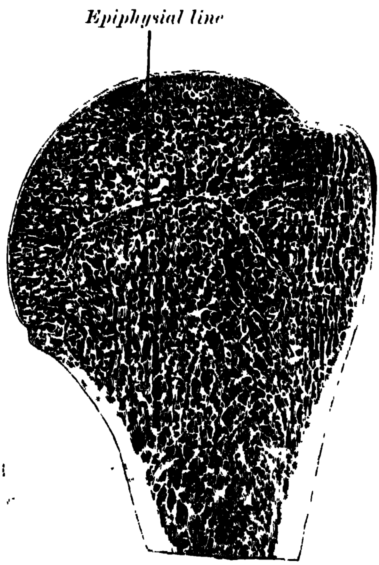


FIG. 355.— Longitudinal section of head of left humerus.

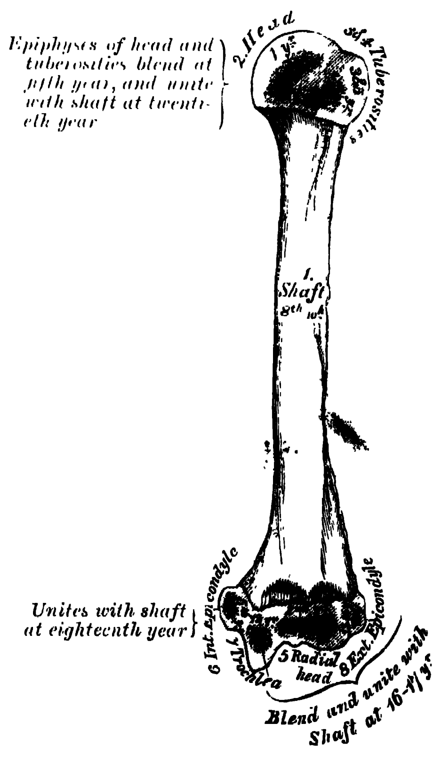
FIG. 356.—Plan of ossification of the humerus.



Structure.—The extremities consist of cancellous tissue, covered with a thin, compact layer (fig. 355); the shaft is composed of a cylinder of compact tissue, thicker at the centre than towards the extremities, and contains a large medullary canal which extends along its whole length.

Ossification (fig. 356). — The humerus is ossified from *eight* centres, one for each of the following parts: the shaft, the head, the greater tuberosity, the lesser tuberosity, the radial head, the trochlear portion of the articular surface, and one for each epicondyle. The centre for the shaft appears near the middle of the bone in the eighth week of fœtal life, and soon extends towards the extremities. At birth the humerus is ossified in nearly its whole length, only the extremities remaining cartilaginous. During the first year, sometimes before birth, ossification commences in the head of the bone, and during the third year the centre for the greater tuberosity, and during the fifth that for the lesser tuberosity, make their appearance. By the sixth year the centres for the head and tuberosities have increased in size and become joined, so as to form a single large epiphysis, which fuses with the shaft about the twentieth year. The lower end of the humerus is ossified as follows. At the end of the second year

ossification begins in the capitellum, and extends inwards, to form the chief part of the articular end of the bone, the centre for the inner part of the trochlea not appearing until about the age of twelve. Ossification commences in the internal epicondyle about the fifth year, and in the external about the thirteenth or fourteenth year. About the sixteenth or seventeenth year, the outer epicondyle and both portions of the articulating surface, having already joined, unite with the shaft, and at the eighteenth year the inner epicondyle becomes joined to it.

Articulations.—The humerus articulates with the scapula, and with the ulna and radius.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of the bone which are strictly subcutaneous are small portions of the internal and external epicondyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forwards and inwards, can be felt on the inner side of the greater tuberosity, just below the acromio-clavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by making firm pressure with the finger, just internal to the greater tuberosity; on rotating the humerus, the groove will be felt to pass under the finger. With the arm abducted from the side the lower part of the head of the bone can be felt by pressing deeply in the axilla. On either side of the elbow-joint, and just above it, are the internal and external epicondyles. Of these the internal is the more prominent, but the internal supracondylar ridge, passing upwards from it, is much less marked than the external, and, as a rule, is not to be felt. Occasionally, however, the hook-shaped process mentioned above is found on this border. The position of the external epicondyle is to be seen most plainly during semiflexion of the forearm, and is indicated by a depression between the attachments of the adjacent muscles. From it a strong bony ridge can be felt running up the outer border of the shaft of the bone. This is the external supracondylar ridge; it is concave forwards, and corresponds with the curved direction of the lower extremity of the humerus.

Applied Anatomy.—There are several points of surgical interest connected with the ossification of the humerus. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from the upper epiphysial line. Hence, in cases of amputation of the arm in young subjects, the humerus continues to grow considerably, and the end of the bone which immediately after the operation was covered with a thick cushion of soft tissue begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place. The region of the upper epiphysis, moreover, is the common site for the growth of tumours, both innocent and malignant.

There are several points of surgical interest in connection with fractures of the humerus. The bone may be broken by direct or indirect violence, like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other bone of this class. It is usually the shaft, just below the insertion of the Deltoid, which is thus broken, and the accident has been known to happen from throwing a stone. Fractures of the upper end may take place either through the anatomical or surgical neck, or a separation of the greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. Fracture of the surgical neck of the bone is not uncommon, and impaction may occur; on the other hand, the upper end of the lower fragment may be displaced into the axilla and may damage the vessels or nerves. The fracture somewhat closely simulates dislocation of the shoulder-joint, but can be distinguished by the fact that the head of the bone remains in its normal position and the great tuberosity still forms the most prominent point of the shoulder. Separation of the upper epiphysis sometimes occurs in the young subject, and is marked by a characteristic deformity, consisting in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower than the upper part of the bone. The points of interest in connection with these fractures are: (1) that the musculo-spiral nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union, which is believed to be more common in the humerus than in any other bone. An important distinction to make in fractures of the lower end is between those that involve the elbow-joint and those which do not; the former are always serious, as they may lead to impairment of the utility of the limb. They include the T-shaped fracture and oblique fractures which

involve the articular surface. Those which do not involve the joint are the transverse fracture above the epicondyles, and the so-called epitrochlear fracture, where the tip of the internal epicondyle is broken off, generally from direct violence.

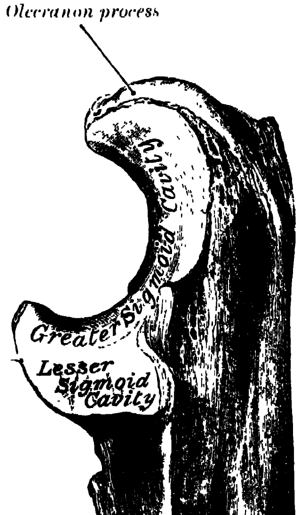
The Ulna

The **Ulna** (figs. 358 and 359) is a long bone, prismatic in form, placed at the inner side of the forearm, parallel with the radius. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; the bone diminishes in size from above downwards, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an interarticular fibro-cartilage. It is divisible into a shaft and two extremities.

The **upper extremity** (fig. 357), the strongest part of the bone, presents two curved processes, the olecranon process and the coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

The **olecranon process** (olecranon) is a large, thick, curved eminence, situated at the upper and back part of the ulna. It is bent forwards at the summit so as to present a prominent lip which is received into the olecranon fossa in extension of the forearm. Its *base* is contracted where it joins the shaft; this is the narrowest part upper end of the ulna, and, the most usual seat Its *posterior surface* backwards, is triangular, , subcutaneous, and covered bursa. Its *superior surface* is of quadrilateral form, marked behind by a rough impression for the insertion of the Triceps muscle, and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its *anterior surface* is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the greater sigmoid cavity. Its *lateral borders* present continuations of the groove on the margin of the superior surface: they serve for the attachment of ligaments—viz. the back part of the ~~internal~~ ulnar Alateral ligament internally, and the posterior ligament externally. From the inner border a part of the Flexor carpi ulnaris arises; while to the outer border the Anconeus is attached.

Fig. 357.—Upper extremity of left ulna. Outer aspect.



The **coronoid process** (processus coronoideus) is a triangular eminence projecting horizontally forwards from the upper and front part of the ulna. Its *base* is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its *apex* is pointed, slightly curved upwards, and in flexion of the forearm is received into the coronoid depression of the humerus. Its *upper surface* is smooth, concave, and forms the lower part of the greater sigmoid cavity. Its *antero-inferior surface* is concave, and marked internally by a rough impression for the insertion of the Brachialis anticus. At the junction of this surface with the front of the shaft is a rough eminence, the *tubercle of the ulna* (tuberositas ulnæ), which gives insertion to a part of the Brachialis anticus; to the outer border of this tubercle the oblique ligament is attached. Its *outer surface* presents a narrow, oblong, articular depression, the *lesser sigmoid cavity*. Its *inner surface*, by its prominent, free margin, serves for the attachment of part of the ~~internal lateral~~ ligament. At the front part of this surface is a small rounded eminence for the origin of one head of the Flexor sublimis digitorum; behind the eminence

Fig. 358.—Bones of left forearm. Anterior aspect.

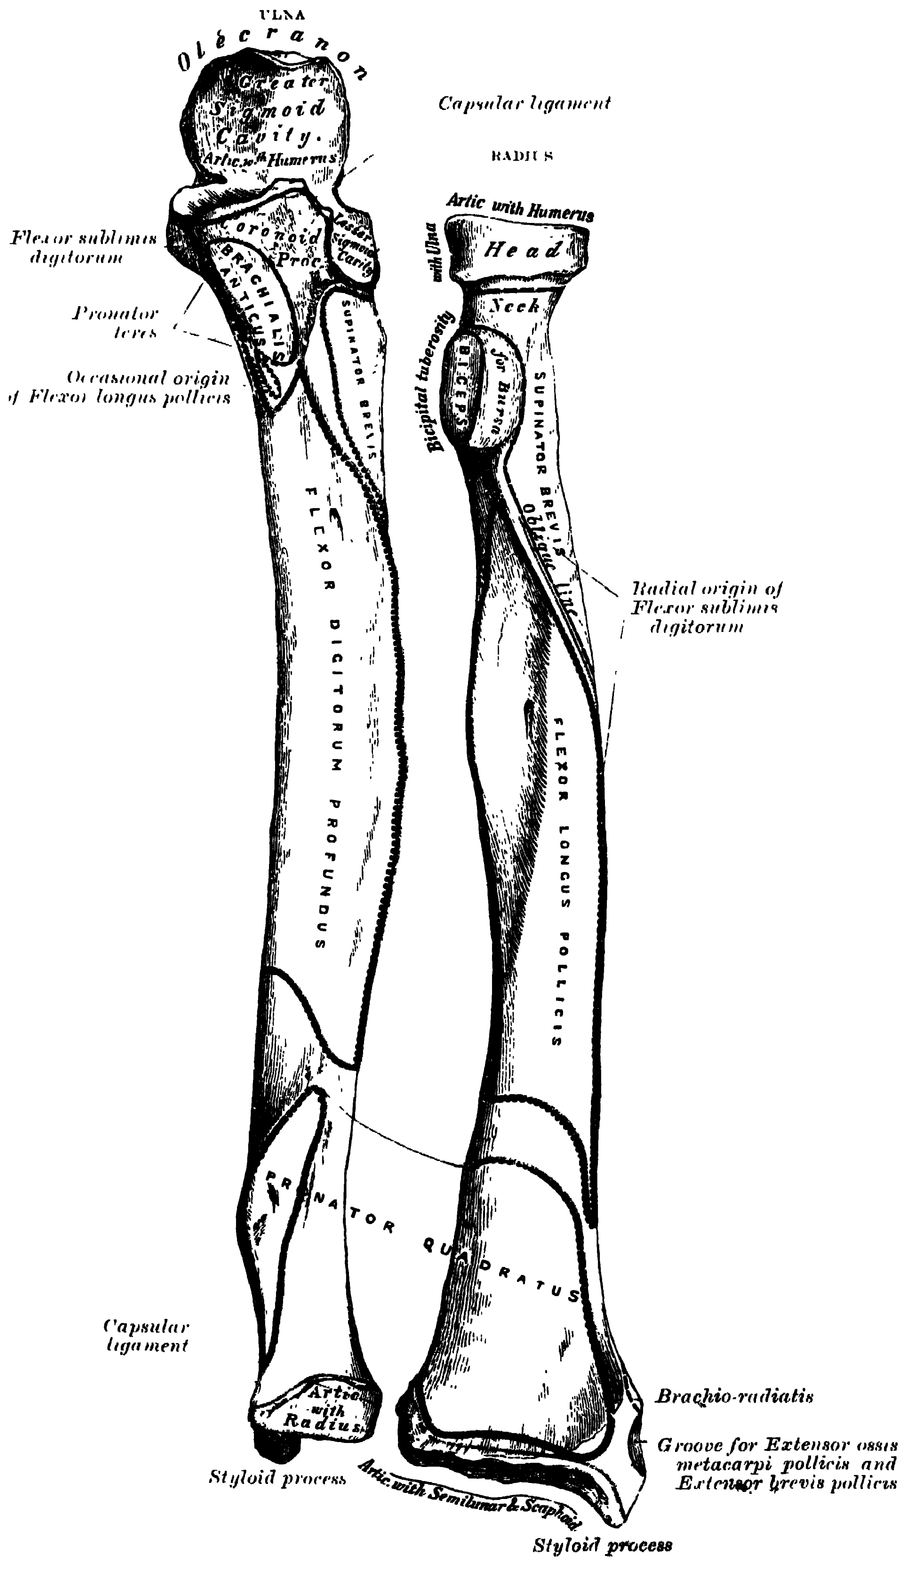


Fig. 359.—Bones of left forearm. Posterior aspect.

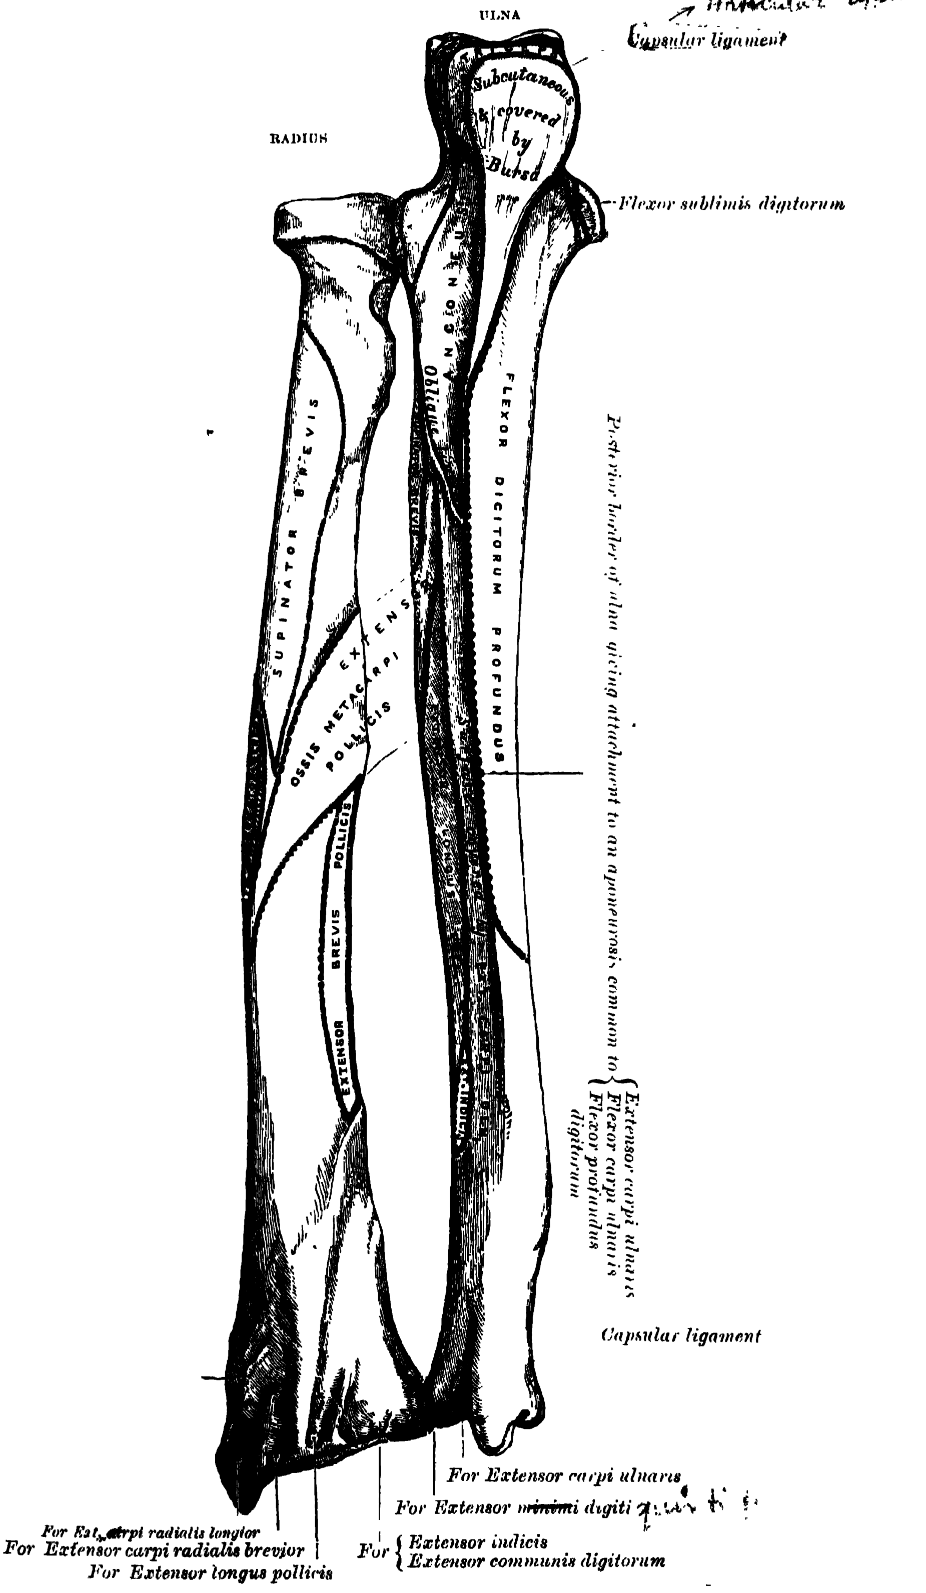


is a depression for part of the origin of the Flexor profundus digitorum; descending from the eminence is a ridge which gives origin to one head of the Pronator teres. Frequently, the Flexor longus pollicis arises from the lower part of the coronoid process by a rounded bundle of muscular fibres.

The **greater sigmoid cavity** (incisura semilunaris) is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the trochlear surface of the humerus. About the middle of either lateral border of this cavity is a notch, which contracts it somewhat, and indicates the junction of the two processes of which it is formed. The cavity is concave from above downwards, and divided into an inner and an outer portion by a smooth ridge running from the summit of the olecranon to the tip of the coronoid process. The inner portion is the larger, and is slightly concave transversely; the outer is convex above, slightly concave below.

The **lesser sigmoid cavity** (incisura radialis) is a narrow, oblong, articular depression on the outer side of the coronoid process, which receives the lateral articular surface of the head of the radius. It is concave from before backwards, and its prominent extremities serve for the attachment of the orbicular ligament.

The **shaft** (corpus ulnæ), at its upper part, is prismatic in form, and curved from behind forwards and from without inwards, so as to be convex behind and externally; its central part is quite straight; its lower part is rounded, smooth, and bent a little outwards. It tapers gradually from above downwards, and has three borders and three surfaces.

The *anterior border* (margo volaris) begins above at the prominent inner angle of the coronoid process, and ends below in front of the styloid process. Its upper part, well defined, and its middle portion, smooth and rounded, give origin to the Flexor profundus digitorum; its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the origin of the Pronator quadratus. This border separates the anterior from the internal surface.

The *posterior border* (margo dorsalis) begins above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and ends below at the back of the styloid process; it is well marked in the upper three-fourths, and gives attachment to an aponeurosis which affords a common origin to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor profundus digitorum; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

The *external* or *interosseous border* (crista interossea) begins above by the union of two lines, which converge from the extremities of the lesser sigmoid cavity and enclose between them a triangular space for the origin of part of the Supinator brevis; it ends below at the head of the ulna. Its two middle fourths are very prominent, its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, and separates the anterior from the posterior surface.

The *anterior surface* (facies volaris), much broader above than below, is concave in its upper three-fourths, and gives origin to the Flexor profundus digitorum; its lower fourth, also concave, is covered by the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge, directed obliquely downwards and inwards; this ridge (the *oblique* or *pronator ridge*) marks the extent of origin of the Pronator quadratus. At the junction of the upper with the middle third of the bone is the nutrient canal, directed obliquely upwards and inwards.

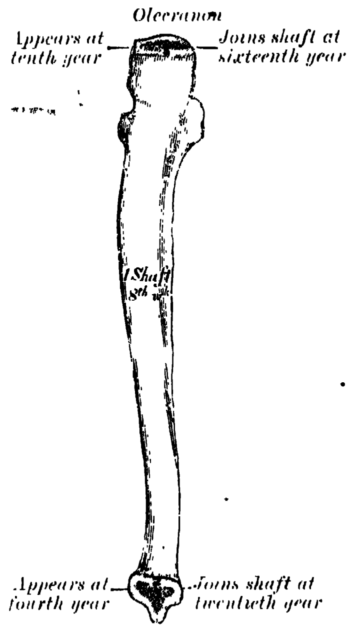
The *posterior surface* (facies dorsalis), directed backwards and outwards, is broad and concave above; convex and somewhat narrower in the middle of its course; narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity downwards to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus, while the upper part of the ridge itself affords attachment to the Supinator brevis. Below this the surface is subdivided by a longitudinal ridge, sometimes called the *perpendicular line*, into two parts: the internal part is smooth, and covered by the Extensor carpi ulnaris; the external portion, wider and rougher, gives origin from above

downwards to the Supinator brevis, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis.

The *internal surface* (facies medialis) is broad and concave above, narrow and convex below. It gives origin by its upper three-fourths to the Flexor profundus digitorum: its lower fourth is subcutaneous.

The **lower extremity** of the ulna is of small size, and presents two eminences; the outer and larger is a rounded, articular eminence, termed the head of the ulna; the inner, narrower and more projecting, is a non-articular eminence, the styloid process. The *head* (capitulum ulnæ) presents an articular surface, part of which, of an oval or semilunar form, is directed downwards, and articulates with the upper surface of the interarticular fibro-cartilage which separates it from the wrist-joint; the remaining portion, directed outwards, is narrow, convex, and received into the sigmoid cavity of the radius. The *styloid process* (processus styloideus) projects from the inner and back part of the bone; it descends a little lower than the head, and ends in a rounded summit, which affords attachment to the internal lateral ligament of the wrist-joint. The head is separated from the styloid process, internally, by a depression for the attachment of the apex of the triangular interarticular fibro cartilage, and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

Fig. 360.—Plan of ossification of the ulna. From three centres.



Structure.—The structure of the ulna is similar to that of the other long bones.

Ossification.—The ulna is ossified from *three* centres: one each for the shaft, the inferior extremity, and the top of the olecranon (fig. 360). Ossification begins near the middle of the shaft about the eighth week of fœtal life, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year, a centre appears in the middle of the head, and soon extends into the styloid process. About the tenth year, a centre appears in the olecranon near its extremity, the chief part of this process being formed by an upward extension of the shaft. The upper epiphysis joins the shaft about the sixteenth, the lower about the twentieth year.

Articulations.—The ulna articulates with the humerus and radius.

Surface Form.—The most prominent part of the ulna, the olecranon process, can always be identified at the back of the elbow-joint. When the forearm is flexed, the upper quadrilateral surface can be felt, directed backwards; during extension it recedes into the olecranon fossa, and the contracting fibres of the Triceps prevent its being perceived. On the back of the olecranon is the smooth, triangular, subcutaneous surface, continuous with the posterior border of the shaft. During extension, the upper border of the olecranon is slightly above the level of the internal epicondyle, and the process itself is nearer to this epicondyle than to the external one. Running down the back of the forearm, from the apex of the triangular surface, is the prominent posterior border of the ulna, which can be felt throughout its entire length. As it passes down the forearm, it pursues a sinuous course and inclines to its inner side, so that it is situated in the middle of the back of the limb above, and on the inner side of the wrist below. It is rounded off in its lower third, and may be traced below to the small subcutaneous surface of the styloid process. Internal to this border the lower fourth of the inner surface can be felt. The styloid process forms a prominent tubercle, continuous above with the posterior subcutaneous border, and terminating below in a blunt apex, which lies on a level with the wrist-joint. The styloid process is best perceived when the hand is in a position midway between supination and pronation. If the forearm be pronated while the finger is placed on the process, the latter will be felt to recede, and another prominence will

appear just behind and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular interarticular fibro-cartilage, and now projects between the tendon of the Extensor carpi ulnaris and that of the Extensor minimi digiti.

The Radius

The **Radius** (figs. 358 and 359) is situated on the outer side of the ulna, which exceeds it in length and size. Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist-joint. It is a long bone, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

The **upper extremity** presents a head, neck, and tuberosity. The *head* (capitulum radii) is of a cylindrical form, depressed on its upper surface into a shallow cup (fovea capituli radii) which articulates with the capitellum of the humerus. Around the circumference of the head is a smooth, articular surface (circumferentia articularis), broad internally where it articulates with the lesser sigmoid cavity of the ulna, narrow in the rest of its circumference, where it rotates within the orbicular ligament. The head is supported on a round, smooth, and constricted portion called the *neck* (collum radii), on the back of which is a slight ridge for the insertion of part of the Supinator brevis. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the *bicipital tuberosity* (tuberositas radii); its surface is divided by a vertical line into a posterior, rough portion, for the insertion of the tendon of the Biceps, and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The **shaft** (corpus radii) is prismoid in form, narrower above than below, and slightly curved, so as to be convex outwards. It presents three borders and three surfaces.

The *anterior border* (margo volaris) extends from the lower part of the tuberosity above, to the anterior part of the base of the styloid process below, and separates the anterior from the external surface. Its upper third is very prominent, and from its oblique direction, downwards and outwards, has received the name of the *oblique line* of the radius; it gives insertion, externally, to the Supinator brevis; internally, there arises from it the Flexor longus pollicis, and between these the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords insertion to the Pronator quadratus, and gives attachment to the posterior annular ligament of the wrist; it terminates in a small tubercle, into which is inserted the tendon of the Brachio-radialis.

The *posterior border* (margo dorsalis) begins above at the back of the neck, and ends below at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

The *internal* or *interosseous border* (crista interossea) begins above, at the back part of the tuberosity, where it is rounded and indistinct; it becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which are continued to the anterior and posterior margins of the sigmoid cavity. To the posterior of the two ridges the lower part of the interosseous membrane is attached, while the triangular surface between the ridges gives insertion to part of the Pronator quadratus. This border separates the anterior from the posterior surface, and throughout the greater part of its extent gives attachment to the interosseous membrane.

The *anterior surface* (facies volaris) is concave in its upper three-fourths, and gives origin to the Flexor longus pollicis; it is broad and flat in its lower fourth, and affords insertion to the Pronator quadratus. A prominent ridge limits the insertion of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle thirds of this surface is the nutrient foramen, which is directed obliquely upwards.

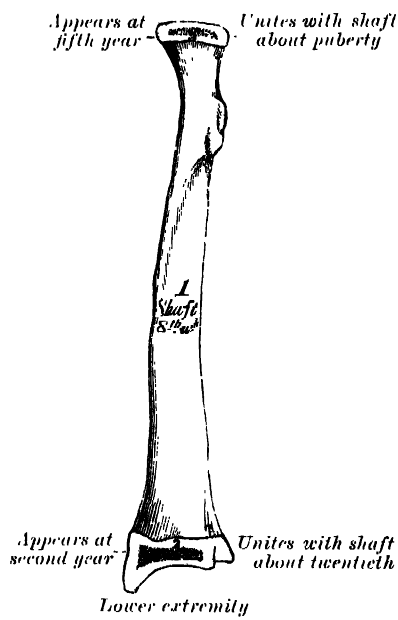
The *posterior surface* (facies dorsalis) is round, convex, and smooth in the upper third of its extent, and covered by the Supinator brevis. Its middle third is broad, slightly concave, and gives origin to the Extensor ossis metacarpi pollicis above, and the Extensor brevis pollicis below. Its lower third is broad,

convex and covered by the tendons of the muscles which subsequently run in the grooves on the lower end of the bone.

The *external surface* (facies lateralis) is round and convex throughout its entire extent. Its upper third gives insertion to the Supinator brevis. About its centre is seen a rough ridge, for the insertion of the Pronator teres. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis.

The lower extremity is large, of quadrilateral form, and provided with two articular surfaces—one on the inferior surface, for articulation with the carpus, and another at the inner side, for articulation with the ulna. The *carpal articular surface* is triangular, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external, triangular, articulates with the scaphoid bone; the inner, quadrilateral, with the semilunar. The *articular surface for the ulna* is called the ***sigmoid cavity*** (incisura ulnaris) of the radius; it is narrow, concave, smooth, and articulates with the head of the ulna. These two articular surfaces are separated from each other by a prominent ridge, to which the base of the triangular fibro-cartilage is attached; this structure separates the wrist-joint from the inferior radio-ulnar articulation. This end of the bone presents three non-articular surfaces—anterior, posterior, and external. The *anterior surface*, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The *posterior surface* is convex, affords attachment to the posterior ligament of the wrist-joint, and is marked by three grooves. Enumerated from without inwards, the first groove is broad, but shallow, and subdivided into two by a slight ridge: the outer of these two transmits the tendon of the Extensor carpi radialis longior, the inner the tendon of the Extensor carpi radialis brevior. The second, near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply defined ridge: it is directed obliquely from above, downwards and outwards, and transmits the tendon of the Extensor longus pollicis. The third and most internal is broad, for the passage of the tendons of the Extensor indicis and Extensor communis digitorum. The *external surface* is prolonged obliquely downwards into a strong, conical projection, the *styloid process* (processus styloideus), which gives attachment by its base to the tendon of the Brachio-radialis, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, for the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis.

FIG. 361.—Plan of ossification of the radius. From three centres.



Structure.—The structure of the radius is similar to that of the other long bones.

Ossification (fig. 361).—The radius is ossified from *three* centres: one for the shaft, and one for either extremity. That for the shaft makes its appearance near the centre of the bone, during the eighth week of fœtal life. About the end of the second year, ossification commences in the lower end; and at the fifth year, in the upper end. The upper epiphysis fuses with the shaft, at the age of seventeen or eighteen, the lower about the age of twenty. An additional centre, sometimes found in the bicipital tuberosity, appears about the fourteenth or fifteenth year.

Articulations.—The radius articulates with four bones: the humerus, ulna, scaphoid, and semilunar.

Surface Form.—Below, and a little in front of, the posterior surface of the external condyle a part of the head of the radius may be felt; its position is indicated by a little dimple in the skin, which is most visible when the arm is extended. If the finger be placed on this dimple and the semiflexed forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half can be readily examined, though covered by tendons and muscles and not strictly subcutaneous, and if traced downwards is felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inwards towards the wrist. About the middle of the posterior aspect of the lower extremity is a well-marked ridge, the *dorsal radial tubercle*, best perceived when the hand is slightly flexed on the wrist. It forms the outer boundary of the oblique groove, through which the tendon of the Extensor longus pollicis runs, and helps to keep that tendon in its place.

Applied Anatomy.—The two bones of the forearm are more often broken together, than is either the radius or ulna separately. It is therefore convenient to consider the fractures of both bones in the first instance and subsequently to mention the principal fractures which take place in each bone. Fractures of both bones may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius as a rule gives way, though both bones may suffer. Fracture from indirect force generally takes place somewhere about the middle of the bones, while that from direct violence may occur at any part, but is most frequent in the lower half of the bones. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other and therefore diminishes the risk of their becoming united across the interosseous membrane. Anterior and posterior splints are applied in these cases, and should be rather wider than the limb, so as to prevent any lateral pressure on the bones.

The special fractures of the ulna are:—(1) Fracture of the olecranon, which is usually caused by direct violence, as in falls on the elbow with the forearm flexed, but occasionally by muscular action in sudden contraction of the Triceps. The most common place for the fracture to occur is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, and even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. The displacement is slight, if the fibrous structures around the process are not torn. (2) Fracture of the coronoid process may occur as a complication of dislocation backwards of the bones of the forearm, but it is doubtful if it ever takes place as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually take place at or a little below the middle of the bone. They are generally the result of direct violence, but may occur as a complication of dislocation of the radius. (4) The styloid process may be knocked off by direct violence.

Fractures of the radius may consist of—(1) Fracture of the head of the bone; this for the most part takes place in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck may also occur, but is usually complicated with other injury. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. They may be caused by direct or indirect violence. In fracture of the upper third of the shaft—that is to say, above the insertion of the Pronator teres—the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator brevis, and flexed by the Biceps; while the lower fragment is pronated and drawn towards the ulna by the two Pronators. If such a fracture be put up in the ordinary position, midway between supination and pronation, the bone will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movement of supination will result; the limb should therefore be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles's fracture). The fracture is transverse, and generally takes place about an inch from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than in the male. In consequence of the manner in which the fracture is caused, the upper fragment is driven into the lower, and impaction is the result; excess of violence may, however, disimpact, the lower fragment being split into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles's fracture may be distinguished from other injuries in this neighbourhood—especially dislocation, with which they are liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna: that is to

Fig. 362.—Bones of the left hand. Palmar surface.

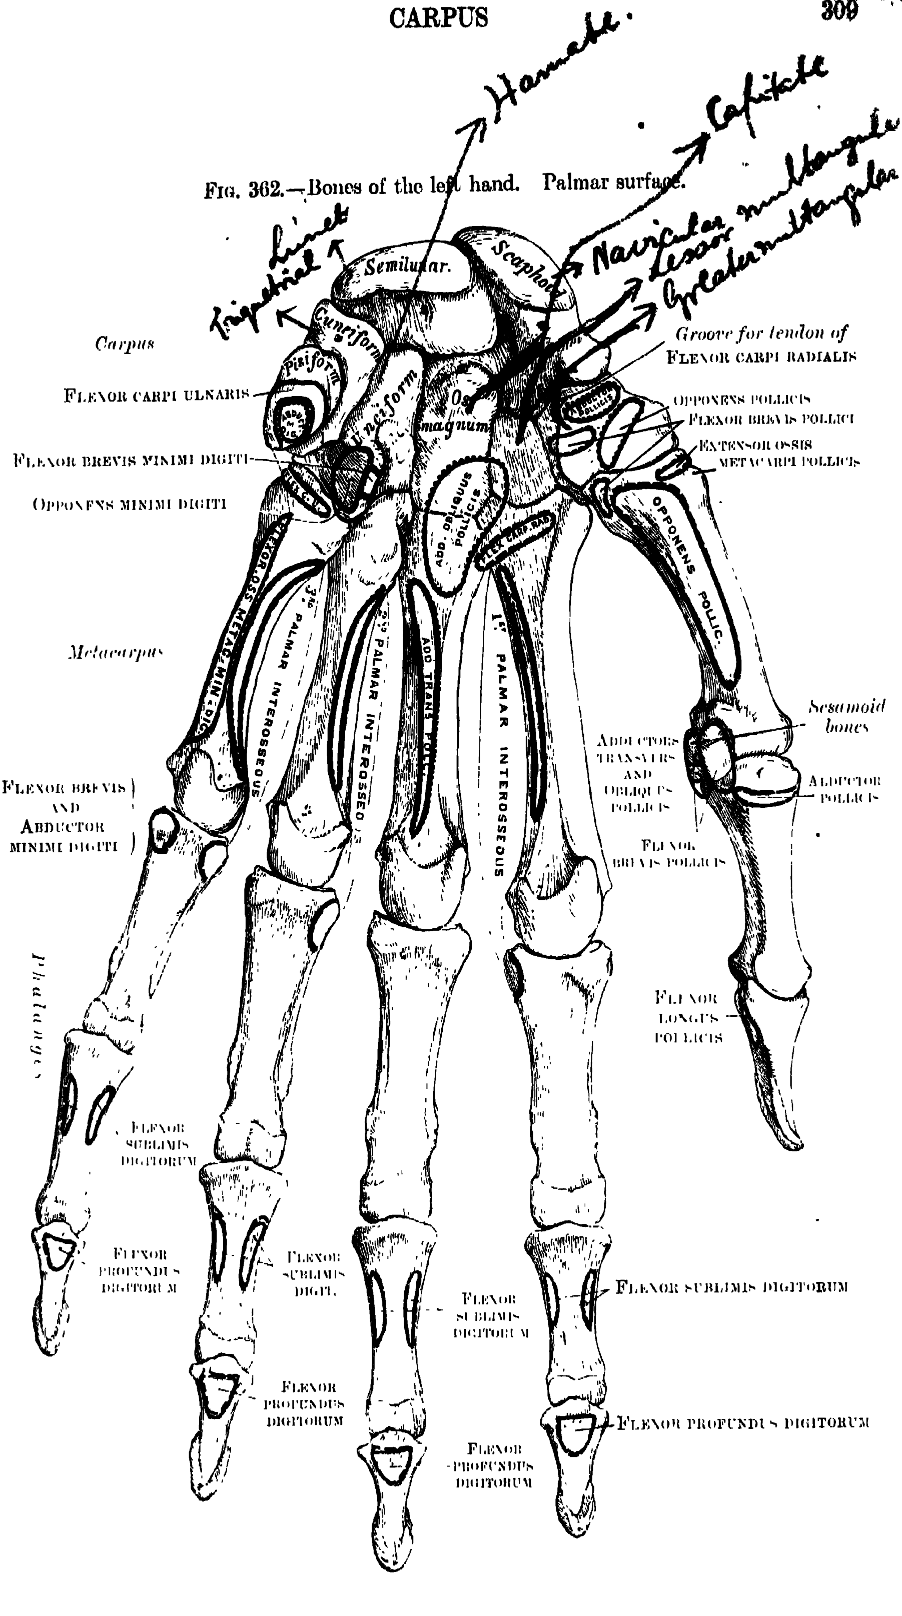


Fig. 363.—Bones of the left hand. Dorsal surface.

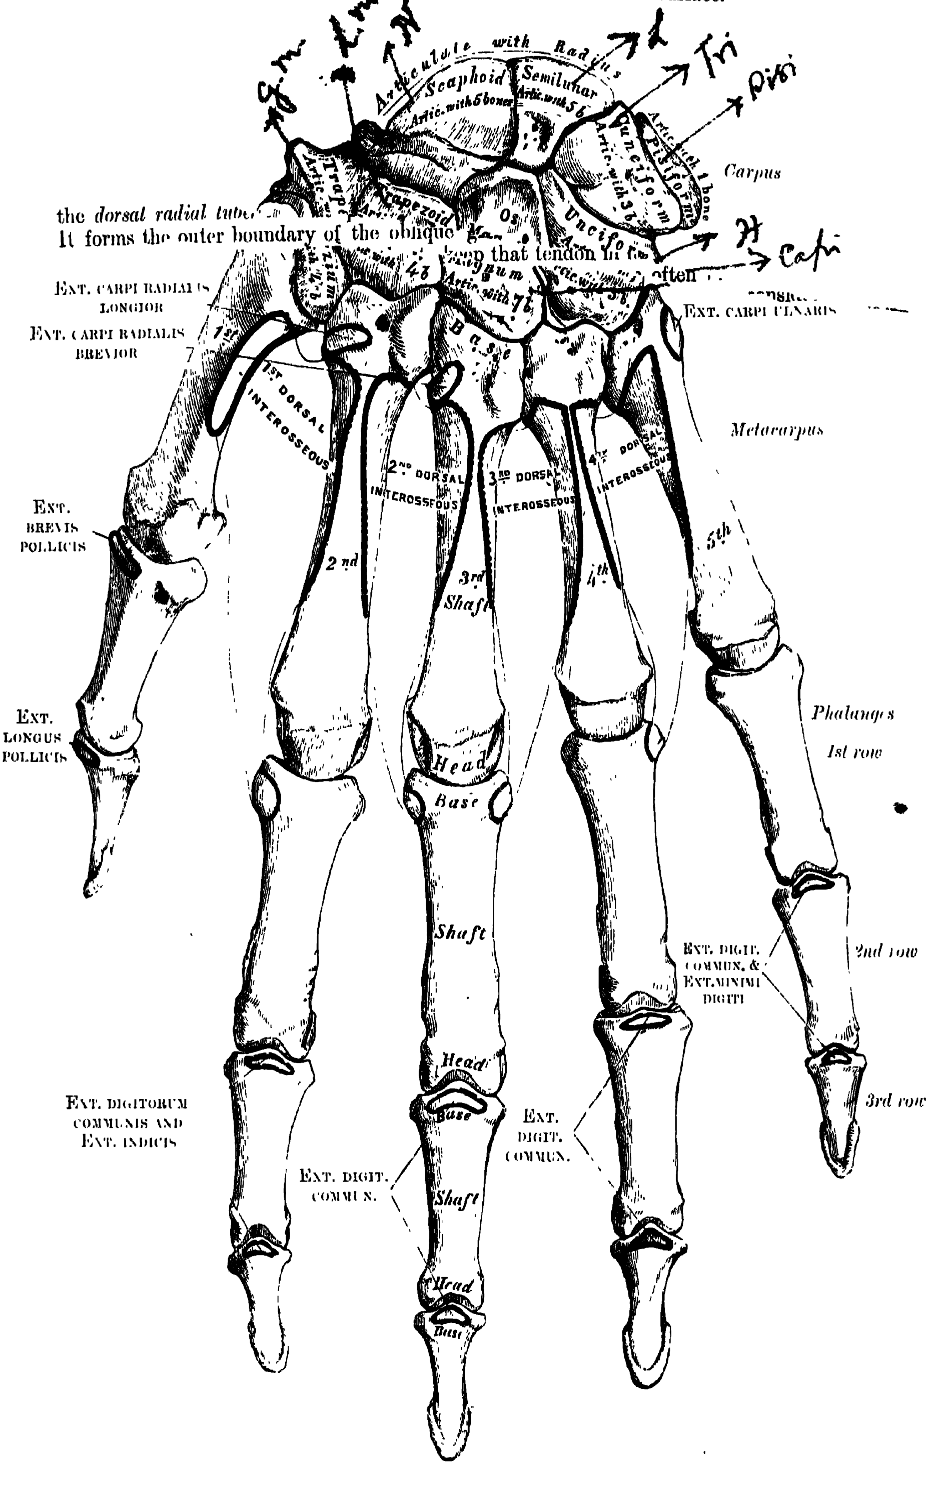


say, nearer the ground. After fracture or separation of the epiphysis the styloid process of the radius is on the same level as, or on a higher level than, that of the ulna, whereas it would be unaltered in position in dislocation. Reduction in the case of Colles's fracture is usually easily effected by traction on the hand, the limb being subsequently splinted with the hand in the position of ulnar flexion.

THE HAND

The skeleton of the hand (figs. 362 and 363) is subdivided into three segments—the carpus or wrist bones; the metacarpus or bones of the palm; and the phalanges or bones of the digits.

THE CARPUS

The **Carpal bones** (ossa carpi), eight in number, are arranged in two rows. Those of the upper row, from the radial to the ulnar side, are named the scaphoid, semilunar, cuneiform, and pisiform; those of the lower row, in the same order, are named the trapezium, trapezoid, os magnum, and unciform.

Common Characters of the Carpal Bones

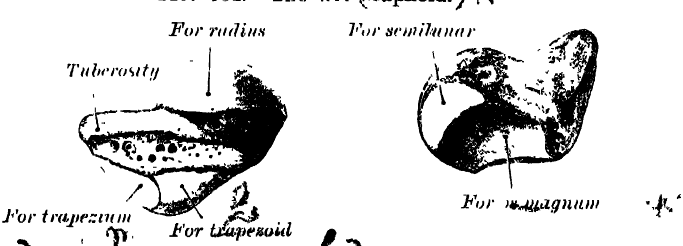
Each bone (excepting the pisiform) presents six surfaces. Of these the *anterior* or *palmar* and the *posterior* or *dorsal* are rough, for ligamentous attachment; the dorsal surfaces being the broader, except in the scaphoid and semilunar. The *superior* or *proximal*, and *inferior* or *distal surfaces* are articular, the superior generally convex, the inferior concave; the *internal* and *external surfaces* are also articular when in contact with contiguous bones, otherwise they are rough and tubercular. The structure in all is similar, consisting of cancellous tissue enclosed in a layer of compact bone. Each bone is ossified from a single centre.

Bones of the Upper Row

Scaphoid (fig. 364)

The **Scaphoid** (os naviculare manus) is the largest bone of the first row. It has received its name from its fancied resemblance to a boat, being broad at one end, and narrow like a prow at the other. It is situated at the upper and outer part of the carpus, its long axis being from above downwards, outwards, and forwards. The *superior surface* is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The *inferior surface*, directed downwards, outwards, and backwards, is also smooth, convex, and triangular, and is divided by a slight ridge into two parts, the external articulating

Fig. 364.—The left scaphoid.



with the trapezium, the inner with the trapezoid. The *dorsal surface* presents a narrow, rough groove, which runs the entire length of the bone, and serves for the attachment of ligaments. The *palmar surface* is concave above, and elevated at its lower and outer part into a rounded projection, the *tuberosity* (tuberculum oss. navicularis), which is directed forwards and gives attachment to the anterior annular ligament of the wrist and sometimes origin to a few fibres of the Abductor pollicis. The *external surface* is rough and narrow, and gives attachment to the external lateral ligament of the wrist. The *internal*

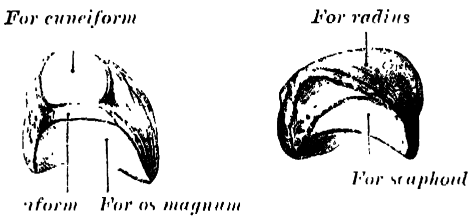
surface presents two articular facets; of these, the superior or smaller is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming with the semilunar bone a concavity for the head of the os magnum.

Articulations.—The scaphoid articulates with five bones: the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

SEMILUNAR (fig. 365)

The **Semilunar** (os lunatum) may be distinguished by its deep concavity and crescentic outline. It is situated in the centre of the upper row of the carpus, between the scaphoid and cuneiform. The *superior surface,* convex and smooth, articulates with the radius. The *inferior surface* is deeply concave, and of greater extent from before backwards than transversely: it articulates with the head of the os magnum, and, by a long, narrow facet (separated by a ridge from the general surface), with the unciform. The *palmar* and *dorsal surfaces* are rough, for the attachment of ligaments, the former being the broader, and of a somewhat rounded form. The *external surface* presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The *internal surface* is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

FIG. 365.—The left semilunar.



Articulations.—The semilunar articulates with five bones: the radius above, os magnum and unciform below, scaphoid externally and cuneiform internally.

CUNEIFORM (fig. 366)

The **Cuneiform** (os triquetrum) may be distinguished by its pyramidal shape, and by an oval isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus. The *superior surface* presents an internal, rough, non-articular portion, and an external convex articular portion, which articulates with the triangular fibro-cartilage of the wrist. The *inferior surface,* directed outwards, is concave, sinuously curved, and smooth for articulation with the unciform. The *dorsal surface* is rough for the attachment of ligaments. The *palmar surface* presents, on its inner part, an oval facet, for articulation with the pisiform; its outer part is rough for ligamentous attachment. The *external surface,* the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The *internal surface,* the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

FIG. 366.—The left cuneiform.

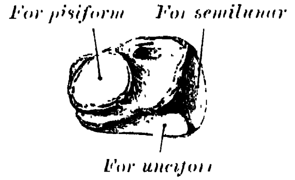


FIG. 367.—The left pisiform.

Articulations.—The cuneiform articulates with three bones: the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibro-cartilage which separates it from the lower end of the ulna.

Pisiform (fig. 367)

The **Pisiform** (os pisiforme) may be known by its small size, and by its presenting a single articular facet. It is situated on a plane anterior to the other carpal bones and is spheroidal in form, with its long diameter directed vertically. Its *dorsal* surface presents a smooth, oval facet, for articulation with the cuneiform: this facet approaches the superior, but not the inferior border of the bone. The *palmar surface* is rounded and rough, and gives attachment to the anterior annular ligament of the wrist, and to the Flexor carpi ulnaris and Abductor minimi digiti. The *outer* and *inner surfaces* are also rough, the former being concave, the latter usually convex.

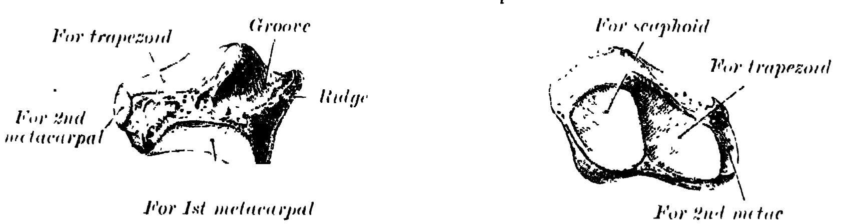
Articulation.—The pisiform articulates with one bone, the cuneiform.

Bones of the Lower Row

Trapezium (fig. 368)

The **Trapezium** (os multangulum majus) may be distinguished by a deep groove, for the tendon of the Flexor carpi radialis. It is situated at the external and inferior part of the carpus, between the scaphoid and first metacarpal bone. The *superior surface* is directed upwards and inwards; internally, it is smooth, and articulates with the scaphoid; externally, it is rough, and continuous with the external surface. The *inferior surface*, directed downwards and outwards, is oval, concave from side to side, convex from before backwards, so as to form a saddle-shaped surface, for articulation with the base of the first metacarpal bone. The *palmar surface* is narrow

Fig. 368.—The left trapezium.



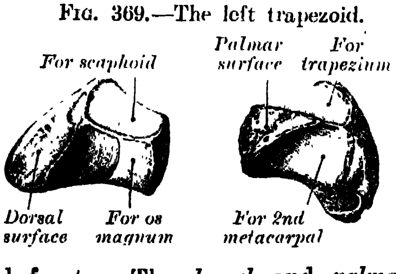
and rough. At its upper part is a deep groove, running from above obliquely downwards and inwards: it transmits the tendon of the Flexor carpi radialis and is bounded externally by an oblique ridge. This surface gives origin to the Abductor, Opponens, and Flexor brevis pollicis muscles, and also affords attachment to the anterior annular ligament of the wrist. The *dorsal surface* is rough. The *external surface* is broad and rough, for the attachment of ligaments. The *internal surface* presents two facets: the upper, large and concave, articulates with the trapezoid; the lower, small and oval, with the base of the second metacarpal.

Articulations.—The trapezium articulates with four bones: the scaphoid above, the trapezoid and second metacarpal internally, the first metacarpal below.

Trapezoid (fig. 369)

The **Trapezoid** (os multangulum minus) is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow end the palmar, surface; and by its having four articular surfaces touching each other, and separated by sharp edges. The *superior surface*, quadrilateral, smooth, and slightly concave, articulates with the scaphoid. The *inferior surface* articulates with the upper end of the second metacarpal bone; it is convex from side to side, concave from before backwards, and subdivided, by an elevated ridge, into two unequal lateral facets. The *dorsal* and *palmar*

Fig. 369.—The left trapezoid.



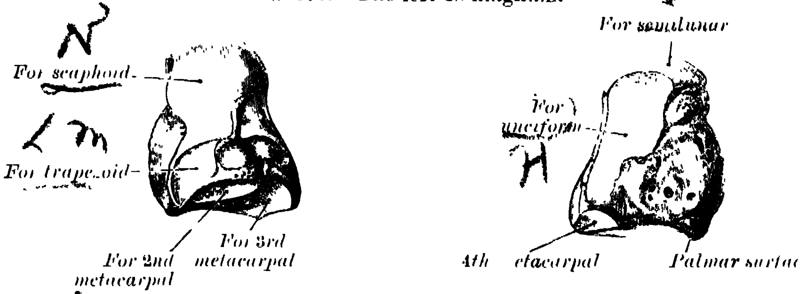
surfaces are rough for the attachment of ligaments, the former being the larger of the two. The *external surface*, convex and smooth, articulates with the trapezium. The *internal surface* is concave and smooth in front, for articulation with the os magnum; rough behind, for the attachment of an interosseous ligament.

Articulations.—The trapezoid articulates with four bones: the scaphoid above, second metacarpal below, trapezium externally, and os magnum internally.

Os Magnum (fig. 370)

The **Os magnum** (os capitatum) is the largest of the carpal bones, and occupies the centre of the wrist. It presents, above, a rounded portion or head, which is received into the concavity formed by the scaphoid and semilunar bones; a constricted portion or neck; and below this, the body. The *superior surface* is round, smooth, and articulates with the semilunar. The *inferior surface* is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third (the middle facet) being the largest. The *dorsal surface* is broad and rough. The *palmar surface* is narrow, rounded, and rough, for the attachment of ligaments and a part of the Adductor obliquus pollicis. The *external surface* articulates

FIG. 370.—The left os magnum.



with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Above this is a deep, rough groove, which forms part of the neck, and serves for the attachment of ligaments; it is bounded superiorly by a smooth, convex surface, for articulation with the scaphoid. The *internal surface* articulates with the unciform by a smooth, concave, oblong facet, which occupies its posterior and superior parts; it is rough in front, for the attachment of an interosseous ligament.

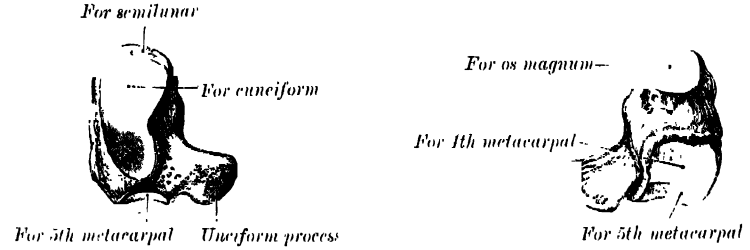
Articulations.—The os magnum articulates with seven bones: the scaphoid and semilunar above; the second, third, and fourth metacarpals below; the trapezoid on the radial side; and the unciform on the ulnar side.

Unciform (fig. 371)

The **Unciform** (os hamatum) may be readily distinguished by its wedge-shaped form, and the hook-like process which projects from its palmar surface. It is situated at the inner and lower angle of the carpus, with its base downwards, resting on the two inner metacarpal bones, and its apex directed upwards and outwards. The *superior surface*, the apex of the wedge, is narrow, convex, smooth, and articulates with the semilunar. The *inferior surface* articulates with the fourth and fifth metacarpal bones, by concave facets which are separated by an antero-posterior ridge. The *dorsal surface* is triangular and rough, for ligamentous attachment. The *palmar surface* presents, at its lower and inner side, a curved, hook-like process, the *unciform process* (hamulus), directed forwards and outwards. This process gives attachment, by its apex, to the anterior annular ligament of the wrist and the Flexor carpi ulnaris; by its inner surface to the Flexor brevis and Opponens minimi digiti; its outer

side is grooved for the passage of the Flexor tendons into the palm of the hand. It is one of the four eminences on the front of the carpus to which the anterior annular ligament of the wrist is attached; the others being the pisiform internally, the oblique ridge of the trapezium and the tuberosity of the scaphoid externally. The *internal surface* articulates with the cuneiform by an oblong

Fig. 371.—The left unciform



facet, cut obliquely from above, downwards and inwards. The *external surface* articulates with the os magnum by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

Articulations.—The unciform articulates with five bones: the semilunar above, the fourth and fifth metacarpals below, the cuneiform internally, the os magnum externally.

THE METACARPUS

The **Metacarpus** consists of five cylindrical bones which are numbered from without inwards (ossa metacarpalia I–V); each consists of a shaft and two extremities.

Common Characters of the Metacarpal Bones

The **shaft** (corpus) is prismoid in form, and curved, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces: two lateral and one dorsal. The *lateral surfaces* are concave, for the attachment of the Interosseous muscles, and separated from one another by a prominent anterior ridge. The *dorsal surface* presents in its distal two-thirds a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This surface is bounded by two lines, which commence in small tubercles situated on either side of the digital extremity, and, running upwards, converge to meet some distance behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral sloping surfaces for the attachment of the Dorsal interossei.* To the tubercles on the digital extremities are attached the lateral ligaments of the metacarpo-phalangeal joints.

The **carpal extremity** or **base** (basis) is of a cuboidal form, and broader behind than in front: it articulates above with the carpus, and on either side with the adjoining metacarpal bones; its *dorsal* and *palmar surfaces* are rough, for the attachment of ligaments.

The **digital extremity** or **head** (capitulum) presents an oblong surface markedly convex from before backwards, less so from side to side, and flattened laterally; it articulates with the proximal phalanx. It is broader, and extends farther forwards, on the palmar than on the dorsal aspect, and is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpo-phalangeal joint. The *dorsal surface*, broad and flat, supports the Extensor tendons; the *palmar surface* is grooved in the middle line for the passage of the Flexor tendons, and marked on either side by an articular eminence continuous with the terminal articular surface.

* By these sloping surfaces the metacarpal bones may be at once distinguished from the metatarsal bones.

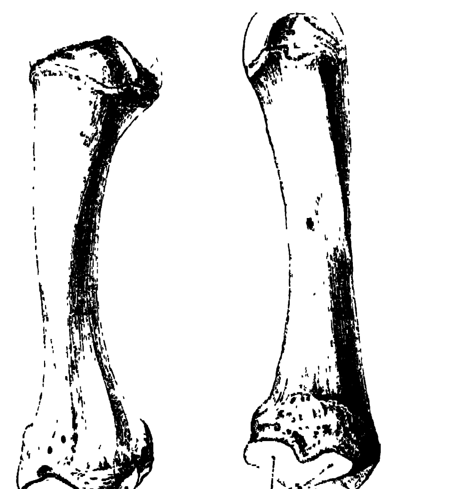
Peculiar Characters of the Metacarpal Bones

The **first metacarpal bone** (fig. 372) is shorter and stouter than the others, diverges to a greater degree from the carpus, and its palmar surface is directed inwards towards the palm. The *shaft* is flattened and broad on its dorsal surface, and does not present the ridge which is found on the other metacarpal bones; its palmar surface is concave from above downwards. On its outer border is inserted the Opponens pollicis; its inner border gives origin to the outer head of the First dorsal interosseous. The *carpal extremity* presents a concavo-convex surface, for articulation with the trapezium; it has no lateral facets, but on its outer side is a tubercle for the insertion of the Extensor ossis metacarpi pollicis. The *digital extremity* is less convex than those of the other metacarpal bones, and is broader from side to side than from before backwards. On its palmar surface are two articular eminences, of which the outer one is the larger, for the two sesamoid bones in the tendons of the Flexor brevis pollicis.

The **second metacarpal bone** (fig. 373) is the longest, and its base the largest, of the four remaining bones. Its *carpal extremity* is prolonged upwards

Fig. 372.—The first metacarpal. (Left.)

Fig. 373.—The second metacarpal. (Left.

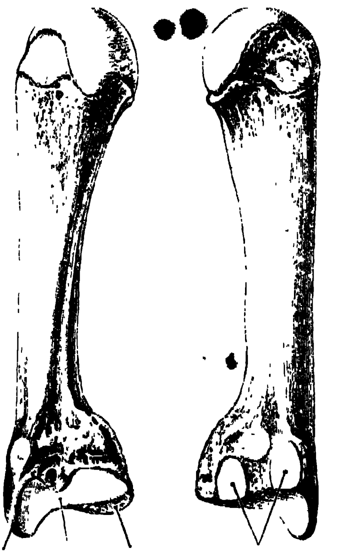


and inwards, forming a prominent ridge. It presents four articular facets: three on the upper surface and one on the inner or ulnar side. Of the facets on the upper surface the middle is the largest and is concave from side to side, convex from before backwards for articulation with the trapezoid; the external is small, flat and oval for articulation with the trapezium; the internal, on the summit of the ridge, is long and narrow for articulation with the os magnum. The facet on the ulnar side articulates with the third metacarpal. The Extensor carpi radialis longior is inserted on the dorsal surface and the Flexor carpi radialis on the palmar surface of this extremity.

The **third metacarpal bone** (fig. 374) is a little smaller than the preceding. The dorsal aspect of its *carpal extremity* presents on its radial side a pyramidal eminence, the *styloid process*, which extends upwards behind the os magnum; immediately below this is a rough surface for the attachment of the Extensor carpi radialis brevior. The carpal articular facet is concave behind, flat in front, and articulates with the os magnum. On the radial side is a smooth, concave facet for articulation with the second metacarpal, and on the ulnar side two small oval facets for articulation with the fourth metacarpal.

The fourth metacarpal bone (fig. 375) is shorter and smaller than the preceding. The *carpal extremity* is small and quadrilateral; its superior surface presents two facets, a large one externally for articulation with the unciform and a small one internally for the os magnum. On the radial side are two oval facets, for articulation with the third metacarpal; and on the ulnar side, a single concave facet, for the fifth metacarpal.

Fig. 374.—The third metacarpal. (Left.)



The **fifth metacarpal bone** (fig. 376) presents on its *carpal extremity* one facet on its superior surface, which is concavo-convex, and articulates with the unciform, and one on its radial side, which articulates with the fourth metacarpal. On its ulnar side is a prominent tubercle for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge, which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle; the inner division is smooth, triangular, and covered by the Extensor tendons of the little finger.

Articulations.—Besides their phalangeal articulations, the metacarpal bones articulate as follows: the first with the trapezium; the second with the trapezium, trapezoid, os magnum and third metacarpal; the third with the os magnum and second and fourth metacarpals; the fourth with the os magnum, unciform, and third and fifth metacarpals; and the fifth with the unciform and fourth metacarpal.

Fig. 375.—The fourth metacarpal. (Left.)

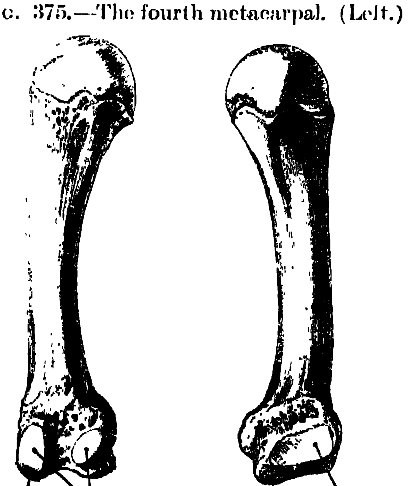


Fig. 376.—The fifth metacarpal. (Left.)

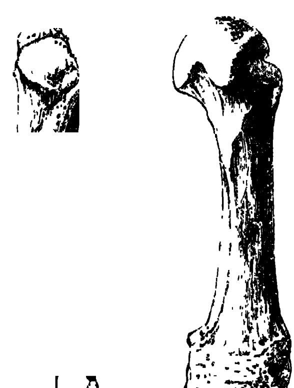
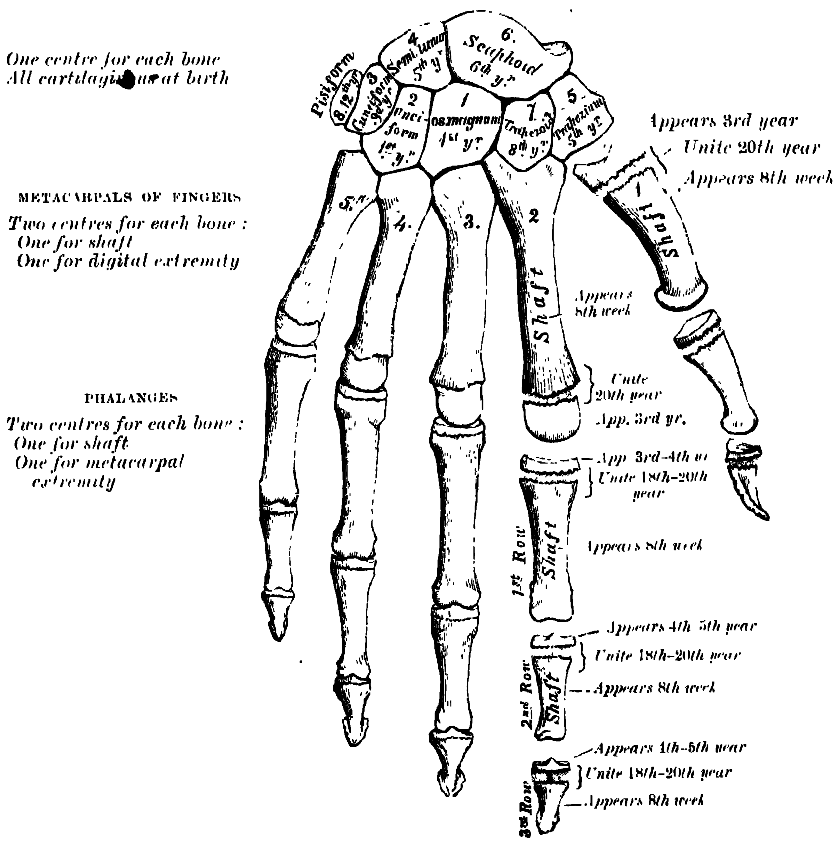


The first has no lateral facets on its carpal extremity: the second has no lateral facet on its radial, but one on its ulnar side; the third has one on its radial and two on its ulnar side; the fourth has two on its radial and one on its ulnar side; and the fifth has one on its radial side only.

THE PHALANGES

The **Phalanges** (phalanges digitorum manus) are fourteen in number, three for each finger, and two for the thumb. Each consists of a shaft and two extremities. The *shaft* tapers from above downwards, is convex posteriorly, concave in front from above downwards, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. The *metacarpal extremities* of the bones of the first row present oval, concave articular surfaces, broader from side to side than from before backwards. The *proximal extremity* of each of the bones of the second and third rows presents a double concavity separated by an antero-posterior median ridge. The *distal extremities* are smaller than the proximal, and each terminates in two lateral condyles separated by a shallow

FIG. 377.—Plan of ossification of the hand.



groove; the articular surface extends farther on the palmar than on the dorsal aspect, a condition best marked in the bones of the first row.

The *ungual phalanges* are convex on their dorsal and flat on their palmar surfaces; they are recognised by their small size, and by a roughened, elevated surface of a horse-shoe form on the palmar aspect of the distal extremity of each which serves to support the sensitive pulp of the finger.

Articulations.—In the four inner digits the phalanges of the first row articulate with those of the second row and with the metacarpals; the phalanges of the second row with those of the first and third rows, and the ungual phalanges with those of the second row. In the thumb, which has only two phalanges, the first phalanx articulates by its proximal extremity with the metacarpal bone and by its distal with the ungual phalanx.

Ossification of the Bones of the Hand

The **Carpal Bones** are each ossified from a single centre, and ossification proceeds in the following order (fig. 377): in the os magnum and unciform during the first year, the former preceding the latter; in the cuneiform, during the third year; in the semilunar and trapezium, during the fifth year, the former preceding the latter; in the scaphoid, during the sixth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

Occasionally an additional bone, the *os centrale*, is found on the back of the carpus, lying between the scaphoid, trapezoid, and os magnum. During the second month of fœtal life it is represented by a small cartilaginous nodule, which usually fuses with the cartilaginous scaphoid. Sometimes the styloid process of the third metacarpal is detached and forms an additional ossicle.

The **Metacarpal Bones** are each ossified from *two* centres; one for the shaft and one for the digital extremity of each of the four inner bones; one for the shaft and one for the carpal extremity of the first metacarpal bone.* It will be seen, therefore, that the first metacarpal bone is ossified in the same manner as the phalanges, and this has led some anatomists to regard the thumb as being made up of three phalanges, and not of a metacarpal bone and two phalanges. Ossification commences in the middle of the shaft about the eighth or ninth week of fœtal life, the centre for the first metacarpal bone being the last to appear, and gradually proceeds towards either end of the bone; about the third year the digital extremities of the four inner metacarpals, and the base of the first metacarpal begin to ossify; they unite with the shafts about the twentieth year.

The **Phalanges** are each ossified from *two* centres; one for the shaft, and one for the proximal extremity. Ossification begins in the shaft, about the eighth week of fœtal life. Ossification of the proximal extremity commences in the bones of the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united in each row between the eighteenth and twentieth years.

In the ungual phalanges the centres for the shafts appear at the distal extremities of the phalanges, instead of at the middle of the shafts, as in the other phalanges. Moreover, of all the bones of the hand, the ungual phalanges are the first to begin to ossify.

Surface Form.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, produced by the tuberosity of the scaphoid and the ridge on the trapezium; the other on the ulnar side, caused by the pisiform bone. The tuberosity of the scaphoid can be felt just below and internal to the apex of the styloid process of the radius, between the tendons of the Extensor ossis metacarpi pollicis and Flexor carpi radialis; it is best perceived by extending the hand on the forearm. Half an inch below this tubercle another and better marked prominence can be felt; this is the ridge on the trapezium, which gives attachment to some of the short muscles of the thumb. On the inner side of the front of the wrist the pisiform bone forms a small but prominent projection. It is some distance below the lower end of the ulna, and just below the level of the styloid process of the radius; it is crossed by the crease which separates the front of the forearm from the palm of the hand. The rest of the front of the carpus is covered by tendons and the annular ligament, and is entirely concealed, with the exception of the hooked process of the unciform, which can be made out only with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that the posterior surface of the cuneiform is the only bone which can be felt. Below the carpus the dorsal surfaces of the metacarpal bones, except the fifth, are covered by tendons, and are only visible in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and is plainly to be perceived and felt. Slightly external to the middle line of the hand is a prominence, frequently well marked, but occasionally indistinct, formed by the styloid process of the metacarpal bone of the middle finger. This prominence is in the same line as the dorsal radial tubercle, and is an inch and a half below it. The heads of the metacarpals are plainly to be felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpals on to their anterior surfaces; so that the heads of these bones form the prominences of the

* Allen Thomson demonstrated the fact that the first metacarpal bone is often developed from three centres: that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone. *Journal of Anat. and Physiol.*, 1869.

knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges can be plainly felt. When the digits are bent, the proximal phalanges of the joints form prominences, which in the joints between the first and second phalanges are slightly hollowed, in accordance with the grooved shape of their articular surfaces, while in those between the second and third rows the prominences are flattened and square-shaped. In the palm of the hand the four inner metacarpal bones are covered by muscles, tendons, and the palmar fascia, and no part of them but their heads is to be distinguished. With regard to the thumb, the base of the metacarpal bone forms a prominence on the dorsal aspect, below the styloid process of the radius; the shaft can be felt, covered by tendons: it terminates at its head in a flattened prominence, in front of which can be felt the sesamoid bones.

Applied Anatomy.—The carpal bones are little liable to fracture, except from extreme violence, when the parts are so comminuted as to necessitate amputation. Occasionally they are the seat of tuberculous disease. The metacarpal bones and the phalanges are sometimes broken from direct violence. There are two diseases of the metacarpal bones and phalanges which require special mention on account of their frequent occurrence. One is tuberculous dactylitis, consisting in a deposit of tuberculous material in the medullary canal, expansion of the bone, with subsequent caseation and necrosis. The other is chondroma, which is perhaps more commonly found in connection with the metacarpal bones and phalanges than with any other bones. The tumours are usually multiple, and spring from beneath the periosteum about the epiphysial line.

BONES OF THE LOWER EXTREMITY

The Os Innominatum

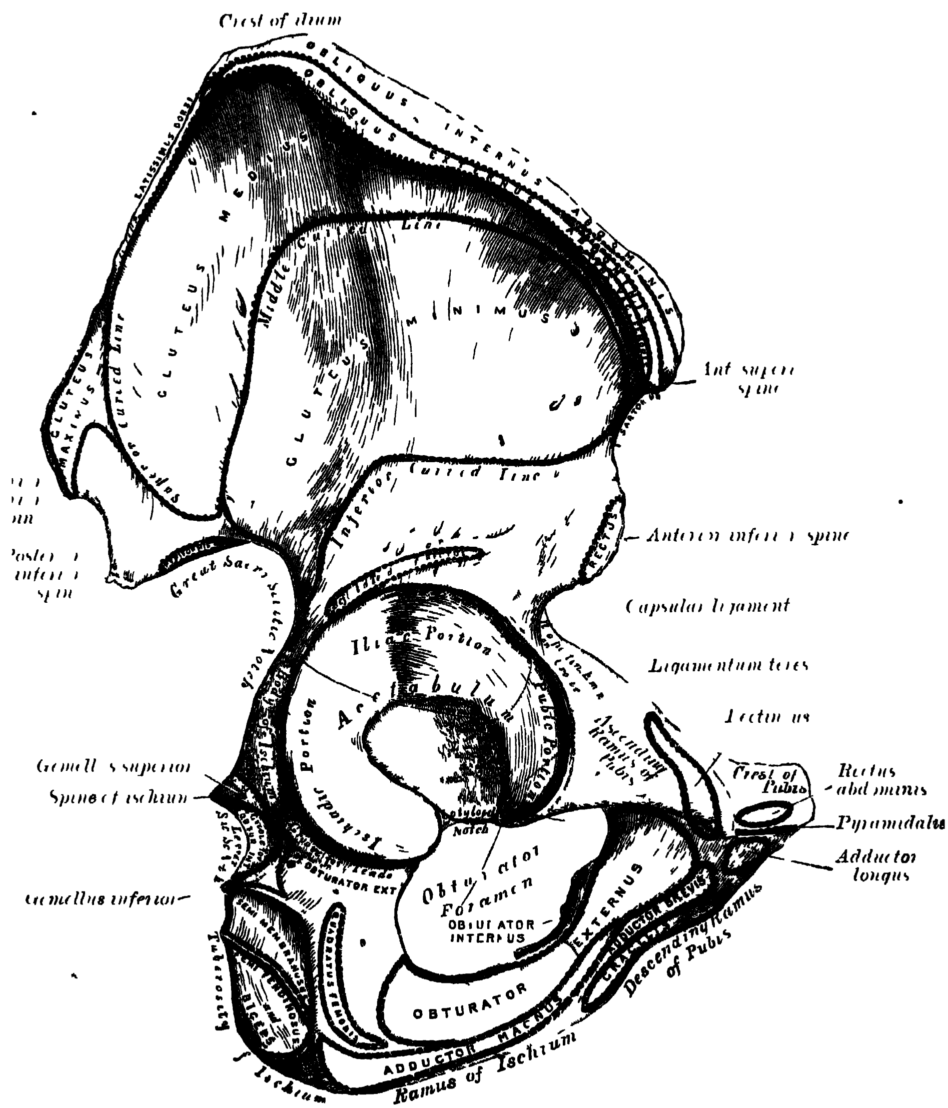
The **Os Innominatum** (os coxæ) is a large, irregularly shaped, flattened bone, constricted in the centre and expanded above and below. It meets its fellow of the opposite side in the middle line in front, and together they form the sides and anterior wall of the pelvic cavity. It consists of three parts, the ilium, ischium, and pubis, which are distinct from each other in the young subject, but are fused in the adult to form a single bone; the union of the three parts takes place in and around a large cup-shaped articular cavity, the acetabulum, which is situated near the middle of the outer surface of the bone. The *ilium*, so called because it supports the flank, is the superior broad and expanded portion which extends upwards from the acetabulum. The *ischium* is the lowest and strongest portion of the bone; it proceeds downwards from the acetabulum, expands into a large tuberosity, and then, curving forwards, forms, with the pubis, a large aperture, the obturator foramen. The *pubis* extends inwards and downwards from the acetabulum and articulates in the middle line with the bone of the opposite side: it forms the front of the pelvis and supports the external organs of generation.

The **Ilium** (os ilium) presents for examination two surfaces an external and an internal a crest, and two borders an anterior and a posterior.

The *external surface* of the ilium (fig. 378) is divided into two parts—an upper or gluteal, and a lower or acetabular. The *upper* or *gluteal portion*, known as the *dorsum ilii*, is directed backwards and outwards behind, and downwards and outwards in front. It is smooth, convex in front, deeply concave behind; bounded above by the crest, below by the upper border of the acetabulum, in front and behind by the anterior and posterior borders. This surface is crossed in an arched direction by three lines—the superior, middle, and inferior curved lines. The *superior* or *posterior curved line* (linea glutaea posterior), the shortest of the three, begins at the crest, about two inches in front of its posterior extremity; it is at first distinctly marked, but as it passes downwards to the upper part of the great sacro-sciatic notch, where it ends, it becomes less distinct, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and gives origin to a portion of the Gluteus maximus; the lower part is smooth and has no muscular fibres attached to it. The *middle curved line* (linea glutaea anterior), the longest of the three, begins at the crest, about an inch and a

half behind its anterior extremity, and, taking a curved direction downwards and backwards, ends at the upper part of the great sacro-sciatic notch. The space between the superior and middle curved lines and the crest is concave, and gives origin to the Gluteus medius. Near the middle of this line a nutrient foramen is often seen. The *inferior curved line* (linea glutaea inferior), the least distinct of the three, begins in front at the notch on the anterior border, and, curving backwards and downwards, ends near

FIG 378.—Right os innominatum External surface.

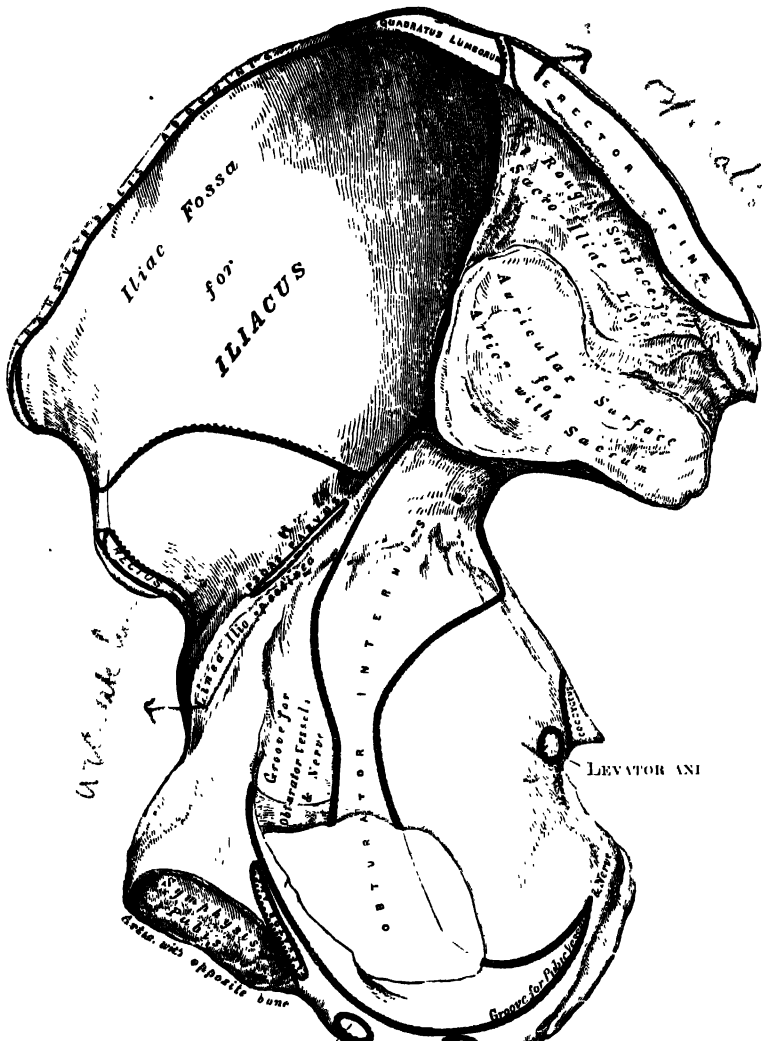


the middle of the great sacro-sciatic notch. The surface of bone included between the middle and inferior curved lines is concave from above downwards, convex from before backwards, and gives origin to the Gluteus minimus. Between the inferior curved line and the upper part of the acetabulum is a rough, shallow groove, from which the reflected tendon of the Rectus femoris arises. The *lower or acetabular part* of the external surface enters into the formation of the acetabulum, of which it forms rather less than two-

fifths. It is separated from the gluteal portion by a prominent rim, which forms part of the margin of the acetabular cavity.

The *internal surface* (fig. 379) of the ilium is bounded above by the crest; below, it is continuous with the pelvic surfaces of the pubis and ischium, only a faint line indicating the place of union; in front and behind, it is bounded by the anterior and posterior borders. It presents a large, smooth, concave surface, called the *iliac fossa* (fossa iliaca), which gives origin to the Iliacus and is perforated at its inner part by a nutrient canal; and below this

FIG. 379.—Right os innominatum. Internal surface.



a smooth, rounded border, the *linea ilio-pectinea*, separating the iliac fossa from the portion of the internal surface which enters into the formation of the true pelvis and gives origin to part of the Obturator internus. Behind the iliac fossa is a rough surface, divided into two portions, an anterior and a posterior. The anterior or *auricular surface* (facies auricularis), so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a similar surface on the side of the sacrum. The posterior portion (tuberositas iliaca) is elevated and rough, for the attachment of the

posterior sacro-iliac ligaments and for the origins of the Erector and Multifidus spinæ.

The *crest* of the ilium (crista iliaca) is convex in its general outline but is sinuously curved, being concave inwards in front, concave outwards behind. It is thinner at the centre than at the extremities, and terminates in the *anterior* and *posterior superior iliac spines*. The surface of the crest is broad, and divided into an external lip, an internal lip, and an intermediate space. About two inches behind the anterior superior iliac spine there is a prominent tubercle on the outer lip. To the external lip (labium externum) are attached the Tensor fasciæ femoris, Obliquus externus abdominis, and Latissimus dorsi, and along its whole length the fascia lata; to the space between the lips (linea intermedia) the Internal oblique; to the internal lip (labium internum), the fascia iliaca, the Transversalis abdominis, Quadratus lumborum, Erector spinæ, and Iliacus.

The *anterior border* of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the *anterior superior iliac spine* (spina iliaca anterior superior); its outer border gives attachment to the fascia lata, and the Tensor fasciæ femoris; its inner border, to the Iliacus; while its extremity affords attachment to Poupart's ligament and gives origin to the Sartorius. Beneath this eminence is a notch which gives origin to the Sartorius, and across which the external cutaneous nerve passes. Below the notch is the *anterior inferior iliac spine* (spina iliaca anterior inferior), which ends in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris and to the ilio-femoral ligament of the hip-joint. On the inner side of the anterior inferior spine is a broad, shallow groove, over which the Ilio-psoas passes. This groove is bounded internally by an eminence, the *ilio-pectineal*, which marks the point of union of the ilium and pubis.

The *posterior border* of the ilium, shorter than the anterior, also presents two projections separated by a notch, the *posterior superior iliac spine* (spina iliaca posterior superior) and the *posterior inferior iliac spine* (spina iliaca posterior inferior). The former corresponds with that portion of the inner surface of the ilium which serves for the attachment of the oblique portion of the sacro-iliac ligaments and the Multifidus spinæ; the latter to the lower extremity of the auricular surface. Below the posterior inferior spine is a deep notch, the *great sacro-sciatic notch* (incisura ischiadica major).

The **Ischium** (os ischii) forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion, the *body*; a large, rough eminence, on which the trunk rests in sitting, the *tuberosity*; and a thin part, which passes forwards and slightly upwards, the *ramus*.

The **body** (corpus oss. ischii), somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The *external surface* corresponds to that portion of the acetabulum which is formed by the ischium; it is smooth and concave, and constitutes a little more than two-fifths of the acetabular cavity. Between the acetabulum and the tuberosity is a deep groove, along which the tendon of the Obturator externus runs as it passes outwards to be inserted into the digital fossa of the femur. The *internal surface* is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity; it is perforated by two or three large, vascular foramina, and gives origin to part of the Obturator internus. The *posterior surface* is quadrilateral in form, broad and smooth. It is limited, externally, by the margin of the acetabulum; behind by the posterior border; it supports the Pyriformis, the two Gemelli, and the Obturator internus, in their passage outwards to the great trochanter. Below, where it joins the tuberosity, it presents a groove continuous with that on the external surface for the tendon of the Obturator externus; the lower edge of this groove is formed by the tuberosity of the ischium, and gives origin to the Gemellus inferior. The *external border* forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid ligament. The *internal border* is thin, and forms the outer circumference of the obturator foramen. The *posterior border* presents a thin and pointed triangular eminence, the *spine of the ischium* (spina

ischiadica), more or less elongated in different subjects; its external surface gives attachment to the Gemellus superior, its internal surface to the Coccygeus, Levator ani, and the pelvic fascia; while to the pointed extremity is attached the small sacro-sciatic ligament. Above the spine is a large notch, the *great sacro-sciatic notch* (incisura ischiadica major), converted into a foramen by the small sacro-sciatic ligament; it transmits the Pyriformis, the gluteal vessels, the superior and inferior gluteal nerves, the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and the nerves to the Obturator internus and Quadratus femoris. Of these, the gluteal vessels and superior gluteal nerve pass out above the Pyriformis, the other structures below it. Below the spine is a smaller notch, the *small sacro-sciatic* (incisura ischiadica minor); it is smooth, coated in the recent state with cartilage, the surface of which presents two or three ridges corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen by the sacro-sciatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve.

The **Tuberosity** (tuber ischiadicum) presents for examination three surfaces: external, internal, and posterior. The *external surface* is quadrilateral in shape, and rough for the attachment of muscles. It is bounded above by the groove for the tendon of the Obturator externus; in front it is limited by the posterior margin of the obturator foramen, and below it is continuous with the ramus; behind, it is bounded by a prominent margin which separates it from the posterior surface. In front of this margin the surface gives origin to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus; the lower part of the surface gives origin to part of the Adductor magnus. The *internal surface* forms part of the bony wall of the true pelvis. In front, it is limited by the posterior margin of the obturator foramen. Behind, it is bounded by a sharp ridge, which gives attachment to a falciform prolongation of the great sacro-sciatic ligament, and, more anteriorly, gives origin to the Transversus perinæi and Erector penis vel clitoridis. The *posterior surface* is divided into two portions: a lower, rough, somewhat triangular part, and an upper, smooth, quadrilateral portion. The anterior portion is subdivided by a prominent longitudinal ridge, passing from base to apex, into two parts; the outer gives attachment to the Adductor magnus, the inner to the great sacro-sciatic ligament. The upper portion is subdivided into two areas by an oblique ridge, which runs downwards and outwards; from the upper and outer area the Semi-membranosus arises; from the lower and inner, the long head of the Biceps and the Semitendinosus.

The **ramus** (ramus inferior oss. ischii) is the thin, flattened part of the ischium, which ascends from the tuberosity upwards and inwards, and joins the descending ramus of the pubis—the junction being indicated in the adult by a raised line. The *outer surface* is uneven, for the origin of the Obturator externus, and some of the fibres of the Adductor magnus; its *inner surface* forms part of the anterior wall of the pelvis. Its *inner border* is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the pubis: to the outer is attached the deep layer of the superficial perineal fascia (fascia of Colles), and to the inner the superficial layer of the triangular ligament of the perinæum. If these two ridges be traced downwards, they will be found to join with each other just behind the point of origin of the Transversus perinæi; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, the Transversus perinæi is attached, and in front of this a portion of the crus penis vel clitoridis and the Erector penis vel clitoridis muscle. Its *outer border* is thin and sharp, and forms part of the inner margin of the obturator foramen.

The **Pubis** (os pubis), the anterior part of the os innominatum, is divisible into a body, an ascending, and a descending ramus.

The **body** (corpus oss. pubis) is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The *anterior surface* is rough, directed downwards and outwards, and serves for the origin of various muscles. The Adductor longus arises from the upper and inner angle,

immediately below the crest; lower down, from without inwards, the Obturator externus, the Adductor brevis, and the upper part of the Gracilis take origin. The *posterior surface*, convex from above downwards, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives origin to the Levator ani and Obturator internus, and attachment to the pubo-prostatic ligaments and to a few muscular fibres prolonged from the bladder. The *upper border* presents a prominent tubercle, which projects forwards, the *pubic spine* (tuberculum pubicum); the outer pillar of the external abdominal ring and Poupart's ligament are attached to it. Passing upwards and outwards from the pubic spine is a well-defined ridge, forming a part of the linea ilio-pectinea which marks the brim of the true pelvis: to it are attached a portion of the conjoined tendon of the Internal oblique and Transversalis, Gimbernat's ligament and the triangular fascia of the abdomen. Internal to the spine of the os pubis is the *crest*, which extends from this process to the inner extremity of the bone. It affords attachment to the conjoined tendon of the Internal oblique and Transversalis, and to the Rectus and Pyramidalis. The point of junction of the crest with the inner border of the bone is called the *angle*; to it, as well as to the symphysis, the internal pillar of the external abdominal ring is attached. The *internal border* is articular; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, placed between it and the central fibro-cartilage. The *outer border* presents a sharp margin, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **ascending** or **superior ramus** (ramus superior oss. pubis) extends from the body to the point of junction of the pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination superior, inferior, and posterior surfaces, and an outer extremity. The *superior surface* presents a continuation of the ilio-pectineal line, already mentioned as commencing at the pubic spine. In front of this line, the surface of bone is triangular in form, wider externally than internally, smooth, and is covered by the Pectineus. The surface is bounded externally by a rough eminence, *eminentia ilio-pectinea*, which serves to indicate the point of junction of the ilium and pubis, and below by a prominent ridge, the *obturator crest* (crista obturatoria), which extends from the cotyloid notch to the spine of the pubis. The *inferior surface* forms the upper boundary of the obturator foramen, and presents, externally, a broad and deep, oblique groove, for the passage of the obturator vessels and nerve; and internally, a sharp margin which forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane. The *posterior surface* constitutes part of the anterior boundary of the true pelvis. It is smooth, convex from above downwards, and affords origin to some fibres of the Obturator internus. The *outer extremity*, the thickest part of the ramus, forms one-fifth of the acetabulum.

The **descending** or **inferior ramus** (ramus inferior oss. pubis) is thin and flattened. It passes outwards and downwards, becoming narrower as it descends and joins with the ramus of the ischium. Its *anterior surface* is rough, for the origin of muscles—the Gracilis along its inner border; a portion of the Obturator externus where it enters into the formation of the Obturator foramen; and between these two, the Adductores brevis et magnus from within outwards. The *posterior surface* is smooth, and gives origin to the Obturator internus, and, close to the inner margin, to the Compressor urethræ. The *inner border* is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downwards, and are continuous with similar ridges on the ramus of the ischium; to the external is attached the fascia of Colles, and to the internal the superficial layer of the triangular ligament of the urethra. The *outer border* is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

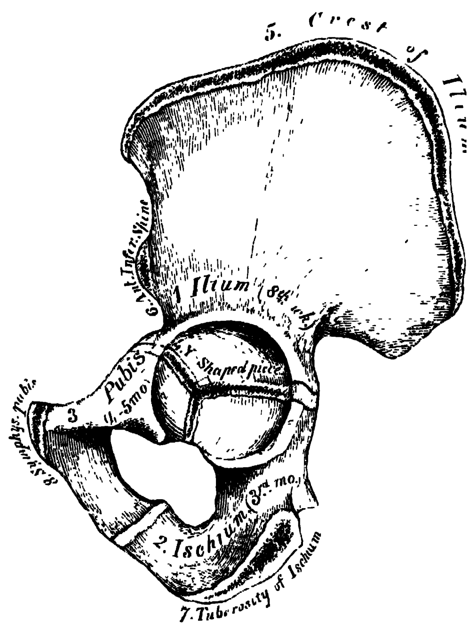
The *acetabulum*, or *cotyloid cavity*, is a deep, cup-shaped, hemispherical depression, directed downwards, outwards, and forwards. It is formed internally by the pubis, above by the ilium, behind and below by the ischium; a little less than two-fifths being contributed by the ilium, a little more than two

fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent, uneven rim, which is thick and strong above, and serves for the attachment of the *cotyloid ligament*, which contracts its orifice, and deepens the surface for articulation. It presents below a deep notch, the *cotyloid notch* (incisura acetabuli), which is continuous with a circular depression, the *fossa acetabuli*, at the bottom of the cavity: this depression is perforated by numerous apertures, and lodges a mass of fat. The notch is converted into a foramen by the transverse ligament; through the foramen nutrient vessels and nerves enter the joint; the margins of the notch serve for the attachment of the ligamentum teres.

The *obturator* or *thyroid foramen* (foramen obturatum) is a large aperture, situated between the ischium and pubis. In the male it is large and of an oval form, its longest diameter being obliquely from before backwards; in the female it is smaller, and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached; and presents, superiorly, a deep

Fig. 380.—Plan of ossification of the os innominatum.

By eight centres { *Three primary* (*Ilium, Ischium, and Os Pubis*) *Five secondary*



The three primary centres unite through Y-shaped piece about puberty. Epiphyses appear about puberty, and unite about 25th year.

groove (sulcus obturatorius), which runs from the pelvis obliquely inwards and downwards. This groove is converted into a foramen by a ligamentous band, a specialised part of the obturator membrane, attached to two tubercles, one (tuberculum obturatorium posterius) on the internal border of the ischium, just in front of the cotyloid notch, the other (tuberculum obturatorius anterius) on the inferior margin of the posterior surface of the ascending ramus of the pubis. Through the foramen the obturator vessels and nerve pass out of the pelvis.

Structure.—The thickest parts of the bone consist of cancellous tissue, enclosed between two layers of compact tissue. The thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, are usually semi-transparent, and composed entirely of compact tissue.

Ossification (fig. 380).—The os innominatum is ossified from *eight* centres: *three* primary—one each for the ilium, ischium, and pubis; and *five* secondary—one for the crest of the ilium, one for the anterior inferior spine (said to occur more

frequently in the male than in the female), one for the tuberosity of the ischium, one for the symphysis pubis (more frequent in the female than in the male), and one or more for the Y-shaped piece at the bottom of the acetabulum. The centres appear in the following order: in the lower part of the ilium, immediately above the sciatic notch, about the eighth or ninth week of fœtal life; in the body of the ischium, about the third month; in the body of the pubis, between the fourth and fifth months. At birth, the three primary centres are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, and the rami of the ischium and pubis being still cartilaginous. By the seventh or eighth year, the rami of the pubis and ischium are almost completely united by bone. About the thirteenth or fourteenth year, the three primary centres have extended their growth into the bottom of the acetabulum, and are there separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the *os acetabuli*, appears about the age of twelve, between the ilium and pubis, and fuses with them about the age of eighteen: it forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the pubis and ischium, through the intervention of this Y-shaped portion. At about the age of puberty, ossification takes place in each of the remaining portions, and they join with the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic and ischial spines, and for the crest and angle of the pubis.

Articulations.—The os innominatum articulates with its fellow of the opposite side, and with the sacrum and femur.

The Pelvis

The **Pelvis**, so called from its resemblance to a basin, is stronger and more massively constructed than the walls of the cranial or thoracic cavities; it is a bony ring, interposed between the movable vertebræ of the spinal column which it supports, and the lower limbs upon which it rests. It is composed of four bones: the two ossa innominata laterally and in front; and the sacrum and coccyx behind.

The pelvis is divided by an oblique plane passing through the prominence of the sacrum, the linea ilio-pectinea, and the upper margin of the symphysis pubis, into the false and true pelvis. The circumference of this plane is termed the *pelvic brim*.

The **false pelvis** (pelvis major) is the expanded portion of the cavity situated above and in front of the pelvic brim. It is bounded on each side by the ilium; in front it is incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch. Its walls support the intestines, and transmit part of their weight to the anterior wall of the abdomen; the term false pelvis is therefore incorrect, and the space ought more properly to be regarded as part of the hypogastric and iliac regions of the abdomen.

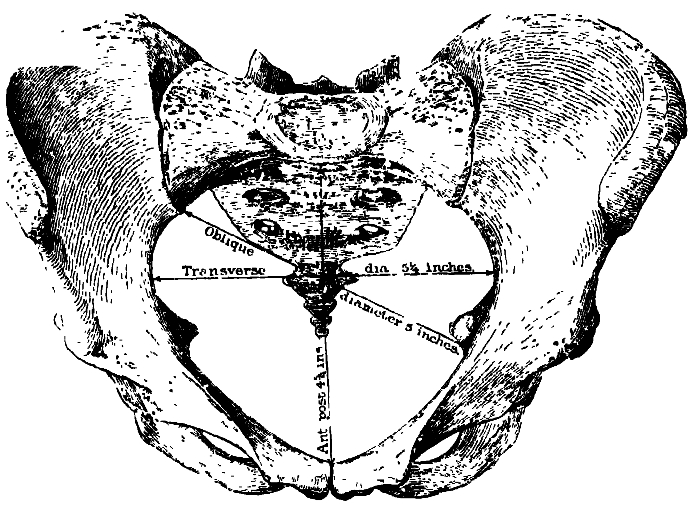
The **true pelvis** (pelvis minor) is that part of the pelvic cavity which is situated below and behind the pelvic brim. It is smaller than the false pelvis, but its bony walls are more perfect. For convenience of description, it is divided into an inlet bounded by the superior circumference, an outlet bounded by the inferior circumference and a cavity.

The *superior circumference* forms the brim of the pelvis, the included space being called the *inlet* (apertura pelvis superior) (fig. 381). It is formed laterally by the ilio-pectineal lines, in front by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacro-vertebral angle. The inlet of the pelvis is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forwards of the promontory of the sacrum. It has three principal diameters: antero-posterior, transverse, and oblique. The *antero-posterior* or *conjugate diameter* extends from the sacro-vertebral angle to the symphysis pubis; its average measurement is four inches in the male, four and three-quarters in the female. The *transverse diameter* extends across the greatest width of the inlet, from the middle of the brim on one side to the same point on the opposite; its average measurement is four and a half inches in the male, five and a

quarter in the female. The *oblique diameter* extends from the ilio-pectineal eminence of one side to the sacro-iliac articulation of the opposite side; its average measurement is four and a quarter inches in the male, and five in the female.

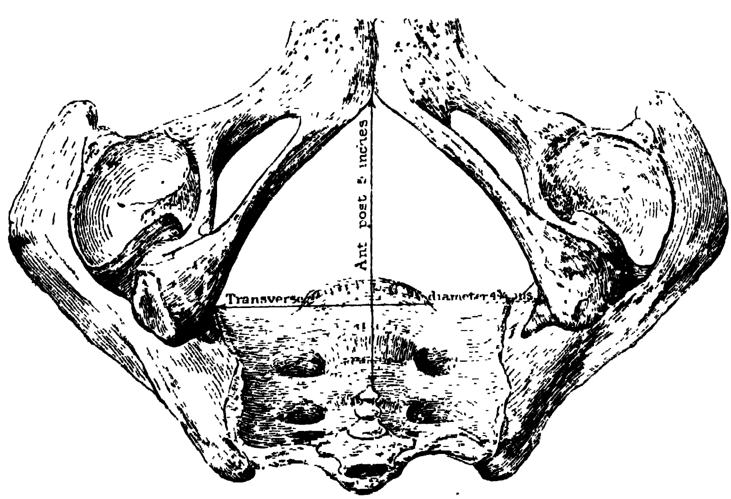
The *cavity* of the true pelvis is bounded in front and below by the symphysis pubis and the bodies of the pubic bones; above and behind, by the

FIG. 381.—Diameters of the pelvic inlet (female).



anterior concave surfaces of the sacrum and coccyx, which, curving forwards above and below, contract the inlet and outlet of the canal; laterally, by a broad, smooth, quadrangular area of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-pectineal line. The cavity measures an inch and a half in depth in front,

FIG. 382.—Diameters of the pelvic outlet (female).



three inches and a half in the middle, and four inches and a half posteriorly. From this description, it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall. It contains, in the recent subject, the pelvic colon, rectum, bladder, and part of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacrum and coccyx; the bladder is in front,

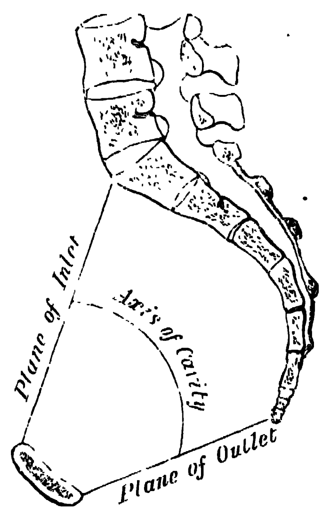
behind the symphysis pubis. In the female, the uterus and vagina occupy the interval between these viscera.

The *lower circumference* of the pelvis is very irregular; the space enclosed by it is named the *outlet* (apertura pelvis inferior) (fig. 382) and is bounded behind by the point of the coccyx; and laterally by the tuberosities of the ischia. These eminences are separated by three notches: one in front, the *pubic arch* (arcus pubis), formed by the convergence of the rami of the ischium and pubis on either side. The other notches, one on either side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above: they are called the *sacro-sciatic notches*; in the natural state they are converted into foramina by the great and small sacro-sciatic ligaments. When the ligaments are *in situ*, the outlet of the pelvis is lozenge-shaped, bounded, in front, by the subpubic ligament and the rami of the pubes and ischia; laterally by the tuberosities of the ischia; and behind, by the great sacro-sciatic ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The *antero-posterior diameter* extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three and three-quarter inches in the male, and five inches in the female. It varies with the length of the coccyx, and is capable of increase or diminution, on account of the mobility of that bone. The *transverse diameter*, measured between the posterior parts of the ischial tuberosities, is three and a half inches in the male, and four and three-quarters in the female.*

Axes (fig. 383).—A line at right angles to the plane of the inlet at its centre would, if prolonged, pass through the umbilicus above and the middle of the coccyx below: the axis of the inlet is therefore directed downwards and backwards. The axis of the outlet, produced upwards, would touch the base of the sacrum, and is also directed downwards and slightly backwards. The axis of the cavity—i.e. an axis at right angles to a series of planes between those of the inlet and outlet—is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes serves to explain the course of the fœtus in its passage through the pelvis during parturition.

Fig. 383.—Mesial sagittal section of pelvis.



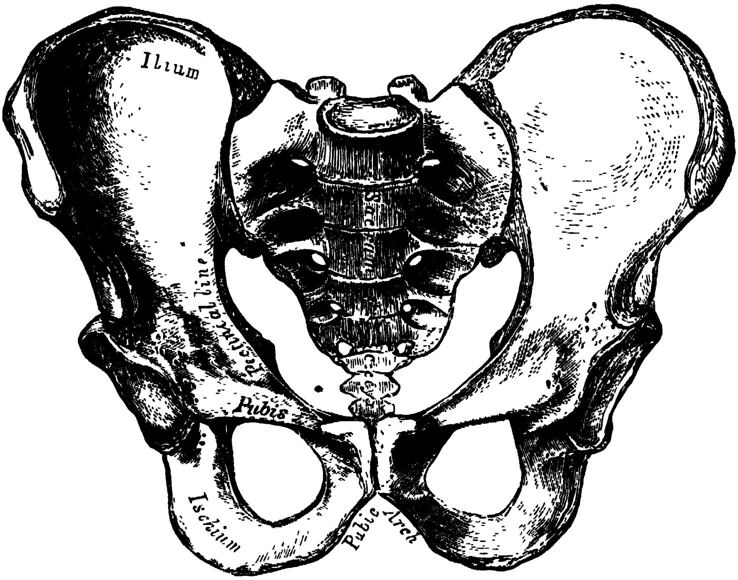
Position of the pelvis (fig. 383).—In the erect posture, the pelvis is placed obliquely with regard to the trunk: the plane of the pelvic inlet forms an angle of from 50° to 60°, and that of the outlet one of about 15° with the horizontal plane. The pelvic surface of the symphysis pubis looks upwards and backwards, the concavity of the sacrum and coccyx downwards and forwards; the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. In consequence of this obliquity of the pelvis, the line of gravity of the head, which passes through the middle of the odontoid process of the axis and the points of junction of the curves of the vertebral column to the sacro-vertebral angle, descends towards the front of the cavity, so that it bisects a line drawn transversely through the centres of the heads of the thigh-bones (see page 199).

Differences between the male and female pelves.—The *female* pelvis (fig. 385) is distinguished from that of the *male* (fig. 384) by its bones being more delicate and its depth less. The whole pelvis is less massive, and its

* The measurements of the pelvis given above are fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken.

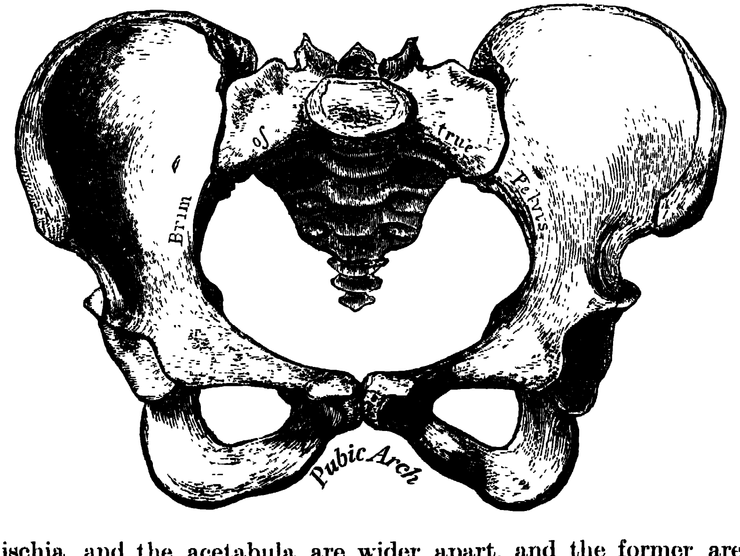
muscular impressions are slightly marked. The ilia are less sloped, and the anterior iliac spines more widely separated; hence the greater prominence of the hips. The *inlet* in the female is larger than in the male; it is more nearly circular, and its obliquity is greater. The *cavity* is shallower and wider; the

FIG. 384.—Male pelvis.



sacrum is shorter, wider, and its upper part is less curved; the obturator foramina are triangular in shape and smaller in size than in the male. The *outlet* is larger and the coccyx more movable. The sacro-sciatic notches are shallower, and the spines of the ischia project less inwards. The tuberosities

FIG. 385.—Female pelvis.



of the ischia, and the acetabula are wider apart, and the former are more everted. The pubic symphysis is less deep, and the pubic arch is wider and more rounded than in the male, where it is an angle rather than an arch. In consequence of this the width of the fore part of the pelvic outlet is greater, a condition which facilitates the passage of the fœtal head during parturition.

The size of the pelvis varies not only in the two sexes, but also in different members of the same sex, and does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelves. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in well-formed women of average height. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior to the transverse diameter. Thus the inlet of the pelvis may be elliptical either in a transverse or an antero-posterior direction; the transverse diameter in the former, and the antero-posterior in the latter, greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular.

The same differences are found in various races. European women are said to have the most roomy pelves. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelves.

In the *fœtus*, and for several years after birth, the pelvis is small in proportion to that of the adult, and the projection of the sacro-vertebral angle less marked. The generally accepted opinion that the pelvis does not acquire its sexual characteristics until after puberty has been shown to be erroneous,* the characteristic differences between the male and female pelvis being distinctly indicated as early as the fourth month of fœtal life.

Surface Form.—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spine of the ilium is easily recognised; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the fold of the groin. In fat subjects its position is marked by an oblique depression, at the bottom of which the bony process may be felt. Proceeding upwards and outwards from this process, the sinuously curved crest of the ilium may be traced throughout its whole length. Its highest point is on a level with the spinous process of the fourth lumbar vertebra: upon its outer lip, about two inches behind the anterior superior spine, is a prominent tubercle. The position of the crest is indicated, in muscular subjects, by a groove or furrow, the *iliac furrow*, below the projection of the fleshy fibres of the External oblique muscle of the abdomen; the iliac furrow lies slightly below the level of the crest. It terminates behind in the posterior superior spine, the position of which is indicated by a slight depression on a level with the spinous process of the second sacral vertebra. Between the two posterior superior spines, but at a lower level, is to be felt the spinous process of the third sacral vertebra. Another part of the bony pelvis which is accessible to touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, easily felt, as it is then uncovered by muscle. Finally, the spine of the pubis can be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is in nearly the same horizontal plane as the upper edge of the great trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following up the tendon of origin of the Adductor longus muscle. A line drawn from the anterior superior spine of the ilium to the most prominent part of the tuberosity of the ischium passes across the hip at a level with the upper border of the great trochanter. It is known as *Nélaton's line*, and is of service in detecting any displacement of the trochanter in fractures ~~or dislocations~~ in this situation. If a line be drawn from the posterior superior spine of the ilium to the outer part of the tuberosity of the ischium, it will cross the spine of the ischium about four inches below the posterior superior iliac spine. The great sciatic foramen will lie above, and the lesser foramen below this point.

Applied Anatomy.—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. 'The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forwards, and the obturator foramen diminished in size, narrowed, and turned outwards. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the ilio-sacral facets turned more outward than normal, while the vertical curve is straightened.' †

† Wood. Heath's *Dictionary of Practical Surgery*, i. 426.

Fractures of the pelvis are divided into those of the false and those of the true pelvis. Fractures of the false pelvis vary in extent; a small portion of the crest may be broken, or one of the spinous processes may be torn off, or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the true pelvis. A fracture of the true pelvis generally occurs through the ascending ramus of the pubis and the ramus of the ischium, as these are the weakest parts of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together and the bone gives way in the same place from indirect violence. Sometimes the fracture may be double, occurring on both sides of the body. It is in these cases that the contained viscera are likely to be injured: the urethra, the bladder, the rectum, the vagina in the female, the small intestines, and even the uterus, have all been lacerated by displaced fragments. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur be driven inwards and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, splitting the bone into its three portions.

The coccyx is not infrequently fractured or displaced forwards to nearly a right angle with the sacrum by kicks or by falls backwards. The fracture is attended with great pain in walking and on making any expiratory effort, such as coughing, defæcation, &c., because the Coccygeus, which is attached to this bone, forms part of the pelvic diaphragm. Falls or blows on the coccyx, unaccompanied by fracture, sometimes give rise to severe pain, which is exceedingly intractable and difficult of cure. The condition is known as *coccygodynia*, and for its relief removal of the coccyx has been practised.

The pelvic bones often undergo important deformity in *rickets*, the effects of which in the adult woman may interfere seriously with child-bearing. The deformity is due mainly to the weight of the spine and trunk, which presses on the sacro-vertebral angle and greatly increases it, so that the antero-posterior diameter of the pelvis is diminished, and may measure as little as 1½ inches, the entrance into the pelvis becoming reniform. In other cases all the pelvic bones give way, so that a general diminution in all the diameters of the pelvis results, the pelvic entrance becoming triangular or asymmetrical. If the pubic symphysis be forced forwards, the rickety pelvis may even come to resemble closely the deformed pelvis of *osteomalacia*; in this disease the weight of the trunk causes an increase in the sacro-vertebral angle, and a lessening of the antero-posterior diameter of the inlet, and at the same time the pressure of the heads of the thigh-bones on the acetabula causes these cavities, with the adjacent bone, to be pushed upwards and backwards, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a tri-radiate shape, with the symphysis pubis pushed forwards.

The Femur

The **Femur** (figs. 387 and 388), the longest, largest, and strongest bone in the skeleton, is almost perfectly cylindrical in the greater part of its extent. In the erect posture it is not vertical, being separated above from its fellow by a considerable interval, which corresponds to the breadth of the pelvis, but inclining gradually downwards and inwards, so as to approach its fellow towards its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than in the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a shaft and two extremities.

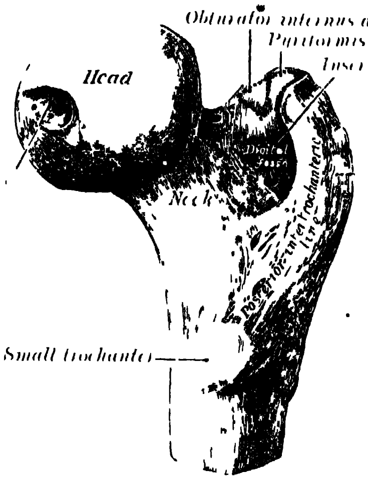
The **upper extremity** (fig. 386) presents for examination a head, a neck, a great and a small trochanter.

The **head** (caput femoris), which is globular, and forms rather more than a hemisphere, is directed upwards, inwards, and a little forwards, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the recent state, except over a depressed ovoid area (fovea capitis femoris), which is situated a little below and behind its centre, and gives attachment to the ligamentum teres.

The **neck** (collum femoris) is a flattened pyramidal process of bone, which connects the head with the shaft, and forms with the latter a wide angle. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the shaft. In the adult, the neck forms an angle of about 125° with the shaft, but this varies in inverse

proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh-bone forms more nearly a right angle with the shaft than it does in the male. It has been stated that the angle diminishes in old age and that the direction of the neck becomes horizontal, but this statement is founded on insufficient evidence. Humphry found that the angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age; it varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide.* The neck is flattened from before backwards, contracted in the middle, and broader externally than internally. The vertical diameter of the outer half is increased by the obliquity of the lower edge, which slopes downwards to join the shaft at the level of the small trochanter, so that it measures one-third more than the antero-posterior diameter. The inner half is smaller, and of a more circular shape. The *anterior surface* of the neck is perforated by numerous vascular foramina. The *posterior surface* is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior intertrochanteric line.

FIG. 386. Upper extremity of right femur viewed from behind and above.



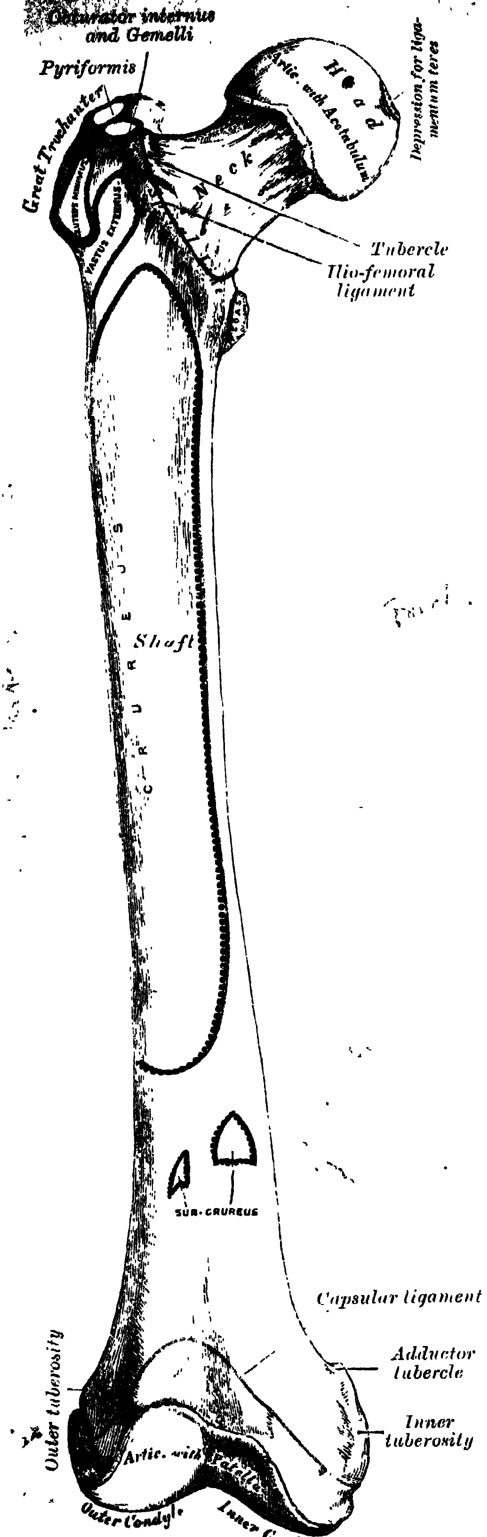
The *superior border* is short and thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The *inferior border*, long and narrow, curves a little backwards, to terminate at the small trochanter.

The **trochanters** are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, the great and the small.

The **great trochanter** (trochanter major) is a large, irregular, quadrilateral eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outwards and backwards, and, in the adult, is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The *external surface*, quadrilateral in form, is broad, rough, convex, and marked by a diagonal impression, which extends from the postero-superior to the antero-inferior angle, and serves for the insertion of the tendon of the Gluteus medius. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between the tendon and the bone. Below and behind the diagonal impression is a smooth, triangular surface, over which the tendon of the Gluteus maximus plays, a bursa being interposed. The *internal surface*, of much less extent

* *Journal of Anatomy and Physiology*, vol. xxiii.

Fig. 387.—Right femur. Anterior surface.



than the external, presents at its base a deep depression, the *digital fossa (fossa trochanterica)*, for the insertion of the tendon of the Obturator externus, and above and in front of this an impression for the insertion of the Obturator internus and Gemelli. The *superior border* is free; it is thick and irregular, and marked near the centre by an impression for the insertion of the Pyriformis. The *inferior border* corresponds to the line of junction of the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives origin to the upper part of the Vastus externus. The *anterior border* is prominent and somewhat irregular; it affords insertion at its outer part to the Gluteus minimus. The *posterior border* is very prominent, and appears as a free, rounded edge, which bounds the back part of the digital fossa.

The **small trochanter** (trochanter minor) is a conical eminence, which varies in size in different subjects; it projects from the lower and back part of the base of the neck. Its *base* is triangular, and connected with the adjacent parts of the bone by three well-marked borders: two of these are above—the *internal* continuous with the lower border of the neck, the *external* with the posterior intertrochanteric line—while the *inferior border* is continuous with the middle division of the linea aspera. Its *summit*, directed inwards and backwards, is rough, and gives insertion to the tendon of the Psoas.

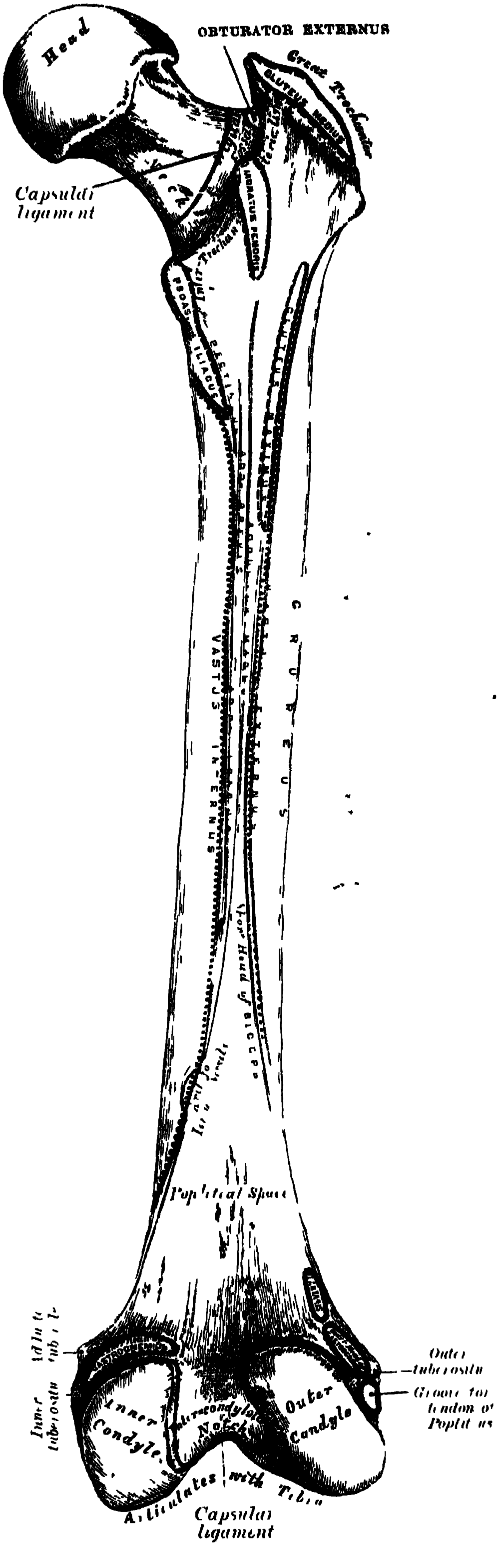
A well-marked prominence, of variable size, which projects at the junction of the upper part of the neck with the great trochanter, is called the *tubercle* of the femur; it is the point of meeting of five muscles: the Gluteus minimus externally, the Vastus externus below, and the tendon of the Obturator internus and two Gemelli above. Running obliquely downwards and inwards from the tubercle is the *spiral line* of the femur, or *anterior intertrochanteric line* (linea intertrochanterica); it winds round the inner side of the shaft, below the lesser trochanter, and terminates about two inches below this eminence in the linea aspera. Its upper half is rough, and affords attachment

to the ilio-femoral ligament of the hip-joint; its lower half is less prominent, and gives origin to the upper part of the Vastus internus. Running obliquely downwards and inwards from the summit of the great trochanter on the posterior surface of the neck is a very prominent ridge, the *posterior intertrochanteric line* (crista intertrochanterica). Its upper half forms the posterior border of the great trochanter, and its lower half runs downwards and inwards to the upper and back part of the lesser trochanter. A slight ridge is sometimes seen commencing about the middle of the posterior intertrochanteric line, and passing vertically downwards for about two inches along the back part of the shaft: it is called the *linea quadrata*, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus. Generally there is merely a slight thickening about the middle of the intertrochanteric line, marking the attachment of the upper part of the Quadratus femoris. This is termed by some anatomists the *tubercle of the Quadratus*.

The **shaft** (corpus femoris) is almost cylindrical in form, but is a little broader above than in the centre, broadest and somewhat flattened from before backwards below. It is slightly arched, so as to be convex in front, and concave behind, where it is strengthened by a prominent longitudinal ridge, the *linea aspera*. It presents for examination three borders, separating three surfaces. Of the three borders, one, the linea aspera, is posterior; the other two are placed laterally.

The *linea aspera* (fig. 388) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an inner and an outer lip, and a narrow, rough, intermediate space. Above, the linea aspera is prolonged by three ridges. The external ridge is very rough, and runs almost vertically upwards to the base of the great trochanter. It is termed

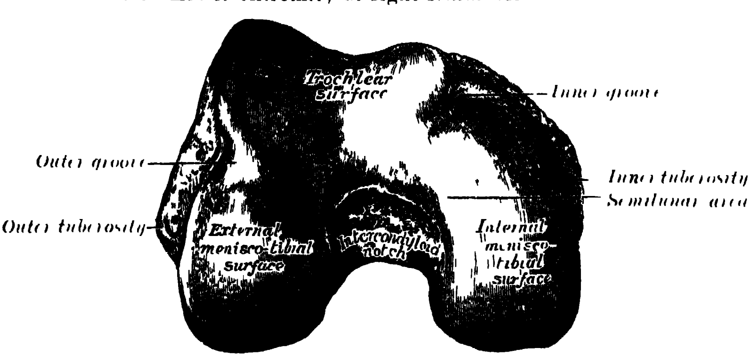
Fig. 388.—Right femur. Posterior surface.



the *gluteal ridge* (tuberositas glutaea), and gives attachment to part of the Gluteus maximus; its upper part is often elongated into a roughened crest, on which a more or less well-marked, rounded tubercle, the *trochanter tertius*, is occasionally developed. The middle ridge (linea pectinea) is continued to the base of the small trochanter and gives attachment to the Pectineus; the internal ridge is lost above in the spiral line of the femur; between these two a portion of the Iliacus is inserted. Below, the linea aspera is prolonged by two ridges, enclosing between them a triangular area, the *popliteal surface* (planum popliteum), upon which the popliteal artery rests. Of these two ridges, the outer is the more prominent, and descends to the summit of the external condyle. The inner is less marked, especially at its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the *adductor tubercle*, which affords insertion to the tendon of the Adductor magnus.

From the inner lip (labium mediale) of the linea aspera and its inner prolongations above and below, the Vastus internus arises; and from the outer lip (labium laterale) and its outer prolongation above, the Vastus externus takes origin. The Adductor magnus is inserted into the linea aspera, to its outer prolongation above, and its inner prolongation below. Between the Vastus externus and the Adductor magnus two muscles are attached—viz. the Gluteus maximus inserted above and the short head of the Biceps arising below. Between the Adductor magnus and the Vastus internus four muscles

FIG. 389.—Lower extremity of right femur viewed from below.



are inserted: the Iliacus and Pectineus above; the Adductor brevis and Adductor longus below. The linea aspera is perforated a little below its centre by the nutrient canal, which is directed obliquely upwards.

The two *lateral borders* of the femur are only slightly marked: the outer extends from the antero inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner from the spiral line, at a point opposite the small trochanter, to the anterior extremity of the internal condyle. The inner border marks the internal limit of attachment of the Crureus.

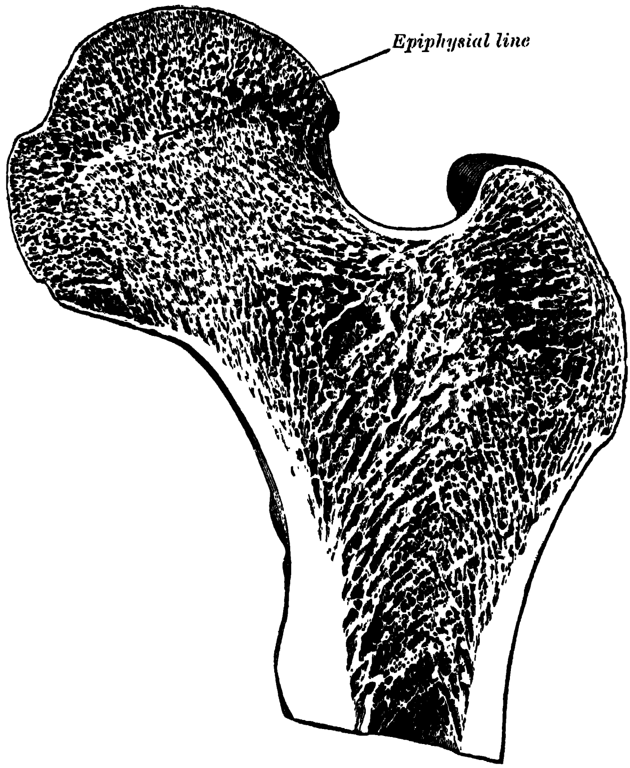
The *anterior surface* includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, and slightly twisted, so that its upper part is directed forwards and a little outwards, its lower part forwards and a little inwards. From the upper three-fourths of this surface the Crureus arises; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and gives origin to the Subcrureus. The *external surface* includes the portion between the external border and the outer lip of the linea aspera; it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle: from its upper three-fourths the outer portion of the Crureus takes origin. The *internal surface* includes the portion between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle: it is covered by the Vastus internus.

The **lower extremity** (fig. 389), larger than the upper, is somewhat cuboid in form, but its transverse diameter is greater than its antero-posterior: it consists of two lateral oblong eminences known as the *condyles*. In front, the condyles are but slightly prominent, and are separated from one another by a smooth shallow articular depression called the *trochlea*; behind, they project considerably, and the interval between them forms a deep notch, the *intercondyloid notch* (fossa intercondyloidea). The *external condyle* (condylus lateralis) is the more prominent and the broader both in its antero-posterior and transverse diameters; the *internal condyle* (condylus medialis) is the longer and, when the femur is held with its shaft perpendicular, projects to a lower level. When, however, the femur is in its natural oblique position the lower surfaces of the two condyles lie practically in the same horizontal plane. The condyles are not quite parallel with one another; the long axis of the external is almost directly antero-posterior, but that of the internal runs backwards and inwards. Their opposed surfaces, viz. the inner surface of the external and the outer of the internal, are small, rough, and concave, and form the lateral walls of the intercondyloid notch. This notch is limited above by a ridge, the *linea intercondyloidea*, and below by the central part of the posterior margin of the trochlear surface. The posterior crucial ligament of the knee-joint is attached to the lower and front part of the inner wall of the notch and the anterior crucial ligament to an impression on the upper and back part of its outer wall. The outer surface of the external condyle and the inner of the internal are each surmounted by a tuberosity. That on the internal condyle—the *inner tuberosity* (epicondylus medialis)—is a large convex eminence to which the internal lateral ligament of the knee-joint is attached. At its upper part is the adductor tubercle, already referred to, and behind it is a rough impression which gives origin to the inner head of the Gastrocnemius. That on the external condyle, the *outer tuberosity* (epicondylus lateralis), smaller and less prominent than the internal, gives attachment to the external lateral ligament of the knee-joint. Directly below it is a small depression from which a smooth well-marked groove curves obliquely upwards and backwards to the posterior extremity of the condyle. This groove is separated from the articular surface of the condyle by a prominent lip across which a second, shallower groove runs vertically downwards from the depression. In the recent state these grooves are covered with cartilage. The Popliteus arises from the depression; its tendon is lodged in the oblique groove when the knee is flexed and in the vertical groove when the knee is extended. Above and behind the outer tuberosity is an area for the origin of the outer head of the Gastrocnemius, above and to the inner side of which the Plantaris arises.

The *articular surface* of the lower end of the femur occupies the anterior, inferior, and posterior surfaces of the condyles. Its front part is named the *trochlea* (facies patellaris) and articulates with the patella; it presents a median groove which extends downwards to the intercondyloid notch and two lateral convexities, the external of which is broader, more prominent, and extends farther upwards than the internal. The lower and posterior parts of the articular surface constitute the *tibial surfaces* for articulation with the corresponding tuberosities of the tibia and semilunar cartilages. These surfaces are separated from one another by the intercondyloid notch and from the trochlea by faint grooves which extend obliquely across the condyles. The outer of these grooves is the better marked; it runs outwards and forwards from the front part of the intercondyloid notch, and expands externally to form a triangular depression. When the knee-joint is fully extended, the outer triangular part of this groove rests upon the anterior portion of the external semilunar cartilage, and its inner part comes into contact with the inner margin of the outer articular surface of the tibia in front of the external tubercle of the tibial spine. The inner groove is less distinct than the outer. It does not reach as far as the intercondyloid notch and therefore exists only on the inner part of the condyle; it receives the anterior edge of the internal semilunar cartilage when the knee-joint is extended. Where the groove ceases externally the trochlear surface is seen to be continued backwards as a semilunar area close to the anterior part of the intercondyloid notch; this semilunar area articulates with the internal vertical facet of the patella in forced flexion of the knee-joint. The tibial surfaces of the condyles are convex from

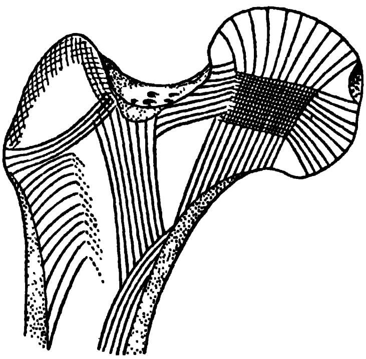
side to side and from before backwards. Each presents a double curve, its posterior segment being an arc of a circle, its anterior, part of a cycloid.*

FIG. 390.—Longitudinal section of head and neck of femur.



Structure.—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The wall of the cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal best formed; but above and below this the wall becomes thinner, while the medullary canal is gradually filled up by cancellous tissue, so that the upper and lower ends of the shaft (fig. 390), and the articular extremities more especially, consist of cancellous tissue, invested by a thin compact layer.

FIG. 391.—Scheme showing disposition of principal cancellous lamellæ in upper extremity of femur.

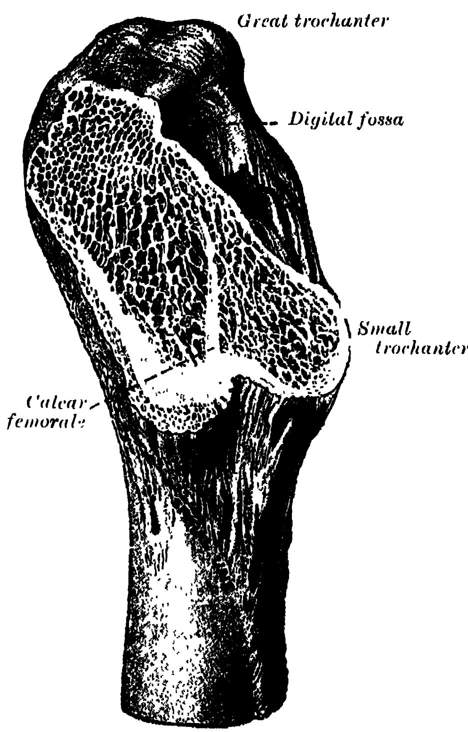


The cancelli in the ends of the femur are disposed along the lines of greatest pressure and tension. In the upper end (fig. 391) the chief lamellæ are arranged in the following manner. A series of bony planes at right angles to the articular surface of the head converge to a central dense wedge, which presents few and dense cancelli. The wedge is supported by strong lamellæ, which extend to the sides of the neck and are specially marked along its upper and lower borders. Any force therefore applied to the head of the femur is transmitted directly to the central wedge and thence to the junction of the neck

* A *cycloid* is a curve traced by a point in the circumference of a wheel when the wheel is rolled along in a straight line.

with the shaft. This junction is specially strengthened by a series of dense lamellæ which extend from the lesser trochanter to the outer end of the superior border of the neck; this arrangement will obviously oppose considerable resistance to either tensile or shearing force. A smaller bar stretching across the junction of the great trochanter with the neck and shaft resists the shearing force of the muscles attached to this prominence. These two bars, one at the junction of shaft and neck, the other at the junction of shaft and great trochanter, form the upper layers of a series of arches which extend across between the sides of the shaft and transmit to the shaft forces applied to the upper end of the bone. In the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the *femoral spur* (*calcar femorale*) which commences at the point where the neck joins the shaft midway between the small trochanter and the internal border of the shaft of the bone, and extends in the direction of the digital fossa (fig. 392). This materially strengthens this portion of the bone. Another point in connection with the structure of the neck of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck, and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the 'true neck,'* and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge towards the outer surface of the bone.

Fig. 392.—Calcar femorale.



In the lower end, the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, however, horizontal planes of cancellous tissue are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of cubical compartments.

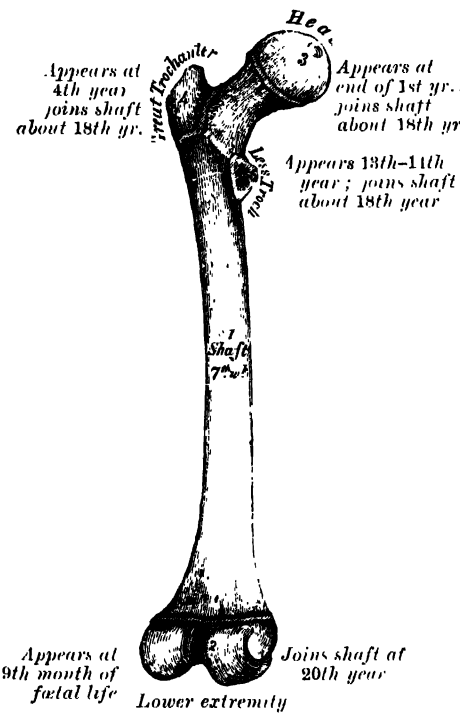
Articulations. — The femur articulates with three bones: the os innominatum, tibia, and patella.

Ossification (fig. 393). — The femur is ossified from *five* centres: one for the shaft, one for the head, one for each trochanter, and one for the lower extremity. Of all the long bones, except the clavicle, it is the first to show traces of ossification; this commences in the middle of the shaft, at about the seventh week of fœtal life, and rapidly extends upwards and downwards. The centres in the epiphyses appear in the following order: in the lower end of the bone, at the ninth month of fœtal life (from this centre the condyles and tuberosities are formed); in the head, at the end of the first year after birth; in the great trochanter, during the fourth year; and in the small trochanter, between the thirteenth and fourteenth years. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: they are not united until after puberty, the small trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity, which is not united until the twentieth year.

* *Bigelow on the Hip*, Philadelphia, 1869.

Surface Form.—The femur is covered with muscles, so that in fairly muscular subjects the shaft cannot be detected, and the only parts accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. The situation of the great trochanter is generally indicated by a depression, owing to the thickness of the Gluteus medius and minimus, which project above it. When, however, the thigh is flexed, and especially if it be crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a level with the centre of the hip-joint, and is indicated by a line drawn from the anterior superior spine of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischium. This is known as Nélaton's line. The outer and inner condyles of the lower extremity are accessible to the touch. The outer one is more subcutaneous than the inner one, and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognised. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp *adductor tubercle* for the insertion of the tendon of the Adductor magnus can be recognised without difficulty. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trochlear surface of the femur can be made out above the patella.

FIG. 393.—Plan of ossification of the femur. From five centres.



Applied Anatomy.—There are one or two points about the ossification of the femur bearing on practice to which allusion must be made. The lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of this ossific centre is, therefore, a proof, in a newly born child found dead, that the child has arrived at the full period of utero-gestation, and is always relied upon in medico-legal investigations. The position of the epiphysial line should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysial cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render the limb almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is of interest principally on account of its being the seat of origin, in a large number of cases, of tuberculous disease of the hip-joint. In the majority of cases the disease begins in the highly vascular and growing tissue at the end of the shaft in the neighbourhood of the epiphysial cartilage, and extends into the joint. It should be noted that the epiphysis for the head is entirely intracapsular.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the shaft; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or of the great trochanter. The first of these, fracture of the neck, is usually termed *intracapsular* fracture, but this is scarcely a correct designation, as, owing to the attachment of the capsular ligament, the fracture is partly within and partly without the capsule when the fracture occurs at the lower part of the neck. It generally takes place in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of its occurrence in old people is the senile degenerative change which takes place in the bone. Merkel believes that it is mainly due to the absorption of the calcar femorale. As a rule the

fragments become united by fibrous tissue, but frequently no union takes place, and the opposed surfaces become smooth and eburnated.

Fractures at the junction of the neck with the great trochanter are usually termed *extra-capsular*, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a fall laterally on the hip. From the manner in which the accident is caused the neck of the bone is driven into the trochanter, where it may remain impacted, or the trochanter may be split into two or more fragments, disimpaction resulting.

Fractures of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence. Fractures of the upper third of the shaft are almost always the result of indirect violence, while those of the lower third are the result, for the most part, of direct violence. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur as well as the other bones of the leg is frequently the seat of acute osteomyelitis in children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Necrosis of portions of the diaphysis frequently ensues, especially in the region of the popliteal surface of the femur, and the disease may continue for years, great trouble being experienced with discharging sinuses which periodically close and reopen to allow of the exit of a piece of dead bone.

Tumours are not infrequently found growing from the femur: the most common forms being sarcoma which may grow either from the periosteum or from the medullary tissue within the interior of the bone, and exostosis which commonly originates in the neighbourhood of the epiphysial cartilage of the lower end. The periosteal sarcomata of the femur and most of the central growths are usually of a very high degree of malignancy; although the 'myeloid' growth, which nowadays cannot be classed as a malignant tumour, may also be found. The region of the lower epiphysial line is by far the commoner seat for all these tumours, and it should be noted that the lower epiphysis has the longest period of active growth, and that these tumours usually begin to grow towards the end of the period of active growth.

Sarcomata about the upper end of the femur are seen occasionally, but very rarely in comparison with those at the lower end. Secondary carcinoma also occurs in this bone, most commonly due to a primary focus in the breast, and spontaneous fracture of the bone may take place in these cases.

THE PATELLA

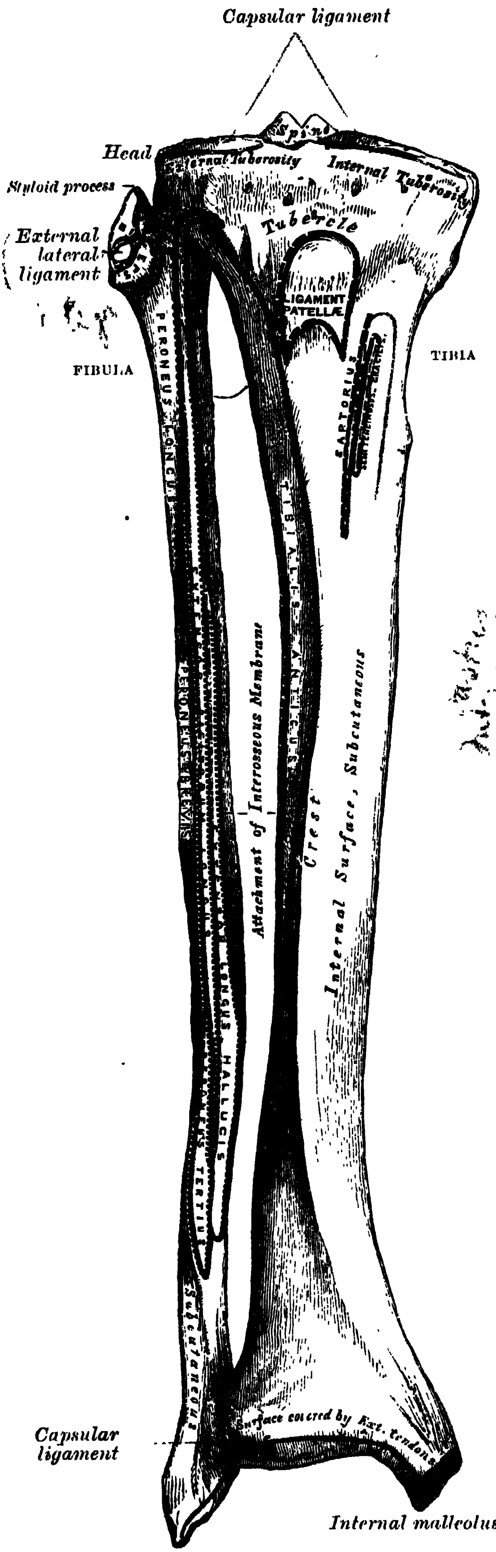
The Patella (figs. 394 and 395) is a flat, triangular bone, situated at the anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor, and resembles these bones (1) in being developed in a tendon; (2) in its centre of ossification presenting a knotty or tubercular outline; (3) in being composed mainly of dense cancellous tissue. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an anterior and a posterior surface, three borders, and an apex.

FIG. 394.—Right patella. Anterior surface.

FIG. 395.—Right patella. Posterior surface.

The *anterior surface* is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patellæ. It is separated from the integument by a bursa. The *posterior surface* (facies articularis)

Fig. 396.—Bones of the right leg. Anterior surface.



presents above a smooth, oval, articular area, covered with cartilage in the recent state, and divided into two facets by a vertical ridge, which descends from the superior border towards the inferior angle of the bone. The ridge corresponds to the groove on the trochlea of the femur, and the two facets to the inner and outer parts of the same surface; the outer facet is the broader and deeper. Below the articular surface is a rough, convex, non-articular depression, the lower half of which gives attachment to the ligamentum patellæ; the upper half is separated from the ~~head of~~ the tibia by adipose tissue.

The *superior border* (basis patellæ) is thick, and sloped from behind, downwards, and forwards: it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus and Crureus. The *lateral borders* are thinner, converging below: they give attachment to those portions of the Quadriceps extensor which are derived from the external and internal Vasti.

The *apex* (apex patellæ) is pointed, and gives attachment to the ligamentum patellæ.

Structure.—The patella consists of a nearly uniform dense cancellous tissue, covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface towards the other parts of the bone.

Ossification.—The patella is ossified from a single centre, which usually makes its appearance in the second or third year, but may be delayed until the sixth year. More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulations.—The patella articulates with the femur.

Surface Form.—The external surface of the patella can be felt in front of the knee. In the extended position of the limb the inner border of the bone is a little more prominent than the outer, and if the Quadriceps extensor be relaxed, the

bone can be moved from side to side and appears to be loosely fixed. When the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly applied to the femur.

Applied Anatomy.—The main surgical interest about the patella is in connection with fractures, which are of frequent occurrence. They are most frequently produced by muscular action—that is to say, by violent contraction of the Quadriceps extensor, while the limb is in a position of semiflexion, so that the bone is snapped across the condyles, and the fracture is transverse. Fracture of the patella is also produced by direct violence, such as falls on the knee, and here the fracture is usually stellate and the bone comminuted. The principal interest in these cases attaches to their treatment. Owing to the displacement of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Truly satisfactory results after this fracture are generally only to be obtained by opening the joint and wiring the fragments together, and this is especially so when there is marked separation of the fragments owing to laceration of the lateral aponeurosis.

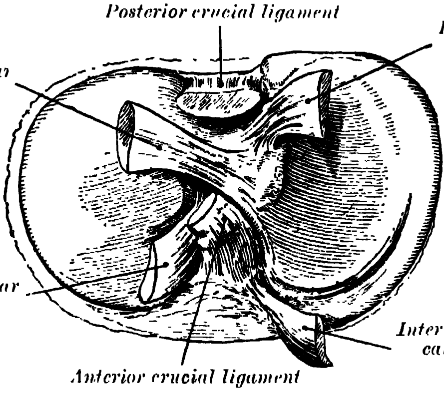
It is an anatomical possibility, if the fracture involve only the lower and non-articular part of the bone, for this to take place without injury to the synovial membrane and without involving the cavity of the knee-joint.

THE TIBIA

The **Tibia** (figs. 396 and 398) is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone of the skeleton. It is prismoid in form, expanded above, where it enters into the knee-joint, more slightly enlarged below. In the male, its direction is vertical, and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downwards and outwards, to compensate for the greater obliquity of the femur inwards. It presents for examination a shaft and two extremities.

The **upper extremity, or head,** is large, and expanded into two lateral eminences, the *tuberosities*. The *superior surface* (facies articularis superior) presents two smooth articular facets, one on either side of the middle line (fig. 397). The inner of these is oval in shape, and slightly concave from side

FIG. 397.—Upper surface of right tibia, showing attachment of crucial ligaments and semilunar cartilages.



to side, and from before backwards. The outer, nearly circular, is concave from side to side, but slightly convex from before backwards, especially at its posterior part, where it is prolonged on to the posterior surface for a short distance. The central portions of these facets articulate with the condyles of the femur, while their peripheral portions support the semilunar cartilages of the knee, which here intervene between the two bones. In the middle line, but nearer the posterior than the anterior aspect of the bone, is an eminence, the *spine of the tibia* (eminentia intercondyloidea), surmounted on either side by a prominent tubercle, on to the lateral aspects of which the facets just described are prolonged; in front of and behind the spinous process are rough depressions for the attachment of the anterior and posterior crucial ligaments and the semilunar fibro-cartilages (fig. 397). The *anterior*

surfaces of the tuberosities are continuous with one another, forming a single large somewhat flattened area: this area is triangular, broad above, and perforated by large vascular foramina: narrow below where it terminates in a prominent oblong elevation of large size, the *tubercle* of the tibia (tuberositas tibiæ), which gives attachment to the ligamentum patellæ; a bursa intervenes between the deep surface of the ligament and the part of the bone immediately above the tubercle. *Posteriorly*, the tuberosities are separated from each other by a shallow depression, the *popliteal notch*, which gives attachment to part of the posterior crucial ligament, and part of the posterior ligament of the knee-joint." The *inner tuberosity* (condylus medialis) presents posteriorly a deep transverse groove, for the insertion of the tendon of the Semi-membranosus. Its *lateral surface* is convex, rough and prominent; it gives attachment to the internal lateral ligament. The *outer tuberosity* (condylus lateralis) presents posteriorly a flat articular facet, nearly circular in form, directed downwards, backwards, and outwards, for articulation with the head of the fibula. Its *lateral surface* is convex and rough, more prominent in front than the internal: it presents an eminence, situated on a level with the upper border of the tubercle of the tibia at the junction of its anterior and outer surfaces, for the attachment of the ilio-tibial band. Just below this a part of the Extensor longus digitorum takes origin and a slip from the Biceps tendon is inserted.

The **shaft** (corpus tibiæ) is of a triangular prismoid form, broad above, gradually decreasing in size to the commencement of its lower fourth, which is its most slender part. It then enlarges again towards its lower extremity. It presents for examination three borders and three surfaces.

The *anterior border*, the most prominent of the three, is called the *crest* or *shin* (crista anterior); it commences above at the tubercle, and terminates below at the anterior margin of the inner malleolus. It is sinuous and prominent in the upper two-thirds of its extent, but smooth and rounded below; it gives attachment to the deep fascia of the leg.

The *internal border* (margo medialis) is smooth and rounded above and below, but more prominent in the centre; it begins at the back part of the inner tuberosity, and ends at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and insertion to some fibres of the Popliteus; from its middle third some fibres of the Soleus and Flexor longus digitorum take origin.

The *external or interosseous border* (crista interossea) is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

The *internal surface* (facies medialis) is smooth, convex, and broader above than below; its upper third, directed forwards and inwards, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forward as the anterior border; in the rest of its extent it is subcutaneous.

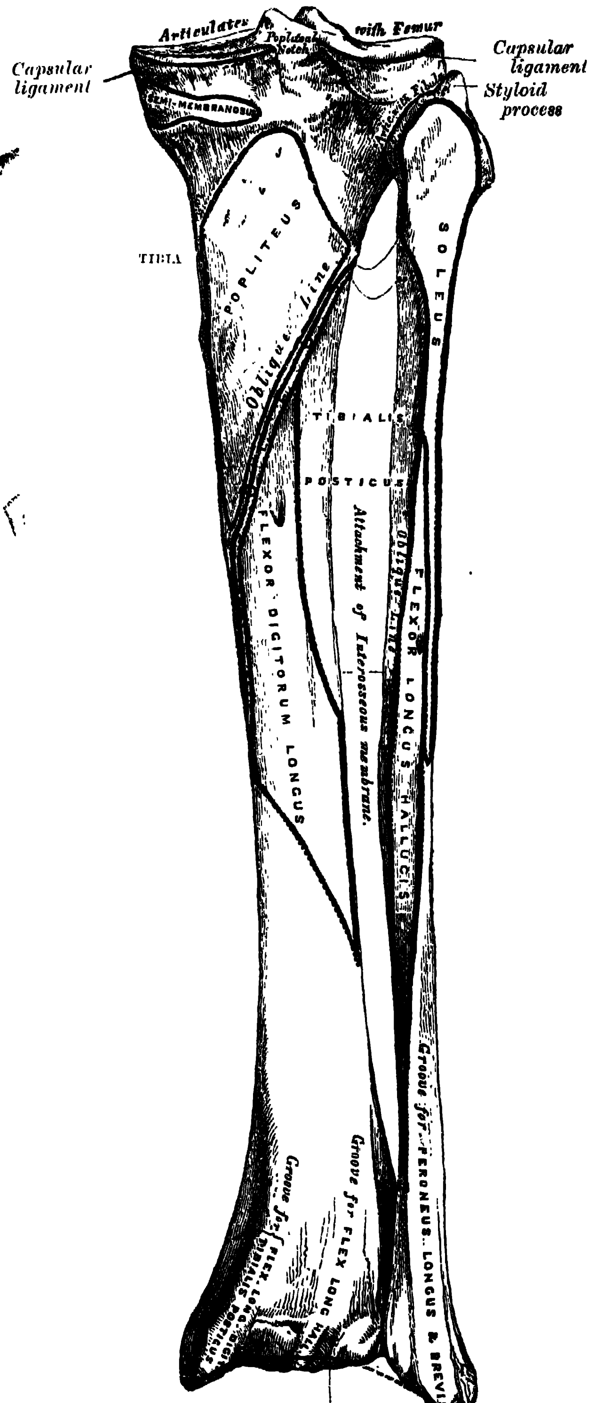
The *external surface* (facies lateralis) is narrower than the internal; its upper two-thirds present a shallow groove for the origin of the Tibialis anticus; its lower third is smooth, convex, curves gradually forwards to the anterior aspect of the bone, and is covered from within outwards by the tendons of the Tibialis anticus, Extensor longus hallucis, and Extensor longus digitorum.

The *posterior surface* (facies posterior) (fig. 398) presents, at its upper part, a prominent ridge, the *oblique line* of the tibia (linea poplitea), which extends from the back part of the articular facet for the fibula obliquely downwards, to the internal border, at the junction of its upper and middle thirds; it marks the lower limit of the insertion of the Popliteus, serves for the attachment of the popliteal fascia, and gives origin to part of the Soleus, Flexor longus digitorum and Tibialis posticus. The triangular area, above and to the inner side of this line, gives insertion to the Popliteus. The middle third of the posterior surface is divided by a vertical ridge into two parts: the ridge is well marked at its commencement at the oblique line, but gradually becomes

indistinct below; the inner and broader portion gives origin to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the posterior surface is smooth and covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis. Immediately below the oblique line is the medullary foramen, which is large and directed obliquely downwards.

The **lower extremity**, much smaller than the upper, presents five surfaces; it is prolonged downwards on its inner side as a strong process, the *internal malleolus*. The *inferior surface* (facies articularis inferior) is quadrilateral, and smooth for articulation with the astragalus. It is concave from before backwards, broader in front than behind, and traversed from before backwards by a slight elevation, separating two lateral depressions. It is continuous internally with that on the inner malleolus. The *anterior surface* of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes; its lower margin presents a rough transverse depression for the attachment of the anterior ligament of the ankle-joint. The *posterior surface* is traversed by a shallow groove directed obliquely downwards and inwards, continuous with a similar groove on the posterior surface of the astragalus, and serving for the passage of the tendon of the Flexor longus hallucis. The *external surface* presents a triangular rough depression for the attachment of the inferior interosseous ligament connecting it with the fibula; the lower part of this

Fig. 398.—Bones of the right leg. Posterior surface.



depression is smooth, covered with cartilage in the recent state, and articulates with the fibula. The surface is bounded by two prominent borders, continuous above with the interosseous ridge; they afford attachment to the anterior and posterior inferior tibio-fibular ligaments. The *internal surface* is prolonged downwards to form a strong pyramidal process, flattened from without inwards—the *internal malleolus* (malleolus medialis). The *inner surface* of this process is convex and subcutaneous; its *outer surface* (facies articularis malleolaris) is smooth and slightly concave, and articulates with the astragalus; its *anterior border* is rough, for the attachment of the anterior fibres of the internal lateral ligament of the ankle-joint; its *posterior border* presents a broad and deep groove (sulcus malleolaris), directed obliquely downwards and inwards, and occasionally double; this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum. The *summit* of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligament of the ankle-joint.

FIG. 399.—Plan of ossification of the tibia. From three centres.

Structure.—The structure of the tibia is like that of the other long bones. The compact wall of the shaft is thickest at the junction of the middle and lower thirds of the bone.

Ossification.—The tibia is ossified from *three* centres (fig. 399): one for the shaft, and one for each extremity. Ossification begins in the centre of the shaft about the seventh week of fœtal life, and gradually extends towards the extremities. The centre for the upper epiphysis appears before or shortly after birth; it is flattened in form, and has a thin tongue-shaped process in front, which forms the tubercle; that for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one joins about the twentieth year. Two additional centres occasionally exist, one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

Articulations.—The tibia articulates with three bones: the femur, fibula, and astragalus.

Surface Form.—A considerable portion of the tibia is subcutaneous. At the upper extremity the tuberosities can be felt just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, is a prominent tubercle for the insertion of the ilio-tibial band. In front of the upper end of the bone, between the tuberosities, is the tubercle of the tibia, forming an oval eminence, which is continuous below with the anterior border or crest of the bone. This border can be felt, in the upper two-thirds of its extent, as a sharp and flexuous ridge. In the lower third of the leg the border disappears, and the bone is concealed by the tendons of the muscles on the front of the leg. Internal to the anterior border is to be felt the broad internal surface of the tibia, slightly encroached upon by the muscles in front and behind. It begins above at the wide expanded inner tuberosity and ends below at the internal malleolus. The internal malleolus is a broad prominence situated on a higher level and somewhat farther forward than the external malleolus. It overhangs the inner border of the arch of the foot. Its anterior border is nearly straight; its posterior border presents a sharp edge, which forms the inner margin of the groove for the tendon of the Tibialis posticus.

The Fibula

The **Fibula** (figs. 396 and 398) is placed on the outer side of the tibia, with which it is connected above and below. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones. Its upper extremity is small, placed towards the back of the head of the tibia, below the level of the knee-joint, and excluded from the formation of this joint; the lower extremity inclines a little forwards, so as to be on a plane anterior to that of the upper end; it projects below the tibia, and forms the outer part of the ankle. The bone presents for examination a shaft and two extremities.

The **upper extremity or head** (capitulum fibulæ) is of an irregular quadrate form, presenting above a flattened articular facet (facies articularis capituli fibulæ), directed upwards, forwards and inwards, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the *styloid process* (apex capituli fibulæ), which projects upwards from the posterior part of the head. The prominence, at its upper and outer part, gives attachment to the tendon of the Biceps, and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The summit of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior fibres of the Peroneus longus, and a surface for the attachment of the anterior superior tibio-fibular ligament; and behind, another tubercle, for the attachment of the posterior superior tibio-fibular ligament and the origin of the upper fibres of the Soleus.

The **shaft** (corpus fibulæ) presents four borders—the antero-external, the antero-internal, the postero-external, and the postero-internal; and four surfaces—anterior, posterior, internal, and external.

The *antero-external border* begins above in front of the head, runs vertically downwards to a little below the middle of the bone, and then curving somewhat outwards, bifurcates so as to embrace a triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the Extensor muscles on the anterior surface of the leg from the Peronei longus et brevis on the outer surface.

The *antero-internal border*, or *interosseous ridge* (crista interossea) is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It begins above just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and ends at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, which separates the Extensor muscles in front from the Flexor muscles behind.

The *postero-external border* is prominent; it begins above at the base of the styloid process, and ends below in the posterior border of the outer malleolus. It is directed outwards above, backwards in the middle of its course, backwards and a little inwards below, and gives attachment to an aponeurosis which separates the Peronei on the outer surface of the shaft from the Flexor muscles on the posterior surface.

The *postero-internal border*, sometimes called the *oblique line*, begins above at the inner side of the head, and ends by becoming continuous with the antero-internal border or interosseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus and Flexor longus hallucis.

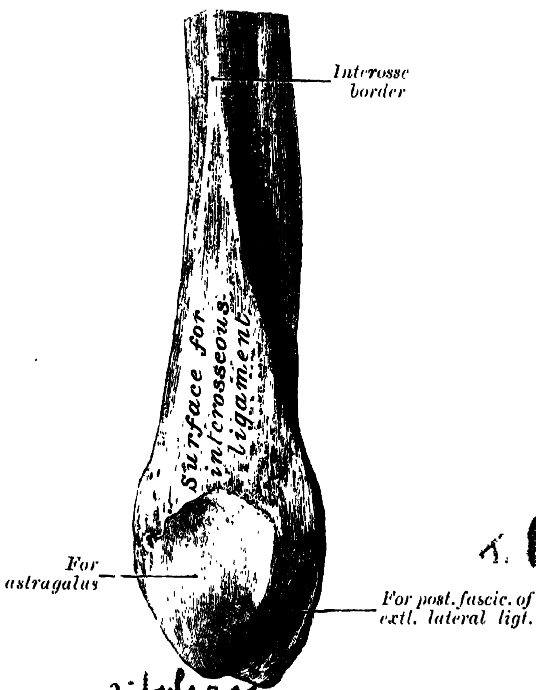
The *anterior surface* is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the origin of three muscles, the Extensor longus digitorum, Extensor proprius hallucis, and Peroneus tertius.

The *posterior surface* is the space included between the postero-external and the postero-internal borders; it is continuous below with the triangular surface above the articular facet of the outer malleolus; it is directed backwards above, backwards and inwards at its middle, directly inwards below. Its upper third is rough, for the origin of the Soleus; its lower part presents a triangular surface, connected to the tibia by a strong interosseous ligament; the intervening part of the surface is covered by the fibres of origin of the Flexor longus hallucis. Near the middle of this surface is the medullary foramen, which is directed downwards.

The *internal surface* is the interval included between the antero-internal and the postero-internal borders. It is grooved for the origin of the Tibialis posticus.

The *external surface* is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved; it is directed outwards in the upper two-thirds of its course, backwards in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peronei longus et brevis.

FIG. 400.—Lower extremity of right fibula. Internal aspect.



The **lower extremity, or external malleolus** (malleolus lateralis), is of a pyramidal form, somewhat flattened from without inwards, and is longer, and descends lower, than the internal malleolus. The *external surface* is convex, subcutaneous, and continuous with the triangular, subcutaneous surface on the outer side of the shaft. The *internal surface* (fig. 400) presents in front a smooth triangular facet (facies articularis malleoli), broader above than below, and convex from above downwards, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the articular surface is a rough depression, which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The *anterior border* is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The *posterior border* is broad and presents a shallow groove (sulcus malleolaris), for the passage of the tendons of the Peronei longus et brevis. The *summit* is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

Articulations.—The fibula articulates with two bones: the tibia and astragalus.

Ossification.—The fibula is ossified from *three* centres (fig. 401): one for the shaft, and one for each extremity. Ossification begins in the shaft about the eighth week of fœtal life, a little later than in the tibia, and extends towards the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one about the fourth year. The lower epiphysis, the first to ossify, unites with the shaft about the twentieth year; the upper epiphysis joins about the twenty-fifth year.

Surface Form.—The only parts of the fibula which are subcutaneous are the head, the lower part of the outer surface of the shaft, and the external malleolus. The head can be felt behind and to the outer side of the outer tuberosity of the tibia, and presents

a small, prominent, triangular eminence slightly above the level of the tubercle of the tibia. The external malleolus is a narrow, elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the Peroneus tertius in front and the tendons of the other two Peronei behind.

Applied Anatomy.—In fractures of the bones of the leg, both bones are generally fractured, but either bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused by either direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at a rather higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are for the most part the result of indirect violence, and the direction of the fracture is downwards, forwards, and inwards in many cases, but may be downwards and outwards, or downwards and backwards. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture of the tibia generally starts as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body while the foot is fixed.

Fig. 401.—Plan of ossification of the fibula. From three centres.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia is the bone which is most commonly and most extensively distorted in rickets. It bends at the junction of the middle and lower third, its weakest part, and presents a curve forwards with generally some lateral displacement.

The tibia is more often the seat of acute infective necrosis than any other bone in the body, and with the formation of the sequestrum, a large amount of new bony material is thrown out by the periosteum. The sequence of events in this disease can be very closely followed in the case of the tibia, and it is not uncommon to find a patient from whom the whole diaphysis of the tibia has been removed, going about with a new bone entirely of periosteal formation. Chronic bone abscess is more frequently met with in the cancellous tissue of the head or lower end of the tibia than in any other bone in the body. These abscesses are very chronic, and in most cases the result of tuberculous osteitis, although they are sometimes due to the organisms of suppuration or even the Bacillus typhosus.

THE FOOT

The skeleton of the foot (figs. 402 and 403) consists of three parts: the tarsus, metatarsus, and phalanges.

THE TARSUS

The **Tarsal bones** (ossa tarsi) are seven in number: viz. the os calcis, astragalus, cuboid, navicular, and the internal, middle, and external cuneiforms.

The Os Calcis (fig. 404)

The **Os Calcis** (calcaneus) is the largest and strongest of the tarsal bones. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It is irregularly cuboidal in form, having its long axis directed forwards and outwards; it presents for examination six surfaces.

FIG. 402.—Bones of the right foot. Dorsal surface.

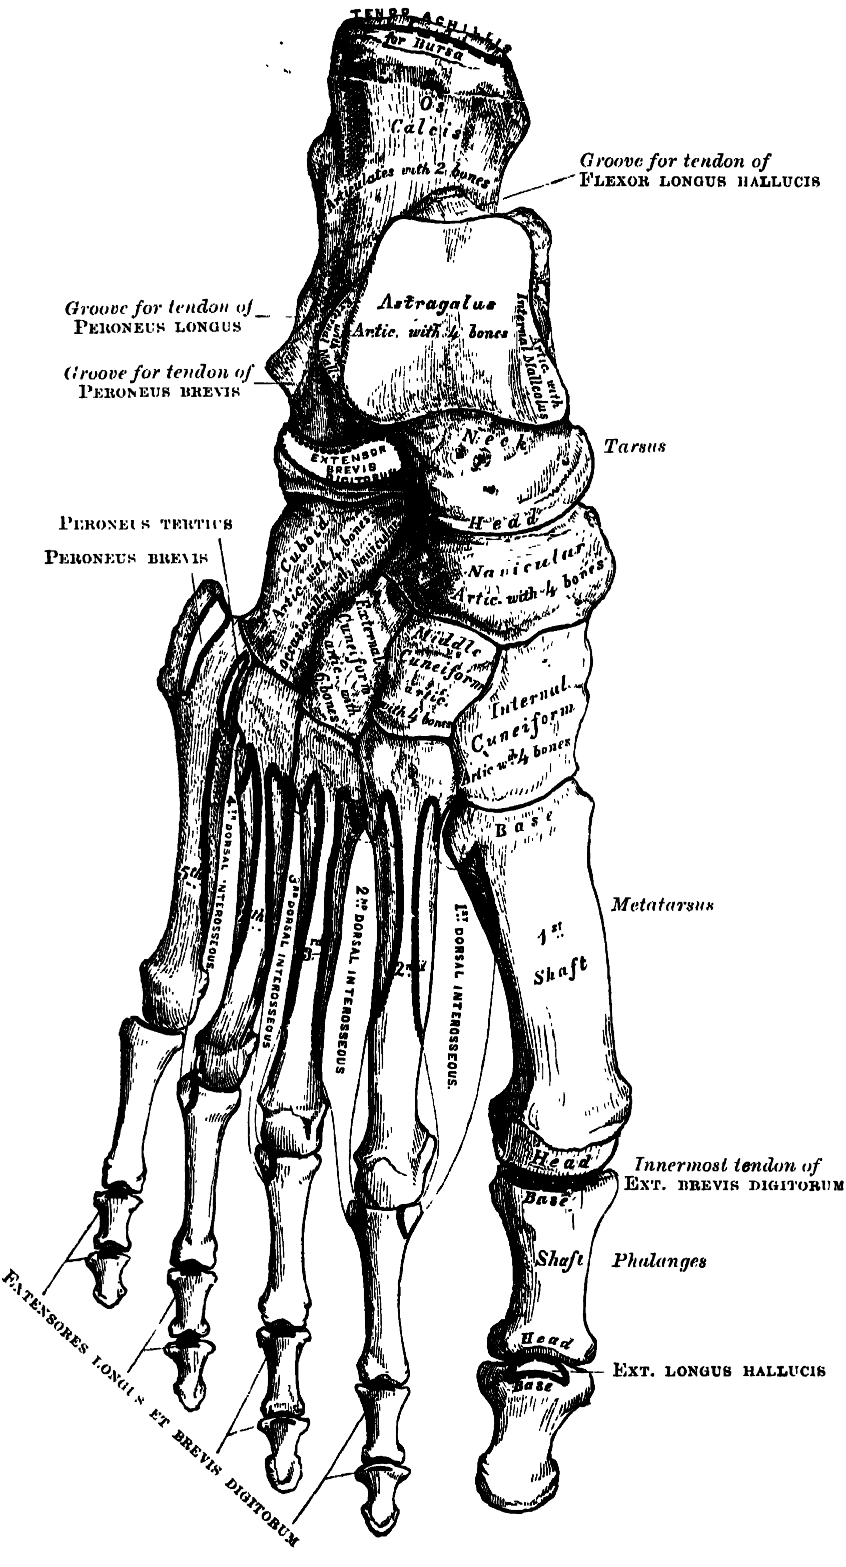


FIG. 403.—Bones of the right foot. Plantar surface.

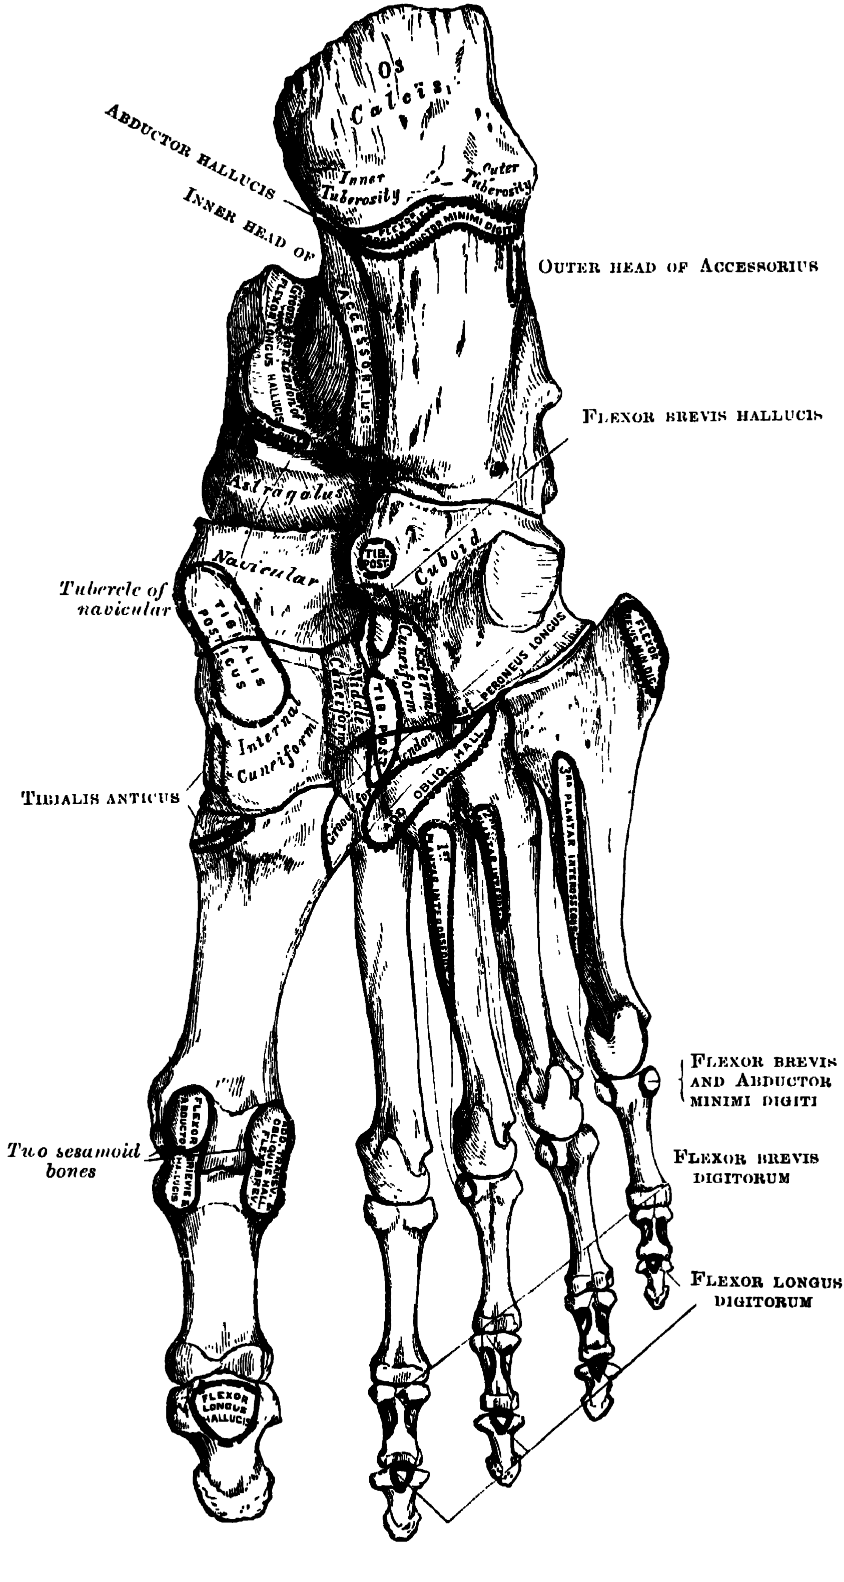
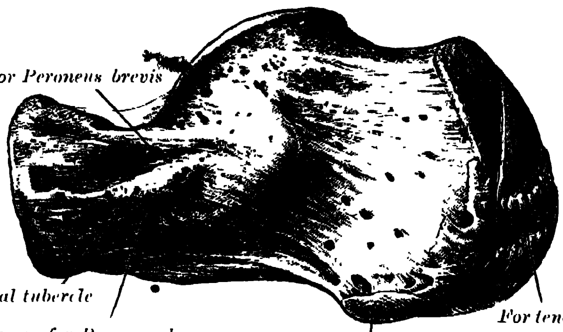


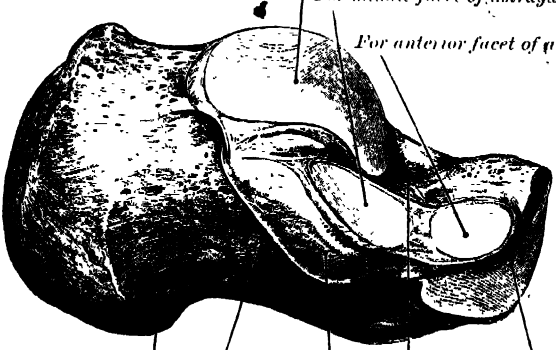
The *superior surface* is formed behind by the upper aspect of that part of the bone which projects backwards to form the heel. This varies in length in different individuals, is convex from side to side, concave from before backwards, and supports a mass of fat placed in front of the tendo Achillis. In front of this area is a large, usually somewhat oval-shaped facet (facies articularis posterior), which looks upwards and forwards; it is convex from behind forwards, and articulates with the posterior calcanean facet on the

FIG. 404.—The left os calcis. A. Postero-external view. B. Antero-internal view.

A



B



under surface of the astragalus. It is bounded anteriorly by a deep depression which is continued backwards and inwards in the form of a groove (sulcus calcanei). In the articulated foot this groove lies below a similar one on the under surface of the astragalus, and the two form a canal (*sinus tarsi*) for the lodgment of the interosseous calcaneo-astragaloid ligament. In front and to the inner side of this groove is an elongated facet, concave from behind forwards, and with its long axis directed forwards and outwards. This facet is frequently divided into two by a notch: of the two, the posterior, and larger (facies articularis media) is supported on a projecting process of bone, termed the *sustentaculum tali*, and articulates with the middle calcanean facet on the under surface of the astragalus; the anterior, and smaller (facies

Talus

articularis anterior) is placed on the anterior part of the body, and articulates with the anterior calcanean facet on the astragalus. The upper surface, anterior and external to the facets, is rough for the attachment of ligaments and for the origin of the Extensor brevis digitorum.

The *inferior surface* is uneven, wider behind than in front, and convex from side to side; it is bounded posteriorly by two tubercles, separated by a depression; the *external* (processus lateralis tuberis calcanei), small, prominent, and rounded, gives origin to part of the Abductor minimi digiti; the *internal* (processus medialis tuberis calcanei), broader and larger, gives attachment, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum and the plantar fascia; the depression between the tubercles gives origin to the Abductor minimi digiti. The rough surface in front of the tubercles gives attachment to the long plantar ligament, and to the outer head of the Flexor accessorius; while to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of the tubercle, is attached the short plantar ligament.

The *external surface* is broad behind, and narrow in front, flat and almost subcutaneous; near its centre is a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part, this surface gives attachment to the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves. The grooves are separated by an elevated ridge, or tubercle, which varies much in size in different bones; it is named the *peroneal tubercle* (processus trochlearis), and gives attachment to a fibrous process from the external annular ligament. The *superior groove* transmits the tendon of the Peroneus brevis; the *inferior*, that of the Peroneus longus.

The *internal surface* is deeply concave; it is directed obliquely downwards and forwards, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords origin to part of the Flexor accessorius. At its upper and fore part is an eminence, the *lesser process* or *sustentaculum tali*, which projects horizontally inwards, and gives attachment to a slip of the tendon of the Tibialis posticus. This process is concave above, and supports the middle articular surface of the astragalus; below, it is grooved for the tendon of the Flexor longus hallucis; its anterior margin gives attachment to the inferior calcaneo-navicular ligament, and its inner, to a part of the internal lateral ligament of the ankle-joint.

The *anterior surface* (facies articularis cuboidea), of a somewhat triangular form, articulates with the cuboid. It is concave from above, downwards and outwards, and convex in a direction at right angles to this. Its inner border gives attachment to the inferior calcaneo-navicular ligament.

The *posterior surface* is prominent, convex, wider below than above, and divisible into three areas. The lowest of these is rough, and covered by the fatty and fibrous tissue of the heel; the middle, also rough, gives insertion to the tendo Achillis and Plantaris; while the highest is smooth, and is covered by a bursa which intervenes between it and the tendo Achillis.

Articulations.—The os calcis articulates with two bones: the astragalus and cuboid.

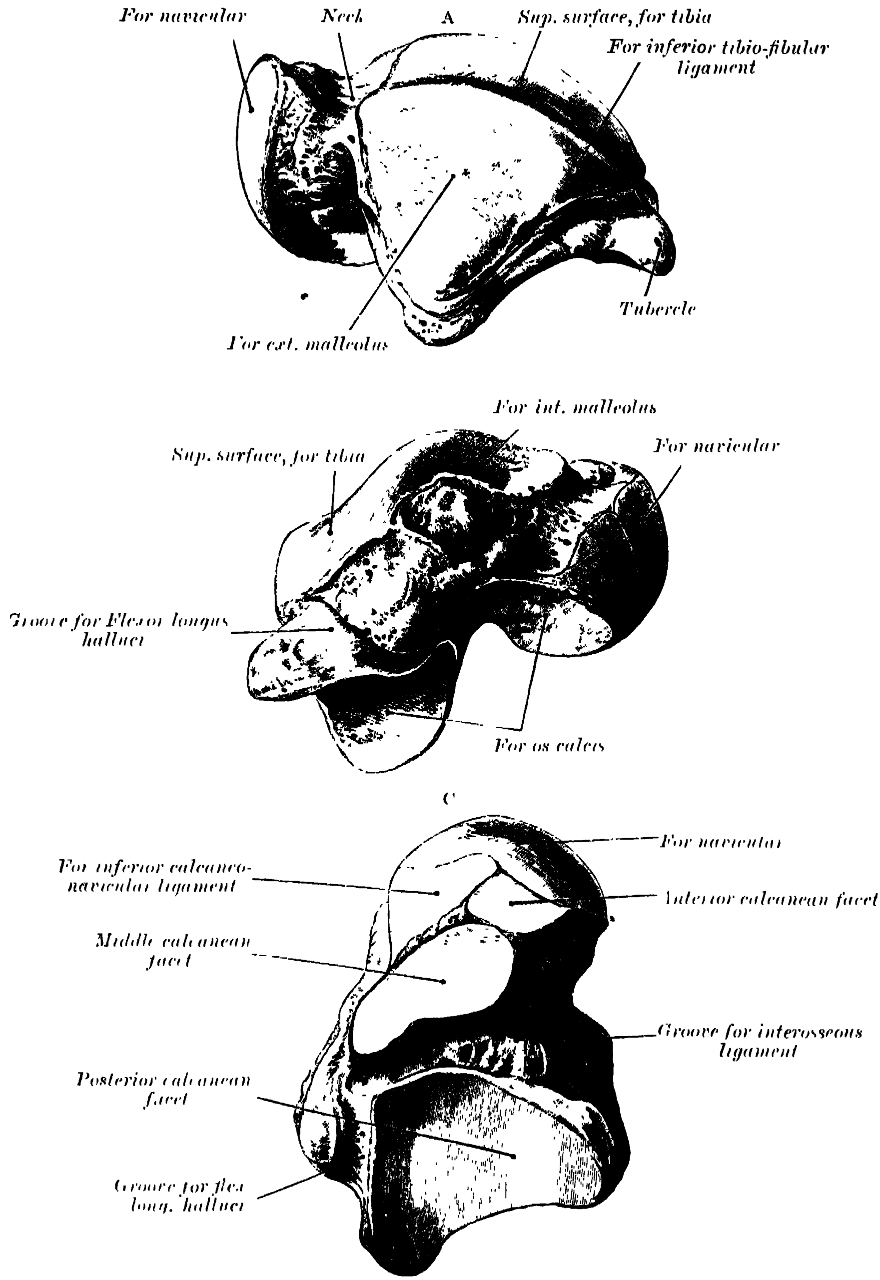
THE ASTRAGALUS (fig. 405) Talus.

The **Astragalus** (talus) is the second largest of the tarsal bones. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon the os calcis, and articulating in front with the navicular. It consists of a body, a neck and a head.

The *superior surface* of the **body** (corpus tali) presents, behind, a smooth trochlear surface (trochlea tali) for articulation with the tibia. The trochlea is broader in front than behind, convex from before backwards, slightly concave from side to side: in front it is confluent with the upper surface of the neck of the bone. The *inferior surface* presents two articular areas, the posterior and middle calcanean facets, separated from one another by a deep groove, the *sulcus tali*. The groove runs obliquely forwards and outwards, becoming gradually broader and deeper in front: it corresponds with a similar groove upon the upper surface of the os calcis, and forms,

when articulated with that bone, a canal (*sinus tarsi*) filled up in the recent state by the interosseous calcaneo-astragaloid ligament. The *posterior calcanean*

FIG. 405.—The left astragalus. A. Supero-external view. B. Infero-internal view. C. Inferior view.



facet (facies articularis calcanea posterior) is larger and of an oval or oblong form. It articulates with the corresponding facet on the upper surface of the os calcis,* and is deeply concave in the direction of its long axis which runs

* Sewell (*Journal of Anatomy and Physiology*, vol. xxxviii.) pointed out that in about 10 per cent. of these bones a small triangular facet, continuous with the posterior calcanean facet, is present at the junction of the external surface of the body with the posterior wall of the sulcus tali.

forwards and outwards at an angle of about 45° with the antero-posterior axis of the body. The *middle calcanean facet* (facies calcanea articularis media) is small, oval in form and slightly convex; it articulates with the upper surface of the sustentaculum tali of the os calcis. The *internal surface* presents at its upper part a pear-shaped articular facet for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression for the attachment of the deep portion of the internal lateral ligament of the ankle-joint. The *external surface* presents a large triangular facet, concave from above downwards, for articulation with the external malleolus; its anterior half is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint. Fawcett * has directed attention to a facet which comes into contact with the inferior tibio-fibular ligament during flexion of the ankle-joint. It is situated between the posterior half of the outer border of the trochlea and the corresponding part of the base of the triangular facet for the external malleolus. It is triangular in shape, the base being directed backwards; below the base is a groove which affords attachment to the posterior fasciculus of the external lateral ligament of the ankle-joint. The *posterior surface* is narrow, and traversed by a groove, which runs obliquely downwards and inwards, and transmits the tendon of the Flexor longus hallucis. External to the groove is a prominent tubercle, to which the posterior fasciculus of the external lateral ligament is attached; this tubercle (processus posterior tali) is sometimes separated from the rest of the astragalus, and is then known as the *os trigonum*. To the inner side of the groove is a second smaller tubercle.

The **neck** (collum tali) is directed forwards and inwards, and comprises the constricted portion of the bone between the body and the oval head. Its *upper* and *inner surfaces* are rough, for the attachment of ligaments; its *external surface* is concave, directed downwards and outwards, and is continuous below with the deep groove for the interosseous calcaneo-astragaloid ligament.

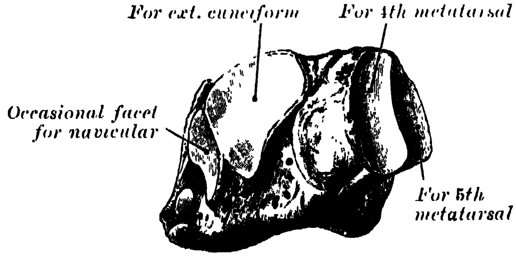
The **head** (caput tali) looks forwards and inwards; its *anterior surface* presents a large, oval, convex facet (facies articularis navicularis), for articulation with the navicular. Its *inferior surface* has two facets, which are best seen in the recent condition. The inner of these, situated immediately in front of the middle calcaneal facet, is convex, triangular or semi-oval in shape, and rests on the inferior calcaneo-navicular ligament; the outer is named the *anterior calcanean facet*; it is somewhat flattened, and articulates with the facet on the upper surface of the anterior part of the os calcis.

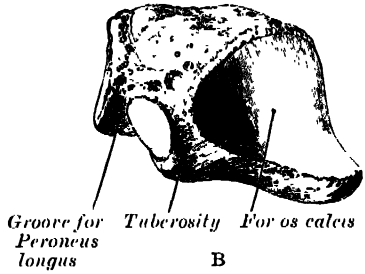
Articulations.—The astragalus articulates with four bones: tibia, fibula, os calcis, and navicular.

The Cuboid (fig. 406)

The **Cuboid** (os cuboideum) is placed on the outer side of the foot, in front

Fig. 406.—The left cuboid. A. Antero-internal view. B. Postero-external view.





of the os calcis, and behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed inwards.

* *Edinburgh Medical Journal*, 1895.

The *superior* or *dorsal surface*, directed upwards and outwards, is rough, for the attachment of numerous ligaments. The *inferior* or *plantar surface* presents in front a deep groove (sulcus m. peronæi), which runs obliquely from without, forwards and inwards; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which the long calcaneo-cuboid ligament is attached. The ridge terminates externally in an eminence, the *tuberosity* (tuberositas oss. cuboidei), the surface of which presents a convex facet; on this facet glides the sesamoid bone or cartilage frequently found in the tendon of the Peroneus longus. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of the Flexor brevis hallucis, and a fasciculus from the tendon of the Tibialis posticus. The *external surface* presents a deep notch formed by the commencement of the peroneal groove. The *posterior surface* is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The *anterior surface*, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets: the inner, quadrilateral in form, articulates with the fourth metatarsal; the outer, larger and more triangular, articulates with the fifth. The *internal surface* is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

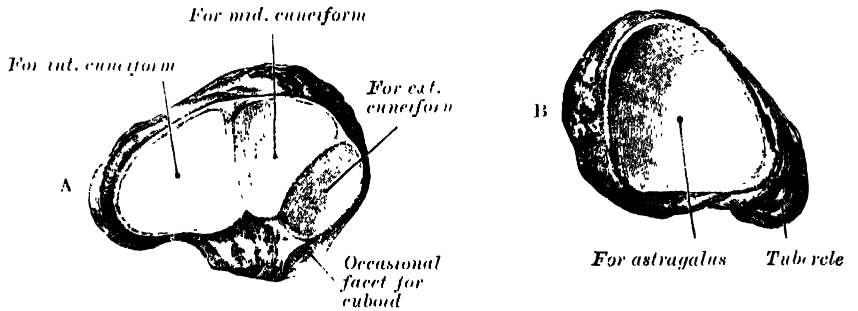
Articulations.—The cuboid articulates with four bones: the os calcis, external cuneiform, and fourth and fifth metatarsals; occasionally with a fifth, the navicular.

THE NAVICULAR (fig. 407)

The **Navicular** or **Scaphoid** (os naviculare pedis) is situated at the inner side of the tarsus, between the astragalus behind and the three cuneiform bones in front.

The *anterior surface* is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The *posterior surface* is oval, concave, broader externally than internally, and articulates with the rounded head of the astragalus. The *superior surface* is convex from side to side, and rough for the attachment of ligaments. The

FIG. 407.—The left navicular. A. Antero-external view. B. Postero-internal view.



inferior surface is irregular, and also rough for the attachment of ligaments. The *internal surface* presents a rounded *tubercle* (tuberositas ossis navicularis), the lower part of which gives attachment to part of the tendon of the Tibialis posticus. The *external surface* is rough and irregular for the attachment of ligaments, and occasionally presents a small facet for articulation with the cuboid bone.

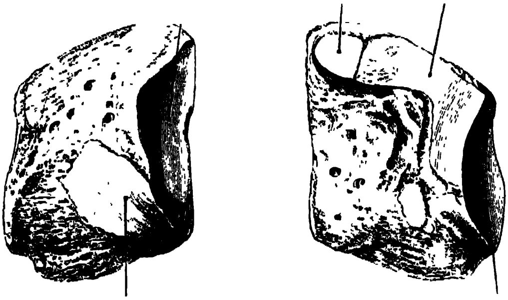
Articulations.—The navicular articulates with four bones: the astragalus and the three cuneiforms; occasionally with a fifth, the cuboid.

THE INTERNAL CUNEIFORM (fig. 408)

The **Internal Cuneiform** (os cuneiforme primum) is the largest of the three cuneiforms. It is situated at the inner side of the foot, between the navicular behind and the base of the first metatarsal in front.

The *internal surface* is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval impression, into which part of the tendon of the Tibialis anticus is inserted; in the rest of its extent it is rough for the attachment of ligaments. The *external surface* is concave, presenting, along its superior and posterior borders, a narrow reversed L-shaped surface, the vertical limb and posterior part of the horizontal limb of which articulate with the middle cuneiform, and the anterior part of the horizontal limb with the second metatarsal bone: the rest of this surface is rough for the attachment of ligaments and part of the tendon of the Peroneus longus. The *anterior surface*, kidney-shaped and much larger than the posterior, articulates with the metatarsal bone of the great toe. The *posterior surface* is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the navicular. The *inferior* or *plantar surface* is rough, and forms the base of the wedge; at its back part is a prominent tuberosity for the insertion of part of the tendon of the Tibialis posticus. It also gives insertion in front to part of the tendon of the Tibialis anticus. The *superior surface* is the narrow pointed end of the wedge, and is directed upwards and outwards, it is rough for the attachment of ligaments.

FIG. 408.—The left internal cuneiform. A. Antero-internal view. B. Postero-external view.

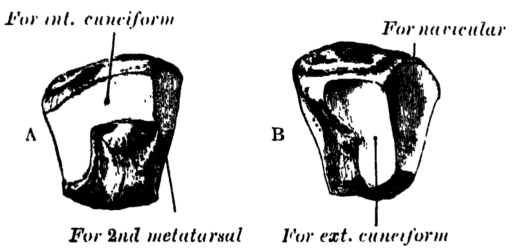


Articulations.—The internal cuneiform articulates with four bones: the navicular, middle cuneiform and first and second metatarsals.

THE MIDDLE CUNEIFORM (fig. 409)

The **Middle Cuneiform** (os cuneiforme secundum), the smallest of the three, is of very regular wedge-like form, the broad extremity being placed upwards, the narrow end downwards. It is situated between the other two cuneiforms, and articulates with the navicular behind, and the second metatarsal in front.

FIG. 409.—The left middle cuneiform. A. Antero-internal view. B. Postero-external view.



The *anterior surface*, triangular in form, and narrower than the posterior, articulates with the base of the second metatarsal bone. The *posterior surface*, also triangular, articulates with the middle facet on the anterior surface of the navicular. The *internal surface* presents a reversed L-shaped articular facet, running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent for the attachment of ligaments. The *external surface* presents posteriorly a smooth facet for articulation with the external cuneiform bone. The *superior surface* forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The *inferior surface*, sharp and tubercular, is also rough for ligamentous attachment, and for the insertion of a slip from the tendon of the Tibialis posticus.

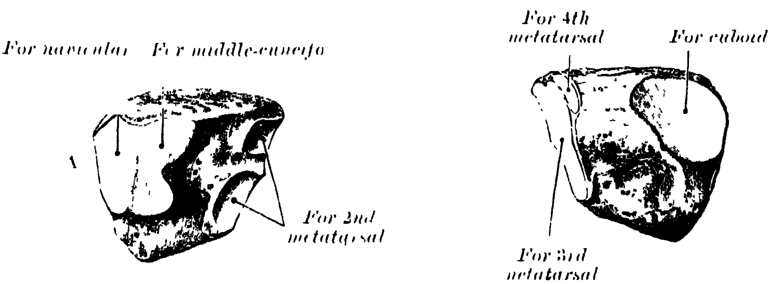
Articulations.—The middle cuneiform articulates with four bones: the navicular, internal and external cuneiforms, and second metatarsal.

THE EXTERNAL CUNEIFORM (fig. 410)

The **External Cuneiform** (os cuneiforme tertium), intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upwards, the narrow end downwards. It occupies the centre of the front row of the tarsal bones, between the middle cuneiform internally, the cuboid externally, the navicular behind, and the third metatarsal in front.

The *anterior surface*, triangular in form, articulates with the third metatarsal bone. The *posterior surface* articulates with the most external facet of the navicular, and is rough below for the attachment of ligamentous fibres. The *internal surface* presents an anterior and a posterior articular facet, separated by a rough depression: the anterior, sometimes divided, articulates with the outer side of the base of the second metatarsal bone; the posterior skirts the posterior border, and articulates with the middle cuneiform; the rough depression gives attachment to an interosseous ligament. The

FIG. 410.—The left external cuneiform. A. Postero-internal view. B. Antero-external view.



external surface also presents two articular facets, separated by a rough non-articular surface; the anterior facet, situated at the superior angle of the bone, is small and semi-oval in shape, and articulates with the inner side of the base of the fourth metatarsal bone; the posterior and larger one is triangular or oval, and articulates with the cuboid; the rough, non-articular surface serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another; those for articulation with the middle cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The *superior* or *dorsal surface* is of an oblong form, its postero-external angle being prolonged backwards. The *inferior* or *plantar surface* is a rounded margin, and serves for the attachment of part of the tendon of the Tibialis posticus, part of the Flexor brevis hallucis, and ligaments.

Articulations.—The external cuneiform articulates with six bones: the navicular, middle cuneiform, cuboid, and second, third, and fourth metatarsals.

THE METATARSUS

The **Metatarsus** consists of five bones which are numbered from within utwards (ossa metatarsalia I.–V.); each presents for examination a shaft and two extremities.

COMMON CHARACTERS OF THE METATARSAL BONES

The *shaft* (corpus) is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is curved longitudinally, so as to be concave below, slightly convex above. The *posterior extremity*, or *base* (basis), is wedge-shaped, articulating by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones: its dorsal and

plantar surfaces are rough for the attachment of ligaments. The ***anterior extremity***, or *head* (capitulum), presents a terminal convex articular surface, oblong from above downwards, and extending farther backwards below than above. Its sides are flattened, and on each is a depression, surmounted by a tubercle, for ligamentous attachment. Its under surface is grooved in the middle line for the passage of the Flexor tendons, and marked on either side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters of the Metatarsal Bones

The **first metatarsal bone** (fig. 411) is remarkable for its great thickness, and is the shortest of all the metatarsal bones. The *shaft* is strong, and of well-marked prismoid form. The *posterior extremity* presents, as a rule, no lateral articular facets, but occasionally on the outer side there is an oval facet, by which it articulates with the second metatarsal. Its terminal articular surface is of large size and kidney-shaped; its circumference is grooved, for the tarso-metatarsal ligaments, and internally gives insertion to part of the tendon of the Tibialis anticus; its inferior angle presents a rough oval prominence for the insertion of the tendon of the Peroneus longus. The *head* is large; on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

Fig. 411.—The first metatarsal. (Left.)

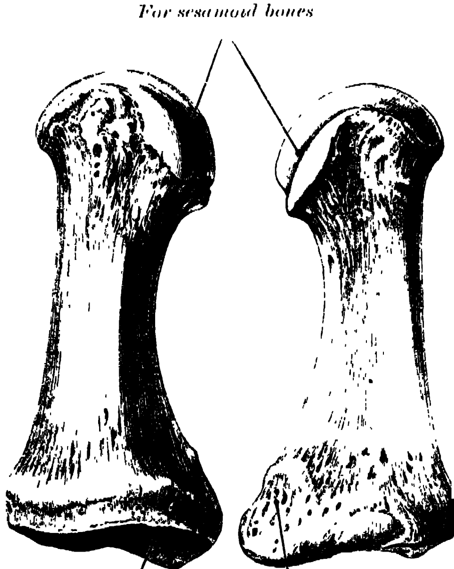


Fig. 412.—The second metatarsal. (Left.)

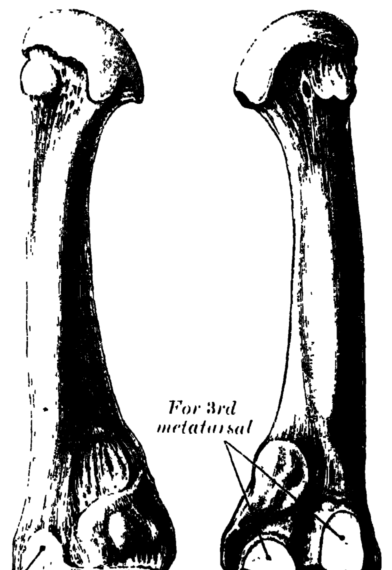

The **second metatarsal bone** (fig. 412) is the longest and largest of the remaining metatarsal bones, being prolonged backwards into the recess formed by the three cuneiform bones. Its *posterior extremity* is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal surface, for articulation with the internal cuneiform; and two on its external surface, an upper and lower, separated by a rough non-articular interval. Each of these external articular surfaces is divided into two by a vertical ridge; the two anterior facets articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform. A fifth facet is occasionally present for articulation with the first metatarsal; it is oval in shape, and is situated on the inner side of the shaft near the base.

The **third metatarsal bone** (fig. 413) articulates behind, by means of a triangular smooth surface, with the external cuneiform ; on its inner side, by two facets, with the second metatarsal ; and on its outer side, by a single

FIG. 413.—The third metatarsal. (Left.)

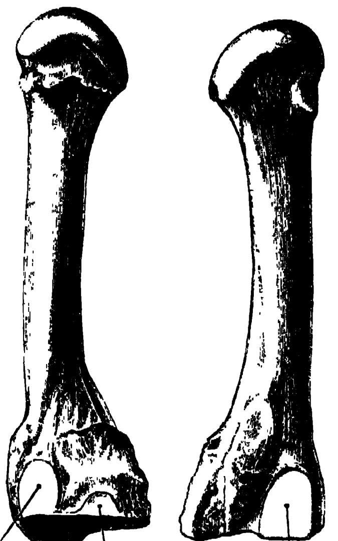

FIG. 414.—The fourth metatarsal. (Left.)

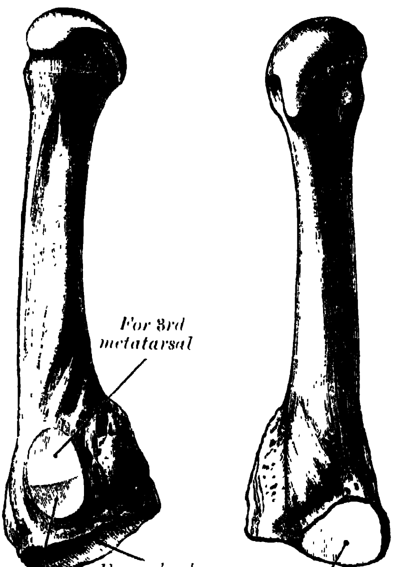
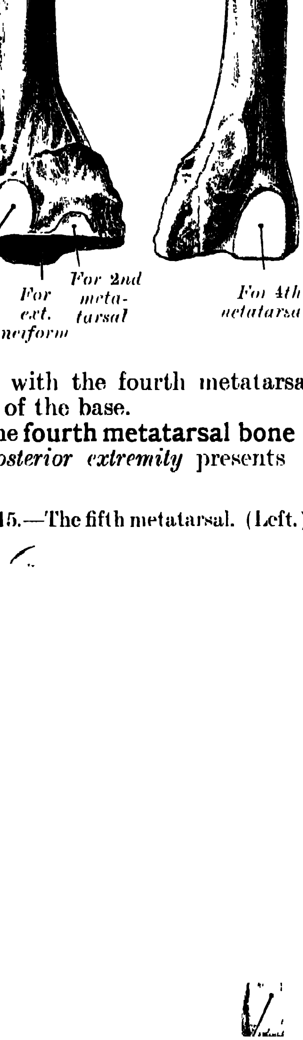


facet, with the fourth metatarsal. The latter facet is situated at the upper angle of the base.

The **fourth metatarsal bone** (fig. 414) is smaller in size than the preceding ; its *posterior extremity* presents an oblique quadrilateral surface for articulation with the cuboid ; a smooth facet on the inner side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior portion for articulation with the external cuneiform ; on the outer side a single facet, for articulation with the fifth metatarsal.

FIG. 415.—The fifth metatarsal. (Left.)



The **fifth metatarsal bone** (fig. 415) is recognised by a tubercular eminence, the *tuberosity*, on the outer side of its base. The *base* articulates behind, by a triangular surface cut obliquely from without inwards, with the cuboid ; and internally, with the fourth metatarsal. On the inner part of its dorsal surface is inserted the tendon of the Peroneus tertius, and on the dorsal surface of the tuberosity that of the Peroneus brevis. A strong band of the plantar fascia connects the projecting part of the tuberosity with the outer tuberosity on the under surface of the os calcis. The plantar surface of the base is grooved for the tendon of the Abductor minimi digiti, and gives origin to the Flexor brevis minimi digiti.

Articulations.—Each metatarsal bone articulates with one or more of the tarsal bones by its proximal extremity, and by the other with one of the first row of

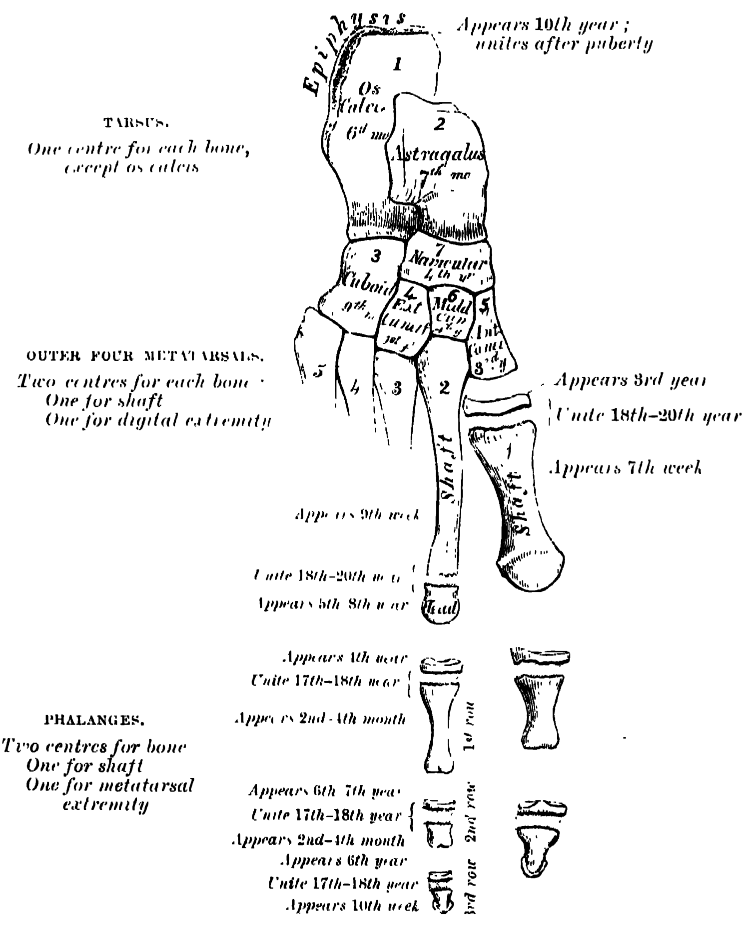
phalanges. The first metatarsal articulates with the internal cuneiform, the second with all three cuneiforms, the third with the external cuneiform, the fourth with the external cuneiform and the cuboid, and the fifth with the cuboid.

PHALANGES

The **Phalanges** (phalanges digitorum pedis), both in number and general arrangement, resemble those of the hand; there being two in the great toe, and three in each of the other toes. They differ from them, however, in their size, the shafts being much reduced in length, and, especially in the first row, laterally compressed.

The phalanges of the **first row** closely resemble those of the hand. The *shaft* of each is compressed from side to side, convex above, concave below. The *posterior extremity* is concave; and the *anterior extremity* presents a trochlear surface for articulation with the second phalanx.

FIG. 416.—Plan of ossification of the foot.



The phalanges of the **second row** are remarkably small and short, but rather broader than those of the first row.

The **ungual phalanges,** in form, resemble those of the fingers; but they are smaller, flattened from above downwards; each presents a broad base for articulation with the corresponding bone of the second row, and an expanded extremity for the support of the nail and end of the toe.

Articulations.—In the four outer toes, the phalanges of the first row articulate behind with the metatarsal bones, and in front with the second phalanges, which

in their turn articulate with the first and third: the ungual phalanges articulate with the second. In the great toe the first phalanx articulates behind with the metatarsal bone and in front with the ungual phalanx.

Ossification of the Bones of the Foot (fig. 416)

The **Tarsal bones** are each ossified from a single centre, excepting the os calcis, which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: os calcis, at the sixth month of fœtal life; astragalus, about the seventh month; cuboid, at the ninth month; external cuneiform, during the first year; internal cuneiform, in the third year: middle cuneiform and navicular, in the fourth year. The epiphysis for the posterior extremity of the os calcis appears at the tenth year, and unites with the rest of the bone soon after puberty. The tubercle on the posterior surface of the astragalus is sometimes ossified from a separate centre, and may remain distinct from the main mass of the bone, when it is named the *os trigonum*.

The **Metatarsal bones** are each ossified from *two* centres: one for the shaft, and one for the digital extremity, in the four outer metatarsals; one for the shaft, and one for the proximal extremity, in the metatarsal of the great toe.* Ossification commences in the centre of the shaft about the ninth week, and extends towards either extremity. The centre for the proximal end of the first metatarsal appears about the third year; the centres for the distal ends of the other bones between the fifth and eighth years; they join the shafts between the eighteenth and twentieth years.

The **Phalanges** are each ossified from *two* centres: one for the shaft, and one for the metatarsal extremity. The centre for the shaft appears about the tenth week, that for the metatarsal extremity between the fourth and tenth years; it joins the shaft about the eighteenth year.

Comparison of the Bones of the Hand and Foot

The hand and foot are constructed on somewhat similar principles, each consisting of a proximal part, the carpus or the tarsus, a middle portion, the metacarpus or the metatarsus, and a terminal portion, the phalanges. The proximal part consists of a series of more or less cubical bones which allow a slight amount of gliding on one another and are chiefly concerned in distributing forces transmitted to or from the bones of the arm or leg. The middle part is made up of slightly movable long bones which assist the carpus or tarsus in distributing forces and also give greater breadth for the reception of such forces. The separation of the individual bones from one another allows of the attachments of the Interossei and protects the dorsi-palmar vascular anastomoses. The distal portion is the most movable, and its separate elements enjoy a varied range of movements, the chief of which are flexion and extension.

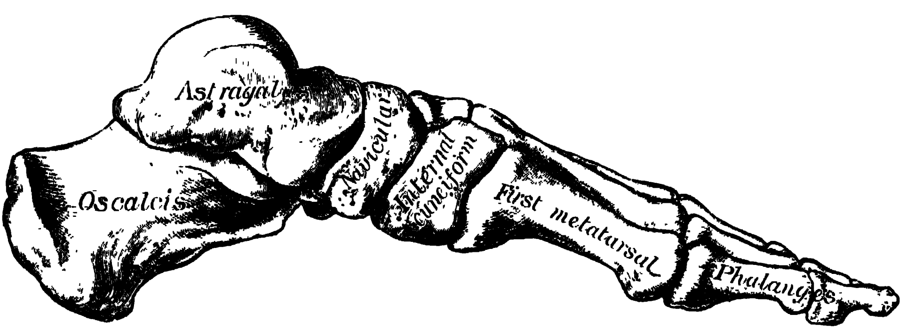
The functions of the hand and foot are, however, very different, and the general similarity between them is greatly modified to meet these requirements. Thus the foot forms a firm basis of support for the body in the erect posture, and is therefore more solidly built up and its component parts are less movable on each other than those of the hand. In the case of the phalanges the difference is readily noticeable; those of the foot are smaller and their movements are more limited than those of the hand. Very much more marked is the difference between the metacarpal bone of the thumb and the metatarsal bone of the great toe. The metacarpal bone of the thumb is constructed to permit of great mobility, is directed at an acute angle from that of the index finger, and is capable of a considerable range of movements at its articulation with the carpus. The metatarsal bone of the great toe assists in supporting the weight of the body, is constructed with great solidity, lies parallel with the other metatarsals, and has a very limited degree of mobility. The carpus is small in proportion to the rest of the hand, is placed in line with the forearm, and forms a transverse arch, the concavity of which constitutes a bed for the flexor tendons and the palmar vessels and nerves. The tarsus forms a considerable part of the foot, and is placed at right angles to the leg, a position which is almost peculiar to man, and has relation to his erect

* As was noted in the first metacarpal, so in the first metatarsal, there is often a second epiphysis for its distal extremity (see footnote, page 319).

posture. In order to allow of their supporting the weight of the body with the least expenditure of material the tarsus and a part of the metatarsus are constructed in a series of arches (figs. 417 and 418), the disposition of which will be considered after the articulations of the foot have been described.

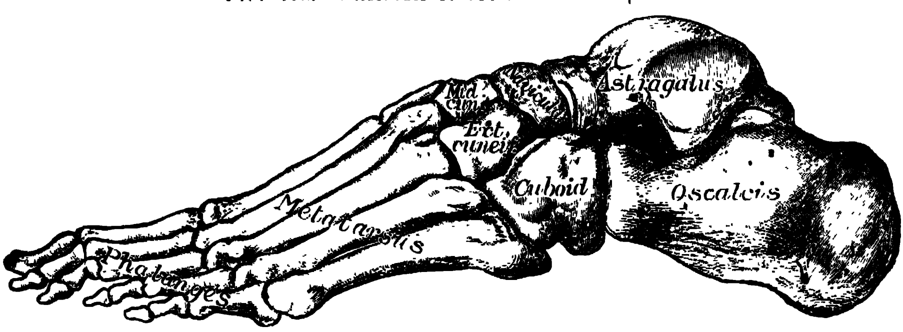
Surface Form.—On the dorsum of the foot the individual bones cannot be distinguished, with the exception of the head of the astragalus, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole surface of the dorsum of the foot forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the navicular, the middle cuneiform, and the second metatarsal bones; from this it inclines gradually outwards and rapidly inwards.

FIG. 417.—Skeleton of foot. Inner aspect.



On the inner side of the foot, the internal tuberosity of the os calcis and the ridge separating the inner from the posterior surface of the bone may be felt. In front of this, and below the internal malleolus, the projection of the sustentaculum tali can be felt. About an inch or an inch and a quarter in front of the internal malleolus is the tuberosity of the navicular. Farther forwards, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the internal sesamoid bone can be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe can be felt. On the outer side of the foot the most posterior bony point is the outer tuberosity of the os calcis, with the ridge separating the posterior from the outer surface of the

FIG. 418. Skeleton of foot. Outer aspect.



bone. In front of this the greater part of the external surface of the os calcis is subcutaneous; on it, below and in front of the external malleolus, the peroneal ridge when present can be felt. Farther forwards, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx, may be made out.

Applied Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface, and joined together by very strong ligaments which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures

are produced by direct violence; and, as there is only a very scanty amount of soft parts over the bones, the fractures are very often compound, and amputation is often necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group—that is, of the os calcis and astragalus—are usually produced by falls from a height on to the feet.

In club-foot (talipes), especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is principally the case in congenital talipes equino-varus, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the navicular. The tarsal bones are peculiarly liable to become the seat of tuberculous caries following comparatively trivial injuries, especially as they are not maintained in a condition of rest to the same extent as some other parts of the body after similar injuries. Caries of the os calcis or astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, since the disease spreads through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the foot is often required either for injury or disease. The principal amputations are as follows:—(1) Syme's: amputation at the ankle-joint by a heel-flap, with removal of the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Pirogoff's: amputation of the whole of the tarsal bones (except the posterior part of the os calcis), and a thin slice from the tibia and fibula including the two malleoli. The sawn surface of the os calcis is then turned up and united to the cut surface of the tibia. (3) Subastragaloid: amputation of the foot below the astragalus through the joint between it and the os calcis.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus for tuberculous disease limited to that bone; or the astragalus may require excision in cases of subastragaloid dislocation, or in cases of inveterate talipes. The cuboid has been removed for the same reason.

Fractures of the metatarsal bones and phalanges are nearly always the result of direct violence, and in the majority of cases the injury is caused by severe crushing accidents, necessitating amputation. The metatarsal bones, and especially that of the great toe, are frequently diseased, either in tuberculous subjects or in patients with perforating ulcer of the foot.

SESAMOID BONES

Sesamoid bones (ossa sesamoidea) are small more or less rounded masses imbedded in certain tendons and usually related to joint surfaces. Their functions probably are to modify pressure, to diminish friction, and occasionally to alter the direction of a muscle pull. That they are not developed to meet certain physical requirements in the adult is evidenced by the fact that they are present as cartilaginous nodules in the fœtus, and in greater numbers than in the adult. They must be regarded, according to Thilenius, as integral parts of the skeleton phylogenetically inherited.* Physical necessities probably come into play in selecting and in regulating the degree of development of the original cartilaginous nodules. Nevertheless, irregular nodules of bone may appear as the result of intermittent pressure in certain regions, e.g. the 'rider's bone,' which is occasionally developed in the Adductor muscles of the thigh.

Sesamoid bones are invested by the fibrous tissue of the tendons, except on the surfaces in contact with the parts over which they glide, where they present smooth articular facets.

In the upper extremity the sesamoid bones of the joints are found only on the palmar surface of the hand. Two, of which the inner is the larger, are constant at the metacarpo-phalangeal joint of the thumb; one is frequently present in the corresponding joint of the little finger, and one (or two) in the same joint of the index finger. Sesamoid bones are also found occasionally at the metacarpo-phalangeal joints of the middle and ring fingers, at the interphalangeal joint of the thumb, and at the distal interphalangeal joint of the index finger.

In the lower extremity the largest sesamoid bone of the joints is the patella, developed in the tendon of the Quadriceps extensor muscle. On the plantar aspect of the foot, two, of which the inner is the larger, are always present at the metatarso-phalangeal joint of the great toe; one sometimes at the

* *Morpholog. Arbeiten*, 1906, v. p. 309.

metatarso-phalangeal joints of the second and fifth toes, one occasionally at the corresponding joint of the third and fourth toes, and one at the inter-phalangeal joint of the great toe.

Sesamoid bones apart from joints are seldom found in the tendons of the upper limb; one is sometimes seen in the tendon of the Biceps opposite the tubercle of the radius. They are, however, present in several of the tendons of the lower limb, viz. one in the tendon of the Peroneus longus, where it glides on the cuboid; one, appearing late in life, in the tendon of the Tibialis anticus, opposite the smooth facet of the internal cuneiform bone; one in the tendon of the Tibialis posticus, opposite the inner side of the head of the astragalus; one in the outer head of the Gastrocnemius, behind the outer condyle of the femur; and one in the conjoined tendon of the Psoas and Iliacus, where it glides over the pubis. Sesamoid bones are found occasionally in the tendon of the Gluteus maximus, as it passes over the great trochanter, and in the tendons which wind round the inner and outer malleoli.

SYNDESMOLOGY

THE various bones of the Skeleton are connected to adjacent bones at different parts of their surfaces, and such connections are termed *Joints* or *Articulations*. Where the joints are *immovable*, as in the articulations between the bones of the skull (with the exception of those of the mandible), the adjacent margins of the bones are almost in contact, being separated merely by a thin layer of fibrous membrane, named the *sutural ligament*. In certain regions at the base of the skull this fibrous membrane is replaced by a layer of cartilage. Where *slight movement* combined with great strength is required, the osseous surfaces are united by tough and elastic *fibro-cartilages*, as in the joints between the vertebral bodies, and in the interpubic articulation. In the *freely movable* joints the surfaces are completely separated; the bones forming the articulation are generally expanded for greater convenience of mutual connection, covered by *cartilage* and held together by strong bands or capsules of fibrous tissue, called *ligaments*: such joints are partially lined by a membrane, the *synovial membrane*, which secretes a fluid to lubricate the various parts of which the joint is formed. The structures, therefore, which enter into the formation of a movable joint are bone, cartilage, fibro-cartilage, ligament, and synovial membrane.

Bone constitutes the fundamental element of all the joints. In the long bones, the extremities are the parts which form the articulations; they are generally somewhat enlarged, and consist of spongy cancellous tissue with a thin coating of compact substance. In the flat bones, the articulations usually take place at the edges; and in the short bones at various parts of their surfaces. The layer of compact bone which forms the joint surface, and to which the articular cartilage is attached, is called the *articular lamella*. It is white, extremely dense, and varies in thickness. It differs from ordinary bone-tissue in that it contains no Haversian canals, and its lacunæ are larger, and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently denser and firmer than ordinary bone, and is evidently designed to form an unyielding support for the articular cartilage.

The **articular cartilage,** which covers the articular surfaces of bones, is of the hyaline variety, and has been described in the section on Histology (page 21).

Ligaments, properly so called, are peculiar to the movable joints, and serve to connect together the articular surfaces of bones. They are composed mainly of bundles of *white fibrous tissue* placed parallel with, or closely interlaced with one another, and presenting a white, shining, silvery aspect. In the freely movable joints, or diarthrodia, they form envelopes or capsules connecting together the articular extremities of bones. Portions of these capsules undergo thickening and form strong ligamentous bands. These constituent parts of the capsule are usually described as distinct ligaments, but in addition to them there are other ligaments derived from the muscles surrounding the joints. Ligaments are pliant and flexible, so as to allow of the most perfect freedom of movement, but strong, tough, and inextensible, so as not to yield readily under the most severely applied force. Some

ligaments consist entirely of *yellow elastic tissue*, as the ligamenta subflava, which connect together the laminæ of adjacent vertebræ, and the ligamentum nuchæ in the lower animals. In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

Synovial membrane is composed of a thin, delicate, connective tissue, with branched connective-tissue corpuscles. Its secretion is thick, viscid, and glairy, like the white of egg, and is hence termed *synovia*. The synovial membranes in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

The *articular synovial membranes* are found in all the freely movable joints. The membrane invests the inner surface of the capsule enclosing the joint, and is reflected over any tendons passing through its cavity, as the tendon of the Popliteus in the knee, and the tendon of the Biceps in the shoulder. Hence the articular synovial membrane may be regarded as a short wide tube, attached by its open ends to the margins of the articular cartilages and covering the inner surface of the capsule which connects the articular surfaces. In the fœtus this membrane is said, by Toynbee, to be continued over the surfaces of the cartilages; but in the adult it is wanting, excepting at the circumference of the cartilage, upon which it encroaches for a short distance and to which it is firmly attached. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called *synovial ligaments*, and are especially distinct in the knee. In other joints there are flattened folds, subdivided at their margins into fringe-like processes, which contain convoluted vessels. These folds generally project from the synovial membrane near the margin of the cartilage, and lie flat upon its surface. They consist of connective tissue, covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. The larger folds often contain considerable quantities of fat. Under certain diseased conditions, similar processes are found covering the entire surface of the synovial membrane, forming a mass of pedunculated fibro-fatty growths which project into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

The *bursal synovial membranes* are found interposed between surfaces which move upon each other, as between tendon and bone, or between the integument and projecting bony surfaces. They admit of subdivision into two kinds, the *bursæ mucosæ* and the *bursæ synoviæ*. The *bursæ mucosæ* are large simple, or irregular sacs in the subcutaneous areolar tissue, enclosing a clear viscid fluid. They are found below the integument in various situations, *e.g.* over the front of the patella, the olecranon, the malleoli, and other prominent parts. The *bursæ synoviæ* are interposed between muscles or tendons, and the projecting bony surfaces over which they play, as between the Gluteus maximus and the great trochanter. Each consists of a thin wall of connective tissue, partially covered by patches of cells, and contains a viscid fluid. Where one of these exists in the neighbourhood of a joint, it may communicate with the joint cavity, as in the case of the bursa between the tendon of the Psoas and Iliacus and the capsular ligament of the hip, or that interposed between the deep surface of the Subscapularis and the capsular ligament of the shoulder-joint.

The *vaginal synovial membranes* (*synovial sheaths*) serve to facilitate the gliding of tendons in the osseo-fibrous canals through which they pass. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the enclosed tendon, the space between the free surfaces of the membrane containing synovia. These sheaths are chiefly found surrounding the tendons of the Flexor and Extensor muscles of the fingers and toes, as they pass through the osseo-fibrous canals in the hand or foot.

Synovia is a transparent, yellowish-white, or slightly reddish fluid, viscid like the white of egg, and has an alkaline reaction and slightly saline taste.

Applied Anatomy.—All synovial membranes, whether articular, bursal, or vaginal, are liable to be affected by acute or chronic forms of inflammation, and the processes are essentially similar, no matter which kind of synovial membrane is affected.

CLASSIFICATION OF JOINTS

The articulations are divided into three classes: *synarthroses* or immovable, *amphiarthroses* or mixed, and *diarthroses* or movable, joints.

1. Synarthroses. Immovable Articulations

Synarthroses include all those articulations in which the surfaces of the bones are in almost direct contact, fastened together by an intervening mass of connective tissue or hyaline cartilage, and in which there is no appreciable motion, as in the joints between the bones of the skull, excepting those of the mandible. There are four varieties of synarthrosis: Sutura, Schindylesis, Gomphosis, and Synchondrosis.

Sutura is that form of articulation where the contiguous margins of the bones are united by a thin layer of fibrous tissue, the *sutural ligament* (fig. 419). It is met with only in the skull. When the articulating surfaces are connected by a series of processes and indentations interlocked together, the articulation

Fig. 419.—Section across the sagittal suture.

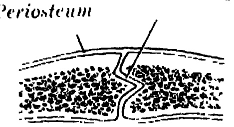


Fig. 420.—Section through occipito-sphenoid synchondrosis of an infant.

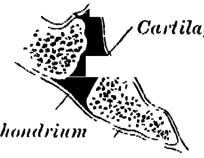
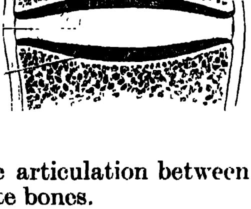


is termed a *true suture* (*sutura vera*); and of this there are three varieties: sutura dentata, serrata, and limbosa. The surfaces of the bones are not in direct contact, being separated by a layer of membrane, continuous externally with the pericranium, internally with the dura mater. The *sutura dentata* is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the *sutura serrata* the edges of the bones are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the *sutura limbosa*, there is besides the dentated processes, a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed a *false suture* (*sutura notha*), of which there are two kinds, the *sutura squamosa*, formed by the overlapping of contiguous bones by broad bevelled margins, as in the squamo-parietal (squamous) suture; and the *sutura harmonia*, where there is simple apposition of contiguous rough surfaces, as in the articulation between the maxillæ, or between the horizontal plates of the palate bones.

Fig. 421.—Diagrammatic section of a symphysis.



Schindylesis is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminæ in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the maxillæ and between the palate bones.

Gomphosis is articulation by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulations of the teeth with the alveoli of the mandible and maxillæ.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a synchondrosis (fig. 420). This is a temporary form of joint, for the cartilage becomes converted into bone before adult life. Such joints are found between the epiphyses and shafts of long bones, between the occipital and the sphenoid at, and for some years after, birth, and between the petrous portion of the temporal and the jugular pro[illegible] occipital.

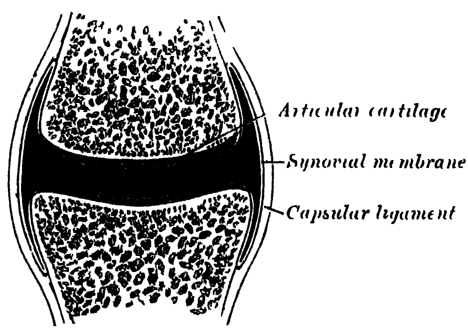
2. Amphiarthroses. Mixed Articulations

In this form of articulation only a slight amount of movement is possible. The contiguous bony surfaces are either connected together by broad flattened discs of fibro-cartilage, of a more or less complex structure, as in the articulations between the bodies of the vertebræ (fig. 421); or are united by an interosseous ligament, as in the inferior tibio-fibular articulation. The first form is termed a **Symphysis,** the second a **Syndesmosis.**

3. Diarthroses. Movable Articulations

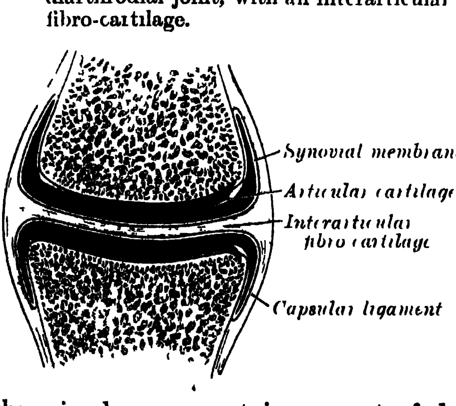
This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing characteristic. A diarthrodial joint is formed by the approximation of two contiguous bony surfaces covered with cartilage, and connected by ligaments lined by synovial membrane (fig. 422). It may be divided, completely or incompletely, by an interarticular fibro-cartilage or *meniscus*, the periphery of which is continuous with the capsular ligament while its free surfaces are covered by synovial membrane (fig. 423).

Fig. 422.—Diagrammatic section of a diarthrodial joint.



The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one form, the Ginglymus, this axis is, practically speaking, transverse; in the other, the Trochoid or pivot-joint, it is longitudinal. There are two varieties where the movement is bi-axial, or around two horizontal axes at right angles to each other, or at any intervening axis between the two. Those are the Condyloid and the Saddle-joint. There is one form where the movement is polyaxial, the Enarthrosis or ball-and-socket joint, and finally there are the Arthrodia or gliding joints.

Fig. 423. — Diagrammatic section of a diarthrodial joint, with an interarticular fibro-cartilage.



Ginglymus or Hinge-joint.—In this form of joint the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forwards and backwards, the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone; there is always a certain amount of deviation from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The best examples of ginglymus

are the interphalangeal joints and the joint between the humerus and ulna; the knee and ankle-joints are less typical, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

Trochoid or Pivot-joint.—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or a ring on a pivot, the ring being formed partly of bone, partly of ligament. In the superior radio-ulnar articulation, the ring is formed by the lesser sigmoid cavity of the ulna and the orbicular ligament; here, the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas, the ring is formed in front by the anterior arch of the atlas, behind, by the transverse ligament; here, the ring rotates round the odontoid process.

Condyloid Articulation.—In this form of joint, an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion, extension, adduction, abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. The wrist-joint is an example of this form of articulation.

Articulation by Reciprocal Reception (*saddle-joint*).—In this variety the opposing surfaces are reciprocally concavo-convex. The movements are the same as in the preceding form; that is to say, flexion, extension, adduction, abduction, and circumduction are allowed, but no axial rotation. The articular surfaces are connected by a capsular ligament. The best example of this form is the carpo-metacarpal joint of the thumb.

Enarthrosis is that variety of joint in which the distal bone is capable of motion around an indefinite number of axes, which have one common centre. It is formed by the reception of a globular head into a deep cup-like cavity (hence the name 'ball-and-socket'), the parts being kept in apposition by a capsular ligament strengthened by accessory ligamentous bands. Examples of this form of articulation are found in the hip and shoulder.

Arthrodia is a variety of joint which admits of only gliding movement; it is formed by the apposition of plane surfaces, or one slightly concave, the other slightly convex, the amount of motion between them being limited by the ligaments or osseous processes surrounding the articulation; as in the joints between the articular processes of the vertebræ, the carpal joints, except that of the os magnum with the scaphoid and semilunar, and the tarsal joints with the exception of that between the astragalus and the navicular.

On the next page, in a tabular form, are the names, distinctive characters, and examples of the different kinds of articulations.

The Kinds of Movement admitted in Joints

The movements admissible in joints may be divided into four kinds: gliding and angular movements, circumduction, and rotation. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that we find only one kind of motion in any particular joint.

Gliding movement is the simplest kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints; but in some, as in most of the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place: (1) forwards and backwards constituting flexion and extension, or (2) inwards and outwards from the mesial line of the body (or in the fingers or toes from the middle line of the hand or foot) constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip, the shoulder, the carpo-metacarpal joint of the thumb, and the wrist.

Circumduction is that form of motion which takes place between the head of a bone and its articular cavity, when the bone is made to circumscribe a conical space; the base of the cone is described by the inferior extremity of the bone, the apex is in the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

- *Synarthrosis*, or Immovable Joint. Surfaces separated by fibrous membrane or cartilage, without any intervening synovial cavity, and immovabiy connected with each other. As in joints of cranium and face (except the mandible).
  - *Sutura*. Articulation by processes and indentations interlocked together.
    - *Sutura vera* (true) articulates by indented borders.
      - *dentata*, having tooth-like processes; as in interparietal suture.
      - *serrata*, having serrated edges like the teeth of a saw; as in interfrontal suture.
      - *limbosa*, having bevelled margins, and dentated processes; as in fronto-parietal suture.
    - *Sutura notha* (false articulates by rough surfaces.
      - *squamosa*, formed by thin bevelled margins, overlapping each other; as in squamo-parietal suture.
      - *harmonia*, formed by the apposition of contiguous rough surfaces; as in intermaxillary suture.
  - *Schindylesis*.—Articulation formed by the reception of a thin plate of one bone into a fissure in another; as in articulation of rostrum of sphenoid with vomer.
  - *Gomphosis*.—Articulation formed by the insertion of a conical process into a socket; as in the teeth.
  - *Synchondrosis*.—When the connecting medium is cartilage, as in the occipito-sphenoid joint.
- *Amphiarthrosis*, Mixed Articulation.
  - *Symphysis*.—Surfaces connected by fibro-cartilage, not separated by synovial membrane, and having limited motion; as in joints between bodies of vertebræ.
  - *Syndesmosis*.—Surfaces united by an interosseous ligament. As in the inferior tibio-fibular articulation.
- *Diarthrosis*, Movable Joint.
  - *Ginglymus*.—Hinge-joint; motion limited to two directions, forwards and backwards. Articular surfaces fitted together so as to permit of movement in one plane; as in the interphalangeal joints and the joint between the humerus and the ulna.
  - *Trochoid or pivot-joint*.—Articulation by a pivot-process turning within a ring, or a ring round a pivot; as in superior radio-ulnar articulation, and atlanto-axial joint.
  - *Condyloid*.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation; as the wrist-joint.
  - *Reciprocal Reception* (*saddle-joint*).—Opposed articular surfaces reciprocally convex in one direction and concave in the other. Movement in every direction but no axial rotation; as in the carpo-metacarpal joint of the thumb.
  - *Enarthrosis*.—Ball-and-socket joint; capable of motion in all directions. Articulation by a globular head received into a cup-like cavity; as in hip- and shoulder-joints.
  - *Arthrodia*.—Gliding-joint; articulation by plane surfaces, which glide upon each other; as in the carpal and tarsal articulations.

Rotation is a form of movement in which a bone moves round a central axis without undergoing any lateral displacement; the axis of rotation may lie in a separate bone, as in the case of the pivot formed by the odontoid process of the axis vertebra around which the atlas turns; or a bone may rotate around its own longitudinal axis, as in the rotation of the humerus at the shoulder-joint; or the axis of rotation may not be quite parallel to the long axis of the bone, as in the

B B 2

movement of the radius on the ulna during pronation and supination of the hand, where it is represented by a line connecting the centre of the head of the radius above with the centre of the head of the ulna below.

Ligamentous Action of Muscles.—The movements of the different joints of a limb are combined by means of the long muscles passing over more than one joint. These, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other—the latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed so as to bring their attachments nearer together. The uses of this arrangement are threefold. 1. It co-ordinates the kinds of movements which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. 'Thus in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended,' in consequence of the passage of the Biceps and Triceps over both joints. 2. It enables the short muscles which pass over only one joint to act upon more than one. 'Thus, if the Rectus femoris remain tonically of such length that when, stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes, not only an extensor of the hip, but an extensor of the knee as well.' 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. 'Taxed beyond its strength a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighbouring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of movement, the muscles adapting themselves tonically to the length required.' The quotations are from a very interesting paper by Cleland in the 'Journal of Anatomy and Physiology,' No. 1, 1866, p. 85; by whom this important fact in the mechanism of joints was first clearly pointed out, though it was independently observed afterwards by other anatomists. W. W. Keen points out how important it is 'that the surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist after Colles's fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed as in "making a fist," flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed.' Keen further points out that 'a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence they can go to sleep and not fall off the perch.'

The articulations may be grouped into those of the trunk, those of the upper extremity, and those of the lower extremity.

ARTICULATIONS OF THE TRUNK

These may be divided into the following groups, viz.:

I. Of the vertebral column.
II. Of the atlas with the axis.
III. Of the vertebral column with the cranium.
IV. Of the mandible.
V. Of the ribs with the vertebræ.
VI. Of the cartilages of the ribs with the sternum, and with each other.
VII. Of the sternum.
VIII. Of the vertebral column with the pelvis.
IX. Of the pelvis.

I. ARTICULATIONS OF THE VERTEBRAL COLUMN

There are two varieties of articulation in the vertebral column: 1. Those between the bodies of the vertebræ, which form a series of amphiarthrodial joints, and are termed the *intercentral.* 2. Those between the articular processes, which form a series of arthrodial joints, and are termed *interneural.*

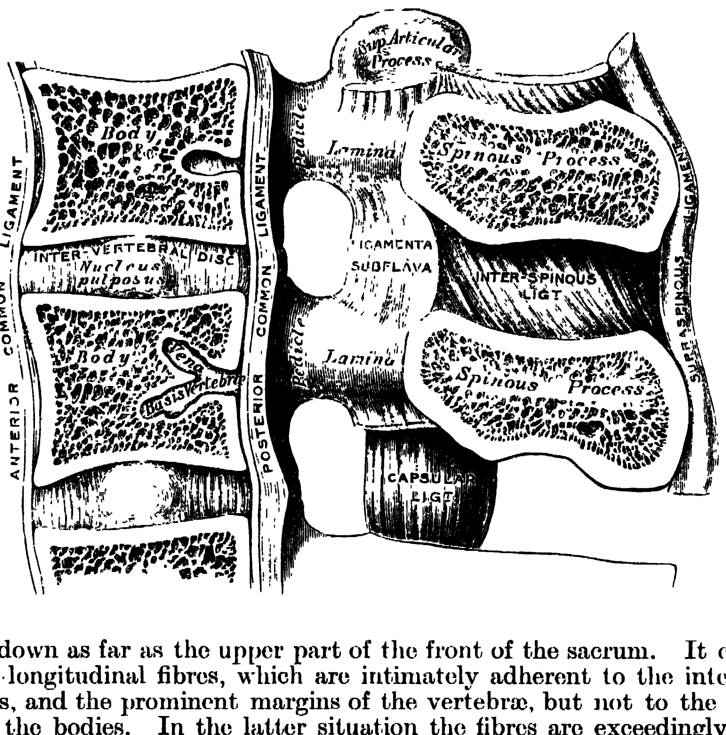
1. Intercentral Articulations

The intercentral articulations, or articulations between the bodies of the vertebræ, belong to the class of amphiarthrodial joints, and the individual vertebræ move only slightly on each other. When, however, this slight degree of movement between the pairs of bones takes place in all the joints of the vertebral column, the total range of movement is very considerable. The ligaments of these articulations are the following :

Anterior Common Ligament. Posterior Common Ligament.
Intervertebral Discs.

The **Anterior Common Ligament** (lig. longitudinale anterius) (figs. 424, 435. and 442) is a broad and strong band of fibres, which extends along the anterior surfaces of the bodies of the vertebræ, from the axis to the sacrum. It is broader below than above, thicker in the thoracic than in the cervical or lumbar region, and somewhat thicker opposite the bodies of the vertebræ than opposite the intervertebral discs. It is attached, above, to the body of the axis, where it is continuous with the anterior atlanto-axial ligament, and

Fig. 424.—Vertical section of two lumbar vertebræ and their ligaments.



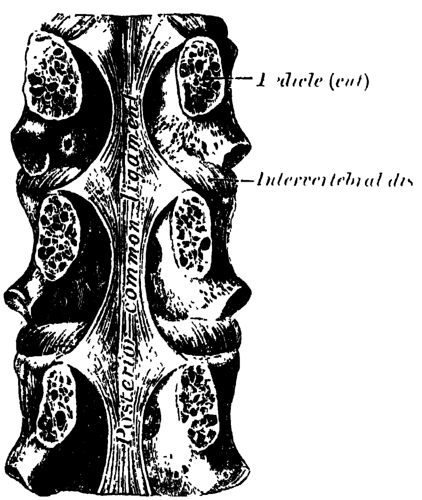
extends down as far as the upper part of the front of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral discs, and the prominent margins of the vertebræ, but not to the middle parts of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on the anterior surfaces, and to make the front of the vertebral column more even. The ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial fibres are the longest and extend between four or five vertebræ. A second, subjacent set extends between two or three vertebræ; while a third set, the shortest and deepest, extends from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by oval apertures for the passage of vessels.

The **Posterior Common Ligament** (lig. longitudinale posterius) (figs. 424, 425) is situated within the spinal canal, and extends along the posterior surfaces of the bodies of the vertebræ, from the body of the axis, where it is continuous with the occipito-axial ligament, to the sacrum. It is broader above than

below, and thicker in the thoracic than in the cervical or lumbar regions. In the situation of the intervertebral discs and contiguous margins of the vertebræ, where the ligament is more intimately adherent, it is broad, and in the thoracic and lumbar regions presents a series of dentations with intervening concave margins; but it is narrow and thick over the centres of the bodies, from which it is separated by the *venæ basis vertebræ*. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and consists of superficial layers occupying the interval between three or four vertebræ, and deeper layers which extend between one vertebra and the next adjacent to it. It is separated from the dura mater of the spinal cord by some loose connective tissue.

The **Intervertebral Discs** (fibrocartilagines intervertebrales) (figs. 424; 436) are interposed between the adjacent surfaces of the bodies of the vertebræ, from the axis to the sacrum, and form the chief bonds of connection between the vertebræ. They vary in shape, size, and thickness, in different parts of the vertebral column. In *shape* and *size* they correspond with the surfaces of the bodies between which they are placed, except in the cervical region, where they are slightly smaller from side to side than the corresponding bodies. In *thickness* they vary not only in the different regions of the column, but in different parts of the same disc; they are thicker in front than behind in the cervical and lumbar regions, and thus contribute to the anterior convexities of the column in these regions; while they are of nearly uniform thickness in the thoracic region, the anterior concavity of this region being almost entirely owing to the shape of the vertebral bodies. The intervertebral discs constitute about one-fourth of the length of the spinal column, exclusive of the first two vertebræ; but this amount is not equally distributed between the various bones, the cervical and lumbar portions having, in proportion to their length, a much greater amount than the thoracic region, with the result that these parts possess greater pliancy and freedom of movement. The intervertebral discs are adherent, by their surfaces, to thin layers of hyaline cartilage which cover the upper and under surfaces of the bodies of the vertebræ, and in which, in early life, the epiphysial plates develop; by their circumferences they are closely connected in front to the anterior, and behind to the posterior, common ligaments. In the thoracic region they are joined laterally, by means of the interarticular ligaments, to the heads of those ribs which articulate with two vertebræ: they consequently form parts of the articular cavities in which the heads of these ribs are received.

FIG. 425.—Posterior common ligament, in the thoracic region.



Structure of the Intervertebral Discs.—Each is composed, at its circumference, of laminæ of fibrous tissue and fibro-cartilage, forming the *annulus fibrosus*; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish colour, which rises up considerably above the surrounding level when the disc is divided horizontally. This pulpy substance (*nucleus pulposus*), especially well developed in the lumbar region, is the remains of the notochord. The laminæ are arranged concentrically; the outermost consist of ordinary fibrous tissue, the others of white fibro-cartilage. The laminæ are not quite vertical in their direction, those near the circumference being curved outwards and closely approximated; while those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each lamina is composed are directed, for the most part, obliquely from above downwards, the fibres of adjacent laminæ passing in opposite directions and varying in every layer: so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This

laminar arrangement belongs to about the outer half of each disc. The pulpy substance presents no concentric arrangement, and consists of a fine fibrous matrix, containing angular cells united to form a reticular structure.

Applied Anatomy.—When an aneurysm presses on the vertebral column, the vertebral bodies are often deeply eroded by the tumour, while the intervertebral discs remain intact. The discs are the first to be destroyed, however, in tuberculosis of the spine, where, as not infrequently happens, the disease begins in the discs, and spreads thence to the bodies of the two adjoining vertebræ simultaneously.

2. Interneural Articulations

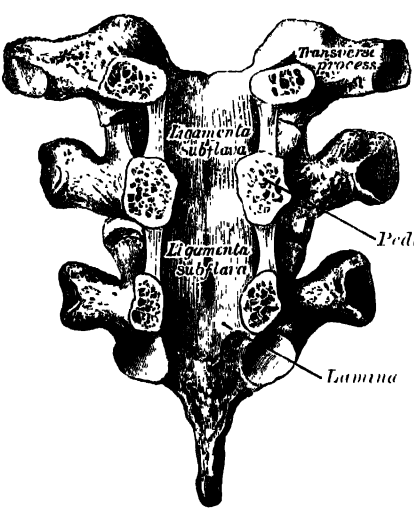
The interneural articulations, or articulations between the articular processes of the vertebræ, belong to the arthrodial variety of movable joints. The processes are connected together by capsular ligaments, which are lined by synovial membranes; but in addition to these are a number of accessory ligaments, which connect together the laminæ, spinous and transverse processes. The ligaments of the interneural articulations are:

Capsular.	Supraspinous.
Ligamenta subflava.	Interspinous.
Intertransverse.	

The **Capsular Ligaments** (capsulæ articulares) (fig. 424) are thin and loose ligamentous sacs, attached to the contiguous margins of the articular processes of adjacent vertebræ. Each ligament is defective internally, where the sac is completed by the ligamentum subflavum. They are longer and looser in the cervical than in the thoracic or lumbar regions. The capsular ligaments are lined on their inner surfaces by synovial membrane.

The **Ligamenta Subflava** (ligg. flava) (fig. 426) connect the laminæ of adjacent vertebræ, from the axis to the first segment of the sacrum. They are best seen when viewed from the interior of the spinal canal: when looked at from the outer surface they appear short, being overlapped by the laminæ. Each ligament consists of two lateral portions, which commence one on either side at the roots of the articular processes, and extend backwards to the point where the laminæ converge to form the spinous process; the posterior margins of the two portions are in contact and to a certain extent united, slight intervals being left for the passage of small vessels. Each ligament consists of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the lamina above, some distance from its inferior margin, and to the posterior surface and upper margin of the lamina below. In the cervical region the ligaments are thin, but very broad and long; they become thicker in the thoracic region, and in the lumbar region acquire very considerable thickness. Their highly elastic property serves to preserve the upright posture, and to assist the vertebral column in resuming it, after flexion. These ligaments do not exist between the occiput and atlas, or between the atlas and axis.

Fig. 426.—Neural arches of three thoracic vertebræ viewed from the front.



The **Supraspinous Ligament** (lig. supraspinale) (fig. 424) is a strong fibrous cord, which connects together the apices of the spinous processes

from the seventh cervical vertebra to the sacrum. It is thicker and broader in the lumbar than in the thoracic region, and intimately blended, in both situations, with the neighbouring aponeurosis. The most superficial fibres of this ligament connect three or four vertebræ; those more deeply seated pass between two or three vertebræ; while the deepest connect the spinous processes of neighbouring vertebræ. It is continued upwards to the external occipital protuberance and crest, as the ligamentum nuchæ.

The **Ligamentum nuchæ** is a fibrous membrane, which, in the neck, represents the supraspinous ligaments of the lower vertebræ. It extends from the external occipital protuberance and crest to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the posterior tubercle of the atlas, and the spinous processes of all the cervical vertebræ, so as to form a septum between the muscles on either side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The **Interspinous Ligaments** (ligg. interspinalia) (fig. 424), thin and membranous, are interposed between the spinous processes. These ligaments extend from the root to the apex of each spinous process, connecting together their adjacent margins. They meet the ligamenta subflava in front and the supraspinous ligament behind. They are narrow and elongated in the thoracic region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

The **Intertransverse Ligaments** (ligg. intertransversaria) are interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the thoracic region they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

Movements.—The movements permitted in the vertebral column are, Flexion, Extension, Lateral movement, Circumduction, and Rotation.

In *Flexion*, or movement forwards, the anterior common ligament is relaxed, and the intervertebral discs are compressed in front; while the posterior common ligament, the ligamenta subflava, and the inter- and supra-spinous ligaments are stretched, as well as the posterior fibres of the intervertebral discs. The interspaces between the laminæ are widened, and the inferior articular processes glide upwards, upon the superior articular processes of the subjacent vertebræ. Flexion is the most extensive of all the movements of the vertebral column.

In *Extension*, or movement backwards, an exactly opposite disposition of the parts takes place. This movement is not extensive, being limited by the anterior common ligament, and by the approximation of the spinous processes.

In *Lateral Movement*, the sides of the intervertebral discs are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments. This movement may take place in any part of the column, but is freest in the neck and loins.

Circumduction is very limited, and is merely a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral discs; this, although only slight between any two vertebræ, produces a considerable extent of movement when it takes place in the whole length of the column, the front of the upper part of the column being turned to one or other side. This movement occurs to a slight extent in the neck, is freer in the upper part of the thoracic region, and absent in the lumbar region.

The extent and variety of the movements are influenced by the shape and direction of the articular surfaces.

In the *cervical* region the upward inclination of the superior articular surfaces allows of free flexion and extension. Extension can be carried farther than flexion; at the upper end of the region it is checked by the locking of the posterior edges of the superior atlantal facets in the posterior condyloid fossæ of the occipital bone; at the lower end it is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic. Flexion is arrested when the cervical convexity is straightened; the movement is checked by the apposition of the

projecting lower lips of the bodies of the vertebræ with the shelving surfaces on the bodies of the subjacent vertebræ. Lateral flexion and rotation are free in the cervical region; they are, however, always combined. The upward and inward inclinations of the superior articular surfaces impart a rotatory movement during lateral flexion, while pure rotation is prevented by the slight inward slope of these surfaces.

In the *thoracic* region, notably in its upper part, all the movements are limited in order to reduce interference with respiration to a minimum. The almost complete absence of an upward inclination of the superior articular surfaces prohibits any marked flexion, while extension is checked by the contact of the inferior articular margins with the laminæ, and the contact of the spinous processes with one another. The mechanism between the seventh cervical and the first thoracic vertebræ, which limits extension of the cervical region, will also serve to limit flexion of the thoracic region when the neck is extended. Rotation is free in the thoracic region: the superior articular processes are segments of a cylinder whose axis is in the mid-ventral line of the vertebral bodies. The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum.

In the *lumbar* region flexion and extension are free. Flexion can be carried farther than extension, and is possible up to the straightening of the lumbar curve; it is, therefore, greatest at the lowest part where the curve is sharpest. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebræ, and on this account a considerable amount of lateral flexion is permitted. For the same reason a slight amount of rotation can be carried out, but this is so soon checked by the interlocking of the articular surfaces that it is negligible.

The principal muscles which produce *flexion* are the Sterno-mastoid, Rectus capitis anticus major, and Longus colli; the Scaleni; the abdominal muscles and the Psoas magnus. *Extension* is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinales dorsi et colli, and the Multifidus spinæ. *Lateral* motion is produced by the fourth and fifth layers of the muscles of the back, by the Splenius, the Scaleni, the Quadratus lumborum and the Psoas magnus, the muscles of one side only acting; and *rotation* by the action of the following muscles of one side only, viz. the Sterno-mastoid, the Rectus capitis anticus major, the Scaleni, the Multifidus spinæ, the Complexus, and the abdominal muscles.

II ARTICULATION OF THE ATLAS WITH THE AXIS

The articulation of the Atlas with the Axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed by the anterior arch of the atlas and the transverse ligament (see fig. 429); here there are two joints: one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process; the other between the anterior surface of the transverse ligament and the back of the process. Between the articular processes of the two bones there is on either side an arthrodial or gliding joint. The ligaments which connect these bones are:

Two Capsular.	Posterior Atlanto-axial.
Anterior Atlanto-axial.	Transverse.*

The Capsular Ligaments (capsulæ articulares) are two thin, loose capsules, connecting the lateral masses of the atlas with the margins of the superior articular surfaces of the axis. Each is strengthened at its posterior and inner part by a ligamentous band, the *accessory ligament*, which is attached below to the body of the axis near the base of the odontoid process, and above to the lateral mass of the atlas near the transverse ligament.

The Anterior Atlanto-axial Ligament (fig. 427) is a strong membrane, fixed, above, to the lower border of the anterior arch of the atlas; below,

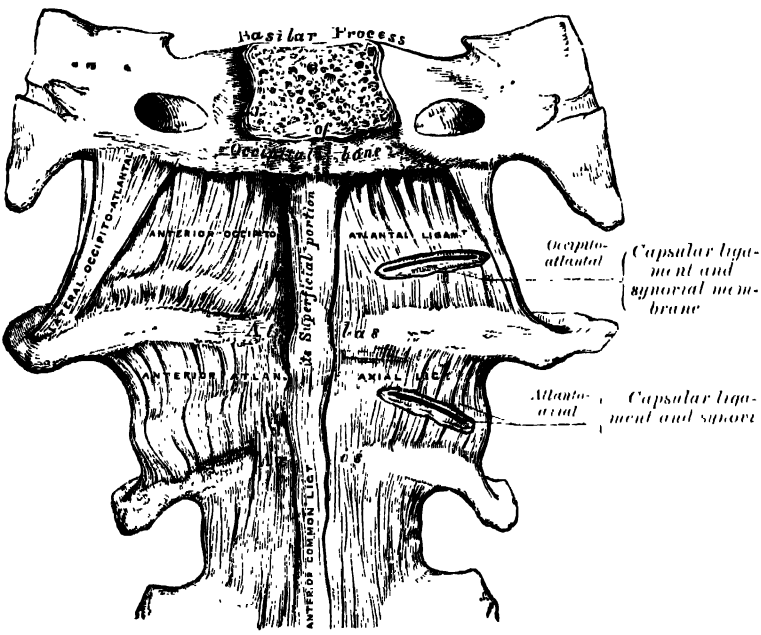
* It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the vertebral column are regulated, so that the connections between the atlas and axis ought always to be studied in association with those between the axis and the skull.

to the front of the body of the axis. It is strengthened in the middle line by a rounded cord, which is connected, above, to the tubercle on the anterior arch of the atlas, and below to the body of the axis, and is a continuation upwards of the anterior common ligament. The ligament is in relation, in front, with the Recti antici majores.

The **Posterior Atlanto-axial Ligament** (fig. 428) is a broad, thin membrane, attached, above, to the lower border of the posterior arch of the atlas; below, to the upper edges of the laminæ of the axis. This ligament supplies the place of the ligamenta subflava, and is in relation, behind, with the Inferior oblique muscles.

The **Transverse Ligament** (lig. transversum atlantis) (figs. 429, 430), is a thick, strong band, which arches across the ring of the atlas, and serves to retain the odontoid process in contact with its anterior arch. It is concave in front, convex behind, broader and thicker in the middle than at either extremity, and firmly attached on either side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a

FIG. 427.—Occipito-atlantal and atlanto-axial ligaments. Front view.

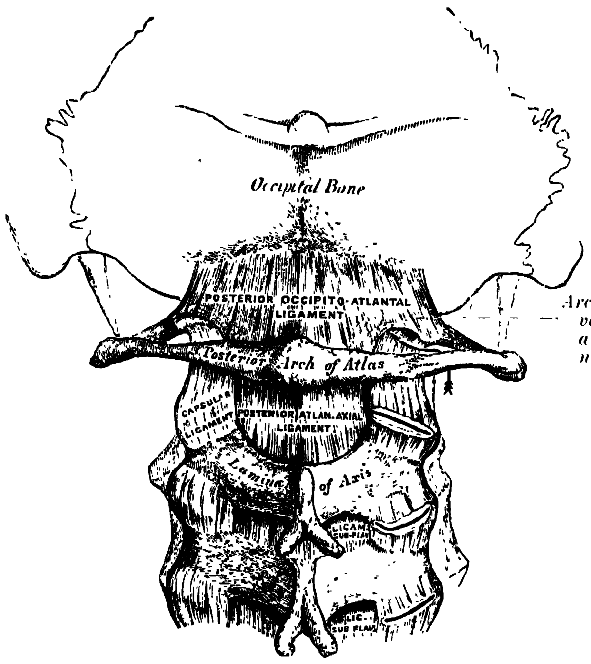


small fasciculus (*crus superius*) is prolonged upwards, and another (*crus inferius*) downwards, from the superficial or posterior fibres of the ligament. The former is inserted into the basilar process of the occipital bone, in close relation with the occipito-axial ligament; the latter descends, to be attached to the posterior surface of the body of the axis; hence, the whole ligament has received the name of *cruciform* (lig. cruciatum atlantis). The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the spinal cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. The neck of the odontoid process is constricted where it is embraced posteriorly by the transverse ligament, so that this ligament suffices to retain the odontoid process in position after all the other ligaments have been divided.

There are *four* **Synovial Membranes** in this articulation: one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, and one between the posterior surface of the odontoid process and the transverse ligament. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

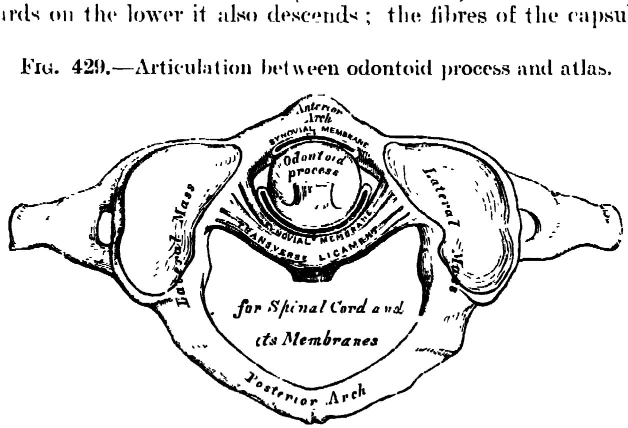
Movements.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments.

Fig. 428.—Occipito-atlantal and atlanto-axial ligaments. Posterior view.



The opposed articular surfaces of the atlas and axis are not reciprocally curved; both surfaces are convex in their long axes. When, therefore, the upper facet glides forwards on the lower it also descends; the fibres of the capsular ligament

Fig. 429.—Articulation between odontoid process and atlas.



are relaxed in a vertical direction, and will then permit of movement in an antero-posterior direction. By this means a shorter capsule suffices and the strength of the joint is materially increased.*

* Corner ('The Physiology of the Atlanto-axial Joints,' *Journal of Anatomy and Physiology*, vol. xli.) states that the movements which take place at these articulations are of a complex nature. The first part of the movement is an eccentric or asymmetrical one; the atlanto-axial joint of the side to which the head is moved is fixed, or practically fixed, by the muscles of the neck, and forms the centre of the movement, while the opposite atlantal facet is carried downwards and forwards on the corresponding axial facet. The second part of the movement is centric and symmetrical, the odontoid process forming the axis of the movement.

The principal muscles by which these movements are produced are the Sterno-mastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Trachelo-mastoid, Rectus capitis posticus major, and Inferior and Superior oblique of the other side.

III. ARTICULATIONS OF THE VERTEBRAL COLUMN WITH THE CRANIUM

The ligaments connecting the vertebral column with the cranium may be divided into two sets, those connecting the atlas with the occipital bone, and those connecting the axis with the occipital bone.

LIGAMENTS CONNECTING THE ATLAS WITH THE OCCIPITAL BONE

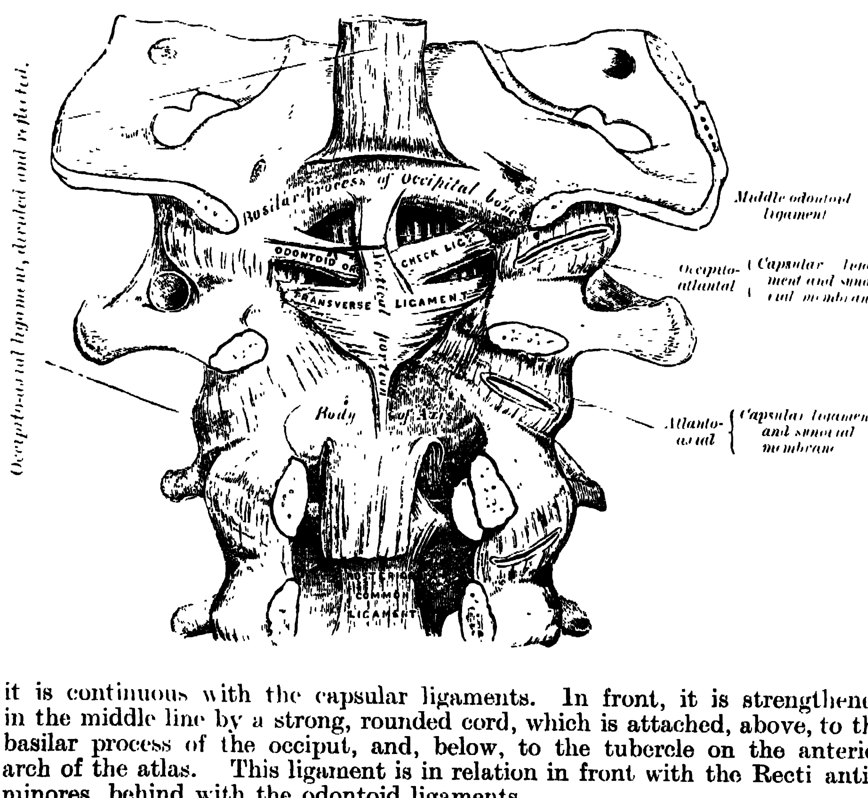
The articulation between the atlas and the occipital bone is a double condyloid joint. Its ligaments are :

Two Capsular.	Posterior Occipito-atlantal.
Anterior Occipito-atlantal.	Two Lateral Occipito-atlantal.

The **Capsular Ligaments** (capsulæ articulares) surround the condyles of the occipital bone, and connect them with the articular processes of the atlas ; they are thin and loose, and are lined by synovial membrane.

The **Anterior Occipito-atlantal Ligament** (membrana atlantooccipitalis anterior) (fig. 427) is a broad membrane, composed of densely woven fibres, which passes between the anterior margin of the foramen magnum above, and the upper border of the anterior arch of the atlas below. Laterally,

FIG. 430.—Occipito-axial and atlanto-axial ligaments. Posterior view, obtained by removing the arches of the vertebræ and the posterior part of the skull.



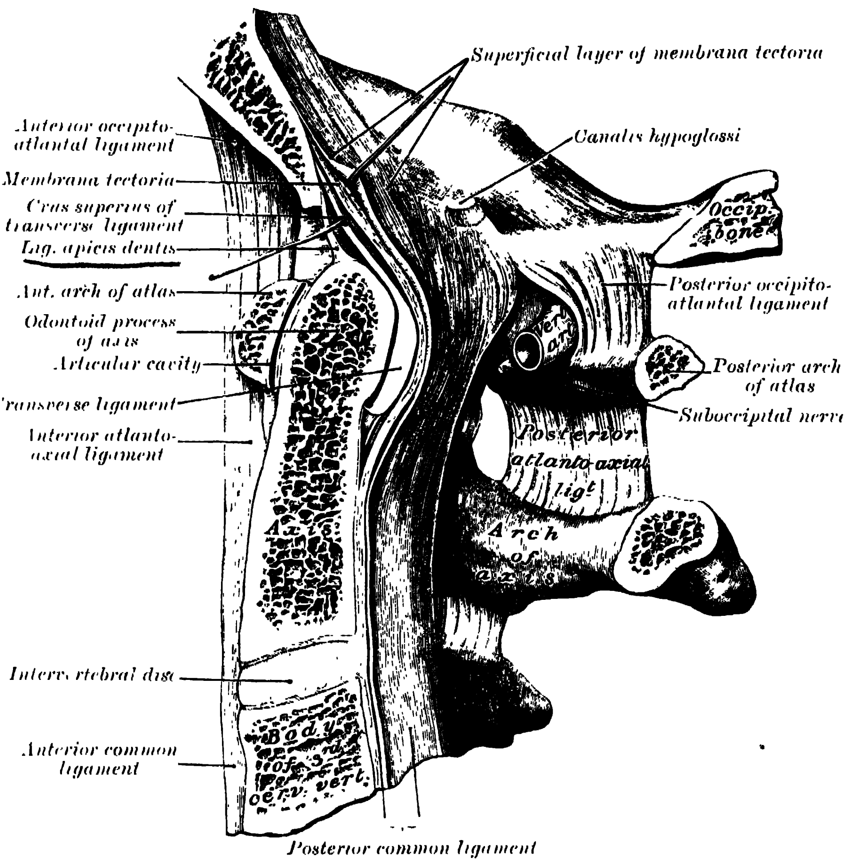
it is continuous with the capsular ligaments. In front, it is strengthened in the middle line by a strong, rounded cord, which is attached, above, to the basilar process of the occiput, and, below, to the tubercle on the anterior arch of the atlas. This ligament is in relation in front with the Recti antici minores, behind with the odontoid ligaments.

The **Posterior Occipito-atlantal Ligament** (membrana atlantooccipitalis posterior) (fig. 428) is a broad but thin membrane connected, above, to the posterior margin of the foramen magnum ; below, to the upper border of the

posterior arch of the atlas. On either side this ligament is defective below, over the superior intervertebral notch, and forms with this notch the boundary of an opening for the passage of the vertebral artery and suboccipital nerve. The free border of the ligament, which arches over the artery and nerve, sometimes becomes ossified. The ligament is in relation, behind, with the Recti postici minores and Obliqui superiores; in front, with the dura mater of the spinal canal, to which it is intimately adherent.

The Lateral Ligaments are thickened portions of the capsular ligament, reinforced by bundles of fibrous tissue, which are directed obliquely upwards and inwards, attached above to the jugular processes of the occipital bone, below, to the bases of the transverse processes of the atlas.

FIG. 431.—Sagittal section through the occipital bone and first three cervical vertebræ. (Spalteholz.)



Synovial Membranes.—There are two synovial membranes: one lining each of the capsular ligaments. The joints occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

Movements.—The movements permitted in this joint are (*a*) flexion and extension, which give rise to the ordinary forward and backward nodding of the head, and (*b*) slight lateral motion to one or other side. *Flexion* is produced mainly by the action of the Recti capitis antici major and minor; *extension* by the Recti capitis postici major and minor, the Superior oblique, the Complexus, Splenius, Sterno-mastoid, and upper fibres of the Trapezius. The Recti laterales are concerned in the *lateral movement*, assisted by the Trapezius, Splenius, Complexus, and the Sterno-mastoid of the same side, all acting together. According to Cruveilhier, there is a slight movement of rotation in this joint.

Ligaments connecting the Axis with the Occipital Bone

Occipito-axial. Three Odontoid.

The **Occipito-axial Ligament** (membrana tectoria) is situated within the spinal canal. It is a broad, strong band, which covers the odontoid process and its ligaments, and appears to be a prolongation upwards of the posterior common ligament of the vertebral column. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it blends with the dura mater of the skull. It is in relation by its anterior surface with the transverse ligament, by its posterior surface with t'articulaticater.

The Odontoid or **Check Ligaments** (ligamenta alaria) (fig. 430) are strong, rounded fibrous cords, which arise one on either side of the upper part of the odontoid process, and, passing obliquely upwards and outwards, are inserted into the rough depressions on the inner sides of the condyles of the occipital bone. In the triangular interval between these ligaments is another fibrous cord, the *ligamentum apicis dentis* or *middle odontoid ligament* (fig. 431), which extends from the apex of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior occipito-atlantal ligament and upper fasciculus of the transverse ligament of the atlas. It is regarded as a rudimentary intervertebral disc, and in it traces of the notochord may persist. The odontoid ligaments serve to limit the extent to which rotation of the cranium may be carried; hence they have received the name of *check ligaments.*

In addition to these ligaments which connect the atlas and axis to the skull, the ligamentum nuchæ must be regarded as one of the ligaments by which the vertebral column is connected with the cranium. It has been described on page 376.

Applied Anatomy.—The ligaments which unite the component parts of the vertebral column together are so strong, and the bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, except in the upper part of the neck, rarely occurs unless accompanied by fracture. Dislocation of the occiput from the atlas has been recorded only in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common: it is the mode in which death is produced in many cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

IV. Articulation of the Mandible (Articulatio Mandibularis)

This is a ginglymo-arthrodial joint; the parts entering into its formation on either side are, above, the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis; and, below, the condyle of the mandible. The ligaments are the following:

Capsular. Internal Lateral.
External Lateral. Interarticular Fibro-cartilage.
Stylo-mandibular.

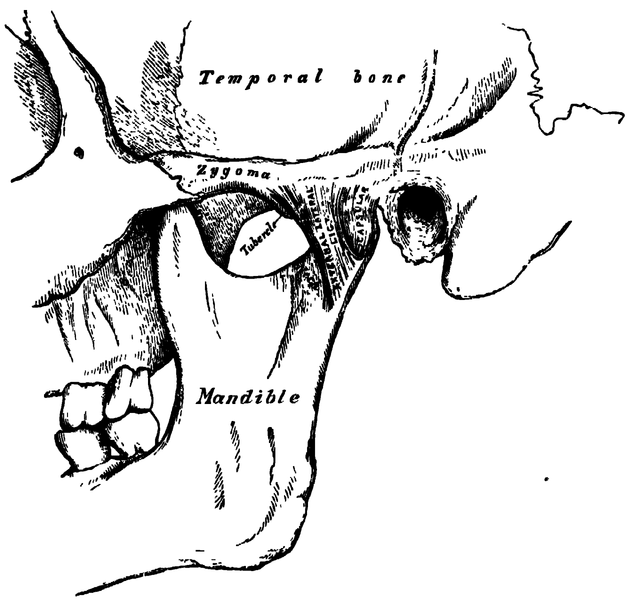
The **Capsular Ligament** (capsula articularis) forms a thin and loose, but distinct capsule, attached above to the circumference of the glenoid cavity and the articular surface immediately in front; below, to the neck of the condyle of the mandible. It is thinnest on the inner side.

The **External Lateral Ligament** (lig. temporomandibulare) (fig. 432) is an accessory band of the capsular ligament, and is not separable from it. It consists of two short, narrow fasciculi, one in front of the other, attached, above, to the outer surface of the zygoma and to the tubercle on its lower border; below, to the outer surface and posterior border of the neck of the mandible. It is broader above than below; its fibres are parallel with one another, and directed obliquely downwards and backwards. Externally, it is covered by the parotid gland, and by the integument.

The **Internal Lateral Ligament** (lig. sphenomandibulare) (fig. 433) is a flat thin band which is attached above to the spinous process of the sphenoid

bone, and, becoming broader as it descends, is inserted into the lingula of the dental foramen. Its outer surface is in relation, above, with the External pterygoid; lower down, it is separated from the neck of the condyle by the

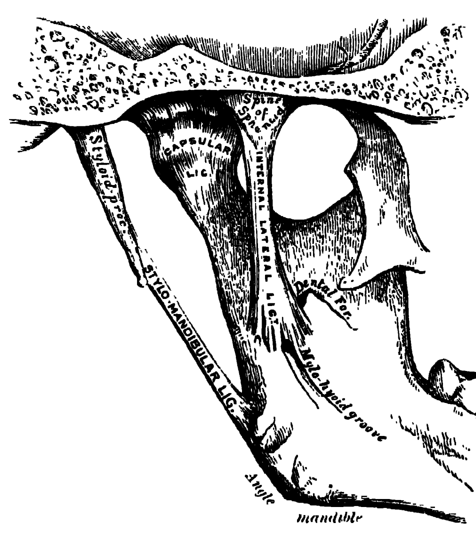
Fig. 432.—Temporo-mandibular articulation. External view.



internal maxillary artery; still more inferiorly, the inferior dental vessels and nerve and a lobule of the parotid gland separate it from the ramus of the mandible. The inner surface is in relation with the Internal pterygoid.

The **Interarticular Fibro-cartilage** (discus articularis) (fig. 434) is a thin plate of an oval form, placed horizontally between the condyle of the mandible and the glenoid cavity. Its upper surface is concavo-convex from before backwards, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, which is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament; and in front to the tendon of the External pterygoid. It is thicker at its periphery, especially behind, than at its centre. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a synovial membrane.

Fig. 433.—Temporo-mandibular articulation. Internal view.



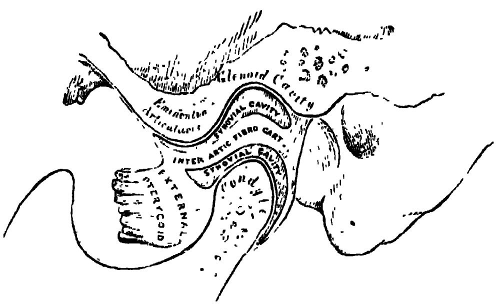
The **Synovial Membranes,** two in number, are placed one above, and the other below, the fibro-cartilage. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the glenoid cavity and eminentia articularis on to the upper surface of the fibro-cartilage. The lower one passes from the under surface of the fibro-cartilage to the neck of the condyle, being prolonged a little farther downwards behind than in front. The interarticular cartilage is sometimes perforated in its centre, and the two synovial sacs then communicate with each other.

The **Stylo-mandibular Ligament** (lig. stylomandibulare) (fig. 433) is a specialised band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible, between the Masseter and Internal pterygoid. This ligament separates the parotid from the submaxillary gland, and from its inner side some fibres of the Stylo-glossus take origin. Although usually classed among the ligaments of the jaw, it can only be considered as accessory to the articulation.

The *nerves* of this joint are derived from the auriculo-temporal and masseteric branches of the inferior maxillary, the *arteries* from the temporal branch of the external carotid.

Movements.—The movements permitted in this articulation are very extensive. Thus, the mandible may be depressed or elevated, or it may be carried forwards or backwards; a slight amount of lateral movement is also permitted. It must be borne in mind that there are two distinct joints in this articulation—one between the condyle and the interarticular fibro-cartilage, and another between the fibro-cartilage and the glenoid fossa. When the mouth is but slightly opened, as during ordinary conversation, the movement is confined to the lower of the two joints. On the other hand, when the mouth is opened more widely, both joints are concerned in the movement; in the lower joint, viz. that between the condyle and the fibro-cartilage, the movement is of a hinge-like character, the condyle moving round a transverse axis on the fibro-cartilage, while in the upper joint the movement is of a gliding character, the fibro-cartilage, together with the condyle, gliding forwards on to the eminentia articularis, round an axis which passes through the dental foramina. These two movements take place simultaneously, the condyle and fibro-cartilage move forwards on the eminence, and at the same time the condyle revolves on the fibro-cartilage. In the opposite movement of shutting the mouth the reverse action takes place; the fibro-cartilage glides back, carrying the condyle with it, and this at the same time revolves back to its former position. When the mandible is carried horizontally forwards, as in protruding the lower incisors in front of the upper, the movement takes place principally in the upper compartment of the joint, the fibro-cartilage and the condyle gliding forwards on the glenoid fossa. The grinding or chewing movement is produced by one condyle, with its fibro-cartilage, gliding alternately forwards and backwards, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on the fibro-cartilage. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

FIG. 434.—Vertical section of temporo-mandibular articulation.



The mandible is *depressed* by its own weight, assisted by the Platysma, the Digastric, the Mylo-hyoid, and the Genio-hyoid. It is *elevated* by the anterior part of the Temporal, Masseter, and Internal pterygoid. It is drawn *forwards* by the simultaneous action of the External and Internal pterygoids, the superficial fibres of the Masseter and the anterior fibres of the Temporal; and it is drawn *backwards* by the deep fibres of the Masseter and the posterior fibres of the Temporal.

The grinding movement is caused by the alternate action of the two Pterygoids of either side.

Surface Form.—The temporo-mandibular articulation is quite superficial, and is situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter. Its position can be ascertained by feeling for the condyle of the jaw, the movements of which can be distinctly felt in opening and shutting the mouth. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the eminentia articularis, and a depression is felt in the situation of the joint.

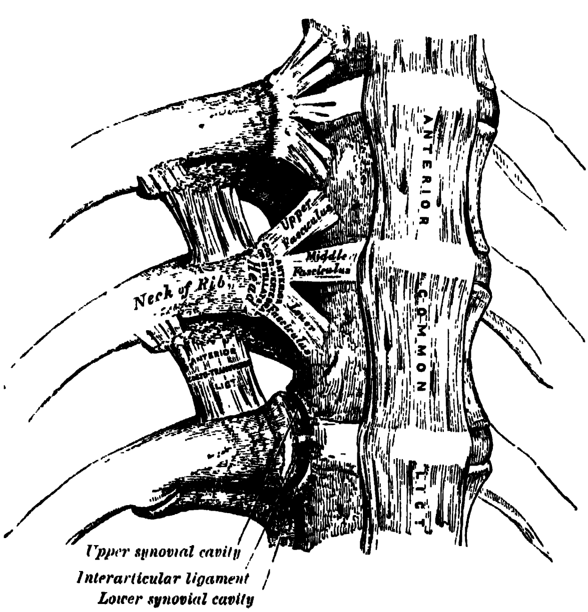
Applied Anatomy.—The mandible is dislocated only in one direction—viz. forwards. The accident is caused by violence or muscular action. When the mouth is open, the condyle is situated on the eminentia articularis, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forwards into the zygomatic fossa. The displacement may be unilateral or bilateral. Reduction is accomplished by depressing the jaw with the thumbs placed on the last molar teeth, and at the same time elevating the chin. The downward pressure overcomes the spasm of the Masseter, Temporal and Internal pterygoid, and elevation of the chin throws the condyle backwards; the above-mentioned muscles then draw the condyle back into its normal position.

In close relation to the condyle of the mandible are the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to the ear; or on the other hand inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. The joint is also occasionally the seat of osteo-arthritis, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the mandible, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

V. ARTICULATIONS OF THE RIBS WITH THE VERTEBRÆ (ARTICULATIONES COSTOVERTEBRALES)

The articulations of the ribs with the vertebral column may be divided into two sets: 1, those which connect the heads of the ribs with the bodies

FIG. 435.—Costo-central and costo-transverse articulations. Anterior view.



of the vertebræ (*costo-central*); 2, those which connect the necks and tubercles of the ribs with the transverse processes (*costo-transverse*).

1. Costo-central Articulations (Articulationes Capitulorum) (fig. 435)

These constitute a series of gliding or arthrodial joints, and are formed by the articulation of the heads of the ribs with the facets on the contiguous margins of the bodies of the thoracic vertebræ and with the intervertebral discs between them; in the case of the first, tenth, eleventh, and twelfth ribs the cavity is formed by a single vertebra. The ligaments of the joints are:

Capsular. Anterior Costo-vertebral or Stellate. Interarticular.

The **Capsular Ligament** (capsula articularis) surrounds and encloses the joint, being composed of short, strong fibres, which pass between the head of the rib and the circumference of the articular cavity formed by the intervertebral disc and the adjacent vertebræ. It is most distinct at the upper and lower parts of the articulation; some of its upper fibres pass through the intervertebral foramen to the back of the intervertebral disc, while its posterior fibres are continuous with the middle costo-transverse ligament.

The **Anterior Costo-vertebral** or **Stellate Ligament** (lig. capituli costæ radiatum) is a specialised part of the capsule, and connects the anterior part of the head of each rib with the sides of the bodies of two vertebræ, and the intervertebral disc between them. It consists of three flat bundles of ligamentous fibres, which are attached to the anterior part of the head of the rib, just beyond the articular surface. The superior bundle passes upwards to be connected with the body of the vertebra above; the inferior one descends to the body of the vertebra below; and the middle one, the smallest and least distinct, passes horizontally inwards, to be attached to the intervertebral disc. The ligament is in relation, in front, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; behind, with the interarticular ligament and synovial membranes.

In the first costo-central joint, where the rib articulates with a single vertebra, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body of the first thoracic. In the costo-central articulations of the tenth, eleventh, and twelfth ribs, each of which articulates with a single vertebra, the division does not exist; but the fibres of the ligament in each case radiate and are connected to the vertebra above, as well as to that with which the rib articulates.

The **Interarticular Ligament** (lig. capituli costæ interarticulare) is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downwards, attached by one extremity to the sharp crest which separates the two articular facets on the head of the rib, and by the other to the intervertebral disc; it divides the joint into two cavities. In the first, tenth, eleventh, and twelfth costo-central joints, the interarticular ligament does not exist; consequently, there is but one cavity. This ligament is the homologue of the *ligamentum conjugale* of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disc.

Synovial Membranes.—There are two synovial membranes in each of the articulations in which there is an interarticular ligament, one above and one below this structure: only one in those joints where there is a single cavity.

2. Costo-transverse Articulations (Articulationes Costotransversariæ) (fig. 436)

The articular portion of the tubercle of the rib forms with the articular facet on the adjacent transverse process an arthrodial joint.

In the eleventh and twelfth ribs this articulation is wanting.

The ligaments connecting these parts are:

Capsular. Middle Costo-transverse (Interosseous).
Anterior Costo-transverse. Posterior Costo-transverse.

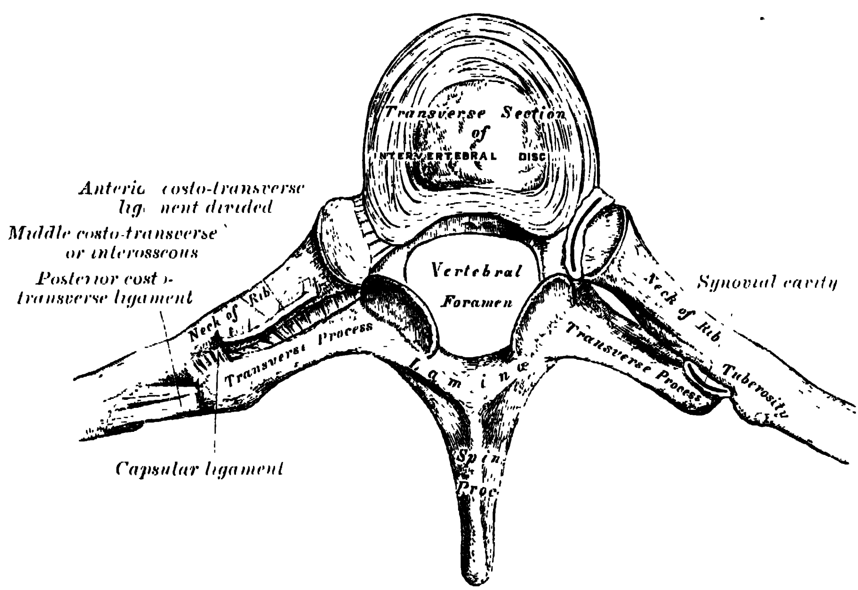
The **Capsular Ligament** (capsula articularis) is a thin, membranous

sac attached to the circumferences of the articular surfaces, and lined by a synovial membrane.

The **Anterior** or **Superior Costo-transverse Ligament** (lig. costotransversarium anterius) consists of two sets of fibres: one (anterior) is attached below to the sharp crest on the upper border of the neck of the rib, and passes obliquely upwards and outwards to the lower border of the transverse process immediately above; the other (posterior) is attached below to the neck of the rib, and passes upwards and inwards to the base of the transverse process and outer border of the inferior articular process of the vertebra above. This ligament is in relation, in front, with the intercostal vessels and nerves; behind, with the Longissimus dorsi. Its *internal border* is thickened and free, and bounds an aperture which transmits the posterior branches of the intercostal vessels and nerves. Its *external border* is continuous with a thin aponeurosis, which covers the External intercostal muscle.

The first rib has no anterior costo-transverse ligament; a band of fibres (*lig. lumbocostale*) in series with the anterior costo-transverse ligaments

FIG. 436.—Costo-transverse articulation. Seen from above.



connects the neck of the twelfth rib to the base of the transverse process of the first lumbar vertebra.

The **Middle Costo-transverse** or **Interosseous Ligament** (lig. colli costæ) consists of short but strong fibres, which pass between the rough surface on the back of the neck of the rib and the anterior surface of the adjacent transverse process.

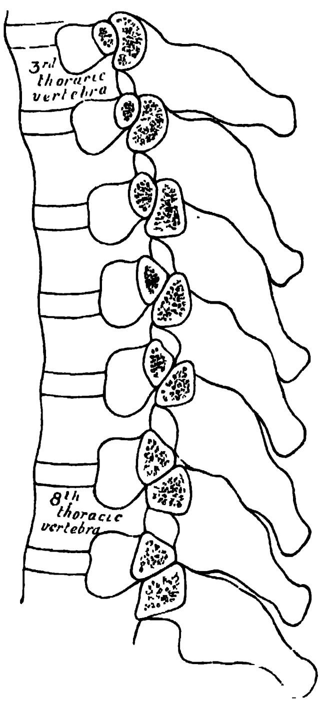
A rudimentary ligament may be present in the case of the eleventh and twelfth ribs.

The **Posterior Costo-transverse Ligament** (lig. costotransversarium posterius) is a short but thick and strong fasciculus, which passes obliquely from the summit of the transverse process to the rough non-articular portion of the tubercle of the rib. The ligaments attached to the upper ribs ascend from the transverse processes; they are shorter and more oblique than those attached to the inferior ribs, which descend slightly.

Movements.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the stellate and interarticular ligaments that only slight gliding movements of the articular surfaces on one another can take place. Similarly, the strong costo-transverse ligaments binding the necks and tuberosities of the

ribs to the transverse processes limit the movements of the costo-transverse joints to slight gliding, the nature of which is determined by the shape and direction of the articular surfaces (fig. 437). In the upper six ribs the articular surfaces on the tuberosities are oval in shape and convex from above downwards; they fit into corresponding concavities on the *anterior surfaces* of the transverse processes, so that upward and downward movements of the tuberosity are associated with rotation of the rib neck on its long axis. In the seventh, eighth, ninth, and tenth ribs the articular surfaces on the tuberosities are flat, and are directed obliquely downwards, inwards, and backwards. The surfaces with which they articulate are placed on the *upper margins* of the transverse processes; when, therefore, the tuberosities are drawn up they are at the same time carried backwards and inwards. The two joints, costo-central and costo-transverse, move simultaneously and in the same directions, the total effect being that the neck of the rib moves as if on a single joint, of which the costo-central and costo-transverse articulations form the extremities. In the upper six ribs the neck of the rib moves but slightly upwards and downwards; its chief movement is one of rotation round its own long axis, rotation backwards being associated with depression, rotation forwards with elevation. In the seventh, eighth, ninth, and tenth ribs the neck of the rib moves upwards, backwards, and inwards, or downwards forwards and outwards; very slight rotation accompanies these movements.

Fig. 437.—Section of the costo-transverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper with the flattened facets on the lower transverse processes.



VI. ARTICULATIONS OF THE CARTILAGES OF THE RIBS WITH THE STERNUM (ARTICULATIONES STERNOCOSTALES) (fig. 438).

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is almost always directly united with the sternum, and which must, therefore, be regarded as a synarthrodial articulation. The ligaments connecting them are:

Capsular.
Anterior Chondro-sternal.
Posterior Chondro-sternal.
Interarticular Chondro-sternal.
Anterior Chondro-xiphoid.
Posterior Chondro-xiphoid.

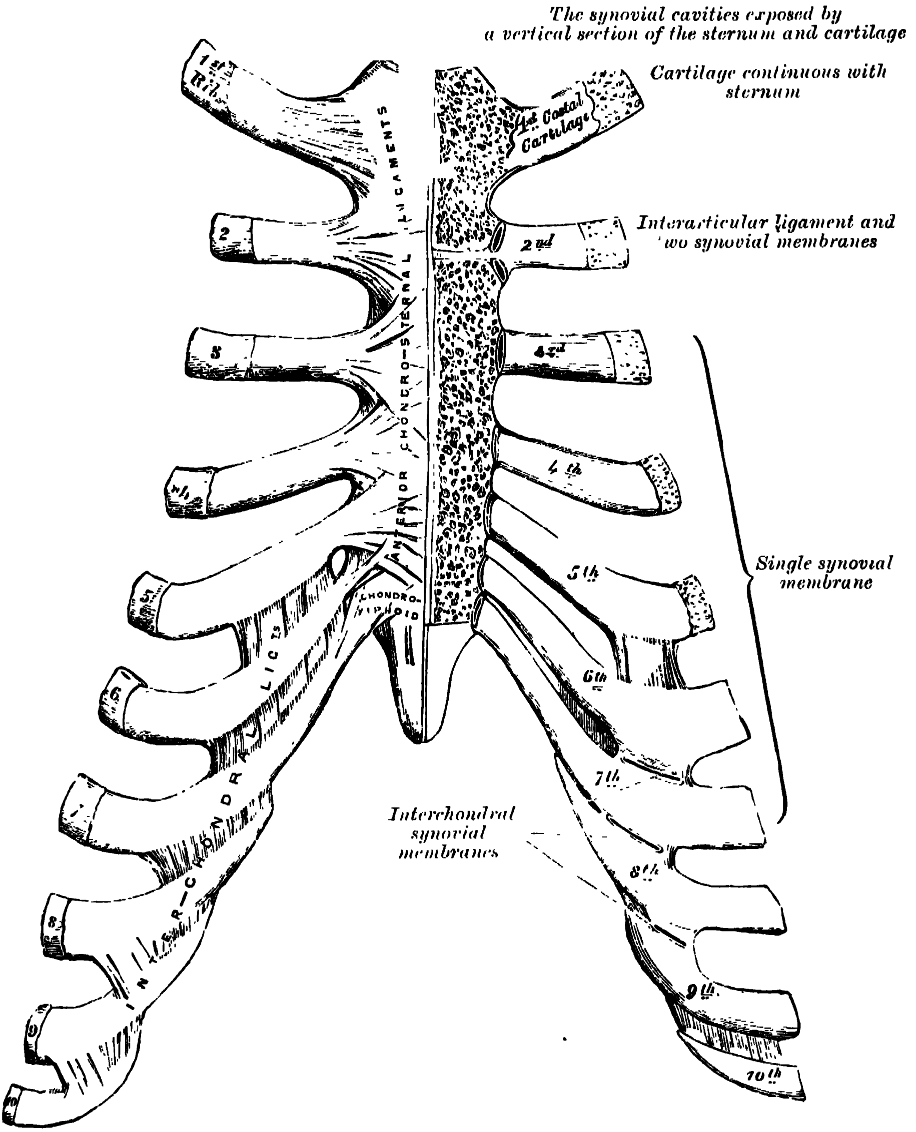
The **Capsular Ligaments** (capsulæ articulares) surround the joints formed between the cartilages of the true ribs and the sternum. They are very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower parts of the articulations by a few fibres, which pass from the cartilages to the side of the sternum.

The **Anterior Chondro-sternal Ligaments** (ligg. sternocostalia radiata) are accessory parts of the capsular ligaments, and consist of broad and thin membranous bands that radiate from the front of the inner extremities of the cartilages of the true ribs to the anterior surface of the sternum. They are composed of fasciculi which pass in different directions. The *superior fasciculi* ascend obliquely, the *inferior* pass obliquely downwards, and the *middle fasciculi* horizontally. The superficial fibres are the longest; they intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane (membrana sterni) which covers the front of the sternum. This is more distinct at the lower than at the upper part.

The **Posterior Chondro-sternal Ligaments** are also parts of the capsular ligaments, but are less thick and distinct than the anterior ; they are composed of fibres which radiate from the posterior surfaces of the sternal ends of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The **Interarticular Chondro-sternal Ligaments** (ligg. sternocostalia interarticularia).—These are found constantly only between the second costal

FIG. 438.—Sterno-costal and interchondral articulations. Anterior view.



cartilages and the sternum. The cartilage of the *second rib* is connected with the sternum by means of an interarticular ligament, attached by one extremity to the cartilage of the rib, and by the other to the fibro-cartilage which unites the first and second pieces of the sternum. This articulation is provided with two synovial membranes. Occasionally the cartilage of the *third rib* is connected with the sternum by means of an interarticular ligament which is attached by one extremity to the cartilage of the rib, and by

the other to the point of junction of the second and third pieces of the sternum. Still more rarely similar ligaments are found in the other four joints of the series. In the lower two the ligament sometimes completely obliterates the cavity, so as to convert the articulation into an amphiarthrosis.

The **Anterior Chondro-xiphoid** (lig. costoxiphoideum anterius).—This is a band of fibres which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform process. It varies in length and breadth in different subjects.

The **Posterior Chondro-xiphoid** (lig. costoxiphoideum posterius) is a similar though less distinct band on the posterior surface.

Synovial Membranes.—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the manubrium. There are two synovial membranes in the articulation of the second costal cartilage with the sternum. There is generally one synovial membrane in each of the joints between the third, fourth, fifth, sixth, and seventh costal cartilages and the sternum; but it is sometimes absent in the sixth and seventh chondro-sternal joints. If an interarticular ligament exists in any of these joints, there are two synovial cavities. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age, the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

Movements.—Slight gliding movements are permitted in the chondro-sternal articulations.

Articulations of the Cartilages of the Ribs with each other (Articulationes Interchondrales) (fig. 438)

The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth, oblong-shaped facets. Each articulation is enclosed in a thin *capsular ligament*, lined by *synovial membrane* and strengthened externally and internally by ligamentous fibres (*interchondral ligaments*) which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates by its lower border with the adjoining cartilage by a small oval facet; more frequently the connection is by a few ligamentous fibres. Occasionally, the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages (Costo-chondral)

The outer extremity of each costal cartilage is received into a depression in the sternal end of the rib, and the two are held together by the periosteum.

VII. Articulations of the Sternum

The first piece of the sternum is united to the second either by an amphiarthrodial joint—a piece of fibro-cartilage connecting the segments—or by a diarthrodial joint, in which each bone is clothed with a lamina of cartilage, adherent on one side, free on the other. In the latter case, the cartilage covering the gladiolus is continued without interruption on to the cartilages of the facets for the second ribs. Rivington found the diarthrodial form of joint in about one-third of the specimens examined by him, Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Rivington's opinion, from the amphiarthrodial form, by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. The two segments are further connected by anterior and posterior intersternal ligaments.

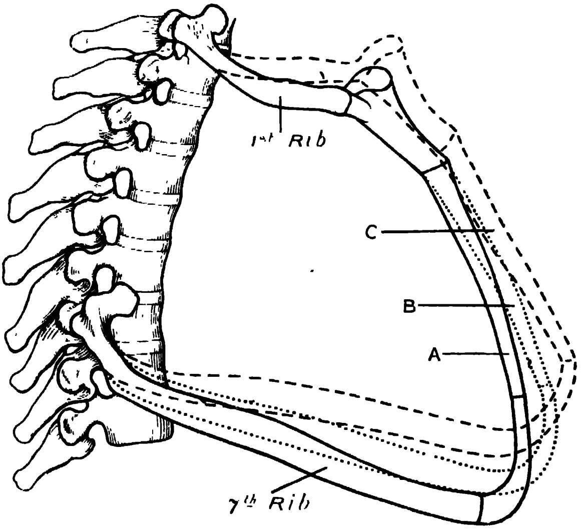
The **Anterior Intersternal Ligament** consists of longitudinal fibres, which blend with those of the anterior chondro-sternal ligaments and with the tendinous fibres of origin of the Pectoralis major. This ligament is rough, irregular, and much thicker below than above.

The **Posterior Intersternal Ligament** is disposed in a somewhat similar manner on the posterior surface of the articulation.

Mechanism of the Thorax

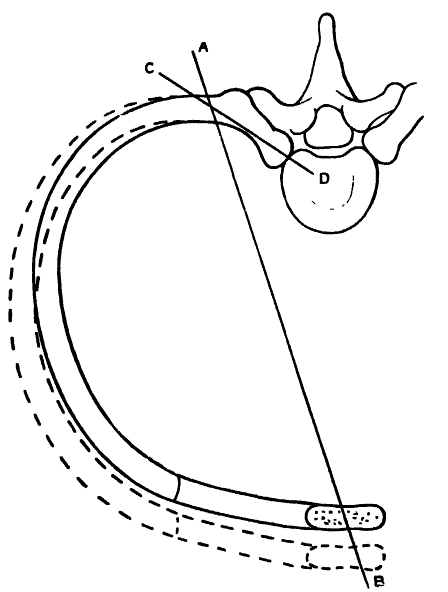
Each rib possesses its own range and variety of movements, but the movements of all are combined in the respiratory excursions of the thorax. Each rib may be regarded as a lever the fulcrum of which is situated immediately outside the costo-transverse articulation, so that when the shaft of the rib is elevated the neck is depressed and *vice versa*; from the disproportion in length of the arms of the lever a slight movement at the vertebral end of the rib is greatly magnified at the anterior extremity.

Fig. 439.—Lateral view of first and seventh ribs in position, showing the movements of the sternum and ribs in, A, ordinary expiration; B, quiet inspiration; C, forced inspiration.



The anterior ends of the ribs lie on a lower plane than the posterior; when therefore the rib-shaft is elevated the anterior extremity is thrust also forwards. Again, the middle of the shaft lies in a plane below that passing through the two extremities, so that when the shaft is elevated relatively to its ends it is at the same time carried outwards from the median plane of the thorax. Further, each rib forms the segment of a curve which is greater than that of the rib immediately above, and therefore the elevation of a rib increases the transverse diameter of the thorax in the plane to which it is raised. The modifications of the rib movements at their vertebral ends have already been described (page 387). Further modifications result from the attachments of their anterior extremities, and it is convenient therefore to consider separately the movements of the ribs of the three groups—vertebro-sternal, vertebro-chondral, and vertebral.

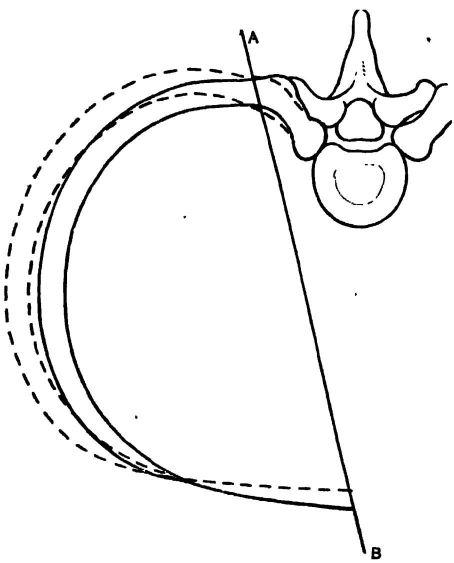
Fig. 440.—Diagram showing the axes of movement (A B and C D) of a vertebro-sternal rib. The interrupted lines indicate the position of the rib in inspiration.



Vertebro-sternal ribs (figs. 439, 440).—The first rib differs from the others of this group in that its attachment to the sternum is a rigid one; this is counterbalanced to some extent by the fact that its head possesses no interarticular ligament, and is therefore more movable. The first pair of ribs with the manubrium sterni move as a single piece, the anterior portion being elevated by rotatory movements at the vertebral extremities. In normal quiet respiration the movement of this arc is practically *nil*; when it does occur the anterior part is raised and carried

forwards, increasing the antero-posterior and transverse diameters of this region of the chest. The movement of the second rib is also slight in normal respiration, as its anterior extremity is fixed to the manubrium, and prevented therefore from moving upwards. The chondro-sternal articulation, however, allows the middle of the shaft to be drawn up, and in this way the transverse thoracic diameter is increased. Elevation of the third, fourth, fifth and sixth ribs raises and thrusts forwards their anterior extremities, the greater part of the movement being effected by the rotation of the rib-neck backwards. The thrust of the anterior extremities carries forwards and upwards the gladiolus, which moves on the manubrio-gladiolar joint, and thus the antero-posterior thoracic diameter is increased. This movement is, however, soon arrested, and the elevating force is then expended in raising the middle part of the rib-shaft and everting its lower border; at the same time the costo-chondral angle is opened out. By these latter movements a considerable increase in the transverse diameter of the thorax is effected.

Fig. 441.—Diagram showing the axis of movement (A B) of a vertebro-chondral rib. The interrupted lines indicate the position of the rib in inspiration.



Vertebro-chondral ribs (fig. 441).—The seventh rib is included with this group, as it conforms more closely to their type. While the movements of these ribs assist in enlarging the thorax for respiratory purposes they are also concerned in increasing the upper abdominal space for viscera displaced by the action of the Diaphragm. The costal cartilages articulate with one another, so that each pushes up that above it, the final thrust being directed to pushing forwards and upwards the lower end of the gladiolus. The amount of elevation of the anterior extremities is limited on account of the very slight rotation of the rib-neck. Elevation of the shaft is accompanied by an outward and backward movement; the outward movement everts the anterior end of the rib and opens up the subcostal angle, while the backward movement pulls back the anterior extremity and counteracts the forward thrust due to its elevation; this latter is most noticeable in the lower ribs, which are the shortest. The total result is a considerable increase in the transverse and a diminution in the median antero-posterior diameters of the upper part of the abdomen; at the same time, however, the lateral antero-posterior diameters of the abdomen are increased.

Vertebral ribs.—These ribs, having only costo-central articulations with no interarticular ligaments and free anterior extremities, are capable of slight movements in all directions. When the other ribs are elevated these are depressed and fixed to form points of action for the Diaphragm.

VIII. ARTICULATION OF THE VERTEBRAL COLUMN WITH THE PELVIS

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which join the movable segments of the vertebral column with each other—viz.: 1. The continuation downwards of the anterior and posterior common ligaments. 2. The intervertebral disc, connecting the body of the last lumbar to that of the first sacral and forming an amphiarthrodial joint. 3. Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the sacral canal. 4. Capsular ligaments connecting

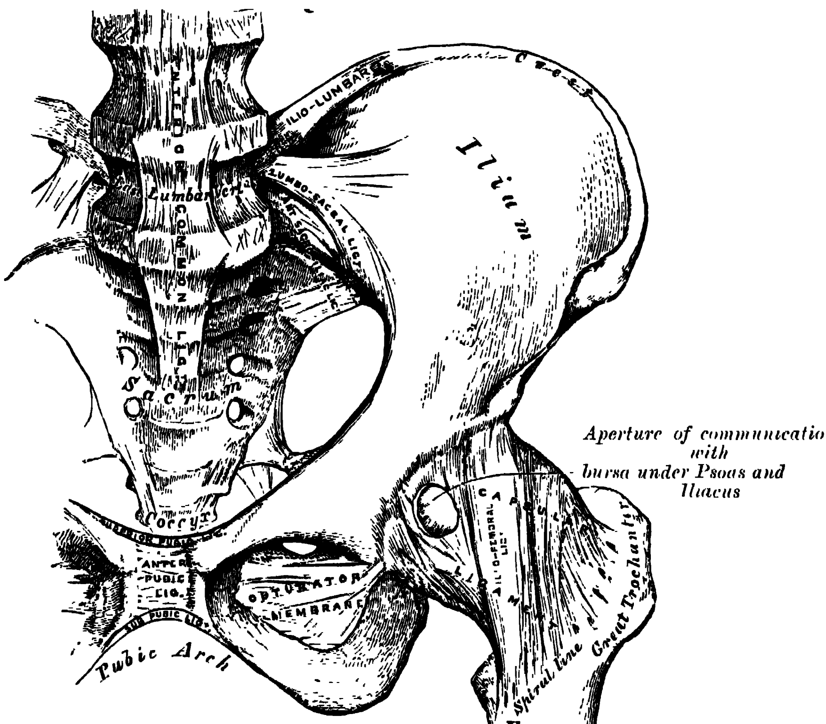
the articular processes and forming a double-arthrodia. 5. Inter- and supraspinous ligaments.

Two additional ligaments connect the pelvis with the vertebral column; these are the lumbo-sacral and the ilio-lumbar.

The **Lumbo-sacral Ligament** (fig. 442) is a short, thick, triangular fasciculus, which is connected above to the lower and front part of the transverse process of the last lumbar vertebra, passes obliquely outwards, and is attached below to the lateral surface of the base of the sacrum, becoming blended with the anterior sacro-iliac ligament. In front this ligament is in relation with the Psoas.

The **Ilio-lumbar Ligament** (lig. iliolumbale) (fig. 442), the thickened lower edge of the anterior lamella of the lumbar fascia, passes horizontally outwards from the apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacro-iliac articulation.

FIG. 442.—Articulations of pelvis and hip. Anterior view.



It is of a triangular form, thick and narrow internally, broad and thin externally. In front it is in relation with the Psoas; behind, with the muscles occupying the vertebral groove; above, with the Quadratus lumborum.

IX. ARTICULATIONS OF THE PELVIS

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those uniting the sacrum and coccyx. 4. Those between the two pubic bones.

1. Articulation of the Sacrum and Ilium (Articulatio Sacroiliaca)

The sacro-iliac articulation is an amphiarthrodial joint, formed between the lateral surfaces of the sacrum and the ilium. The articular, ear-shaped surface of each bone is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. These cartilaginous plates are in close contact with each other, and to a certain extent are united together by irregular

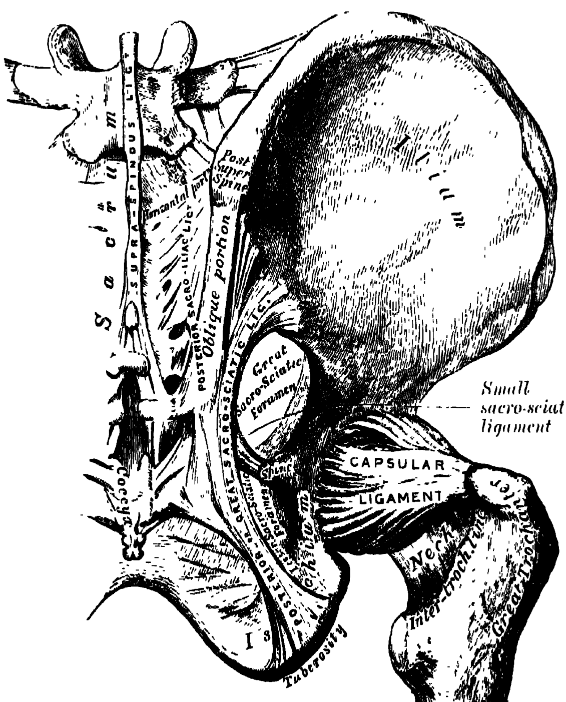
patches of softer fibro-cartilage, and at their upper and posterior part by fine interosseous fibres. In a considerable part of their extent, especially in advanced life, they are not connected together, but are separated by a space containing a synovia-like fluid, and hence the joint presents the characters of a diarthrosis.

The ligaments connecting these surfaces are the anterior and posterior sacro-iliac.

The **Anterior Sacro-iliac Ligament** (lig. sacroiliacum anterius) (fig. 442) consists of numerous thin bands, which connect the anterior surfaces of the sacrum and ilium.

The **Posterior Sacro-iliac Ligament** (lig. sacroiliacum posterius) (fig. 443) is a strong ligament, situated in a deep depression between the sacrum and ilium behind, and forming the chief bond of connection between those bones. It consists of numerous strong fasciculi, which pass between the bones in various directions. The upper part of the ligament (lig. sacroiliacum posterius breve) is nearly horizontal in direction, and passes

FIG. 443.—Articulations of pelvis and hip. Posterior view.



from the first and second transverse tubercles on the posterior surface of the sacrum to the rough, uneven surface at the posterior part of the inner surface of the ilium. The lower part (lig. sacroiliacum posterius longum), oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; the lower part is sometimes called the *oblique sacro-iliac ligament.*

Surface Form.—The position of the sacro-iliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

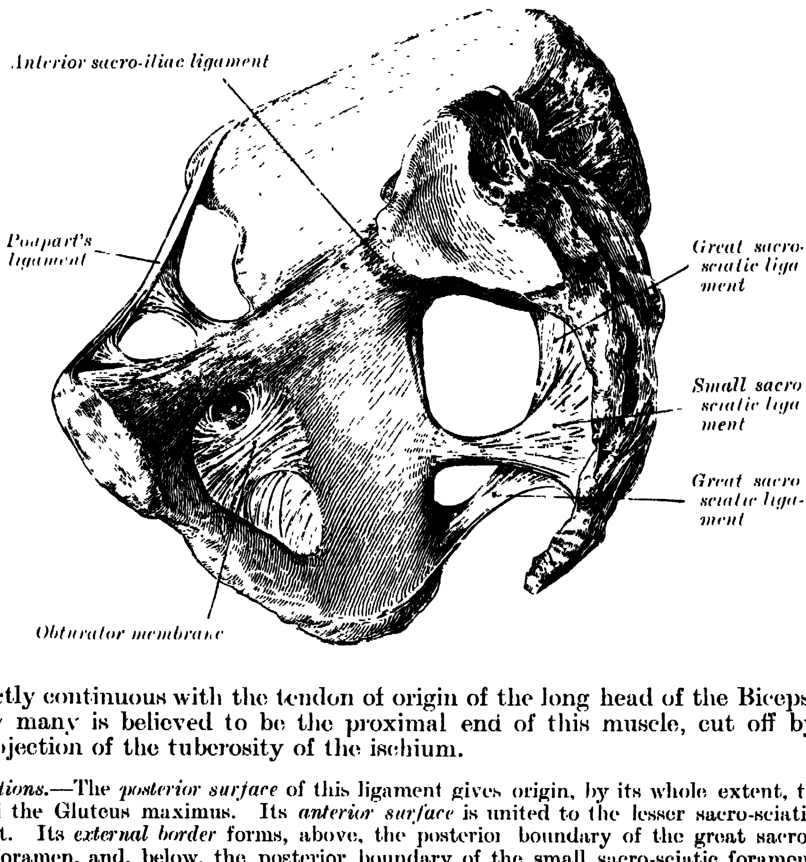
2. Ligaments passing between the Sacrum and Ischium (fig. 444)

The Great Sacro-sciatic. The Small Sacro-sciatic.

The **Great or Posterior Sacro-sciatic Ligament** (lig. sacrotuberosum) is situated at the lower and back part of the pelvis. It is flat, and triangular in

form ; narrower in the middle than at the extremities ; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downwards, outwards, and forwards, it becomes narrow and thick, but at its insertion into the inner margin of the tuberosity of the ischium, it increases in breadth, and is prolonged forwards along the inner margin of the ramus, forming what is known as the *falciform ligament*, the free concave edge of which gives attachment to the obturator fascia. One of its surfaces is turned towards the perinæum, the other towards the Obturator internus. The lower border of the ligament

FIG. 444.—Side view of pelvis, showing the great and lesser sacro-sciatic ligaments.



is directly continuous with the tendon of origin of the long head of the Biceps, and by many is believed to be the proximal end of this muscle, cut off by the projection of the tuberosity of the ischium.

Relations.—The *posterior surface* of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus. Its *anterior surface* is united to the lesser sacro-sciatic ligament. Its *external border* forms, above, the posterior boundary of the great sacro-sciatic foramen, and, below, the posterior boundary of the small sacro-sciatic foramen. Its *lower border* forms part of the boundary of the perinæum. It is pierced by the coccygeal branch of the sciatic artery, and coccygeal nerve.

The **Small or Anterior Sacro-sciatic Ligament** (lig. sacrospinosum), much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, in front of the attachment of the great sacro-sciatic ligament with which its fibres are intermingled.

Relations.—It is in relation *anteriorly*, with the Coccygeus to which it is closely connected ; *posteriorly*, it is covered by the great sacro-sciatic ligament, and crossed by the internal pudic vessels and nerve. Its *superior border* forms the lower boundary of the great sacro-sciatic foramen ; its *inferior border*, part of the margin of the small sacro-sciatic foramen.

These two ligaments convert the sacro-sciatic notches into foramina. The *superior* or *great* sacro-sciatic foramen (foramen ischiadicum majus) is bounded, in front and above, by the posterior border of the os innominatum ; behind, by the great sacro-

sciatic ligament; and below, by the small sacro-sciatic ligament. It is partially filled up, in the recent state, by the Pyriformis which passes through it. Above this muscle, the gluteal vessels and superior gluteal nerve emerge from the pelvis; and below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, the inferior gluteal nerve, and the nerves to the Obturator internus and Quadratus femoris make their exit from the pelvis. The *inferior* or *small* sacro-sciatic foramen (foramen ischiadicum minus) is bounded, in front, by the tuber ischii; above, by the spine of the ischium and small sacro-sciatic ligament; behind, by the great sacro-sciatic ligament. It transmits the tendon of the Obturator internus, its nerve, and the internal pudic vessels and nerve.

3. Articulation of the Sacrum and Coccyx

This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum, and the base of the coccyx. It is homologous with the joints between the bodies of the vertebræ, and is connected by similar ligaments. They are:

Anterior Sacro-coccygeal.	Lateral Sacro-coccygeal.
Posterior Sacro-coccygeal.	Interposed Fibro-cartilage.
Interarticular.	

The **Anterior Sacro-coccygeal Ligament** (lig. sacrococcygeum anterius) consists of a few irregular fibres, which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum.

The **Posterior Sacro-coccygeal Ligament** (lig. sacrococcygeum posterius) is a flat band, of a pearly tint, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal and its superficial fibres are much longer than the more deeply seated. It is in relation, behind, with the Gluteus maximus.

A **Lateral Sacro-coccygeal Ligament** (lig. sacrococcygeum laterale) exists on either side of the joint and connects the transverse process of the coccyx to the lower lateral angle of the sacrum.

A disc of **Fibro-cartilage** is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from those between the bodies of the vertebræ in being thinner, and its central part firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally the coccyx is freely movable, most notably during pregnancy; in such cases a synovial membrane is present.

The **Interarticular Ligaments** are thin bands of ligamentous tissue, which unite the cornua of the two bones.

The different segments of the coccyx are connected together by the extension downwards of the anterior and posterior sacro-coccygeal ligaments, thin annular discs of fibro-cartilage being interposed between the segments. In the adult male, all the pieces become ossified together at a comparatively early period; but in the female, this does not commonly occur until a later period of life. At a more advanced age the joint between the sacrum and coccyx is obliterated.

Movements.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are forwards and backwards; they are very limited. Their extent increases during pregnancy.

4. Articulation of the Pubic Bones (Symphysis Pubis)

The articulation between the pubic bones is an amphiarthrodial joint, formed between the two oval articular surfaces of the pubic bones. The ligaments of this articulation are:

Anterior Pubic.	Superior Pubic.
Posterior Pubic.	Subpubic.
Interpubic Disc.	

The **Anterior Pubic Ligament** (lig. pubicum anterius) (fig. 442) consists of several superimposed layers, which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating

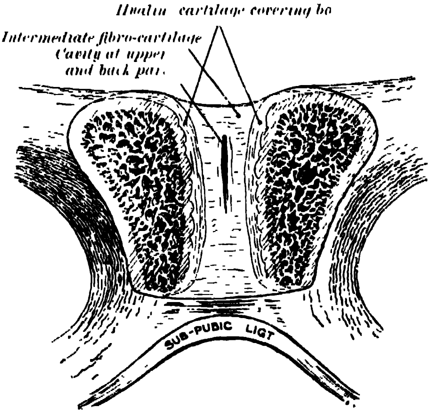
and forming an interlacement with the fibres of the aponeurosis of the External oblique and the inner tendons of origin of the Recti. The deep fibres pass transversely across the symphysis, and are blended with the fibro-cartilage.

The **Posterior Pubic Ligament** (lig. pubicum posterius) consists of a few thin, scattered fibres, which unite the two pubic bones posteriorly.

The **Superior Pubic Ligament** (lig. pubicum superius) is a band of fibres, which connects together the two pubic bones superiorly.

The **Subpubic Ligament** (lig. pubicum inferius) is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below, and forming the upper boundary of the pubic arch. Above, it is blended with the interarticular fibro-cartilage; laterally, it is attached to the descending rami of the pubic bones; below, it is free, and is separated from the triangular ligament of the perinæum by an opening through which the deep dorsal vein of the penis passes into the pelvis.

Fig. 445.—Coronal section of the symphysis pubis. Made near its posterior surface.



The **Interpubic Disc** (lamina fibrocartilaginea interpubica) connects the opposed surfaces of the pubic bones. Each of the bony surfaces is covered by a thin layer of hyaline cartilage firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate lamina of fibro-cartilage which varies in thickness in different subjects. It often contains a cavity in its interior, probably formed by the softening and absorption of the fibro-cartilage, since it rarely appears before the tenth year of life and is not lined by synovial membrane. This cavity is larger in the female than in the male, but it is very doubtful whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint; but it occasionally reaches to the front, and may extend the entire length of the cartilage. It may be easily demonstrated by making a coronal section of the symphysis pubis near its posterior surface (fig. 445).

The **Obturator Membrane** (membrana obturatoria) is more properly regarded as analogous to the muscular fasciæ, with which it will be described (page 575).

Mechanism of the Pelvis

The pelvic girdle supports and protects the contained viscera and affords surfaces for the attachments of the trunk and lower limb muscles. Its most important mechanical function, however, is to transmit the weight of the trunk and upper limbs to the lower extremities.

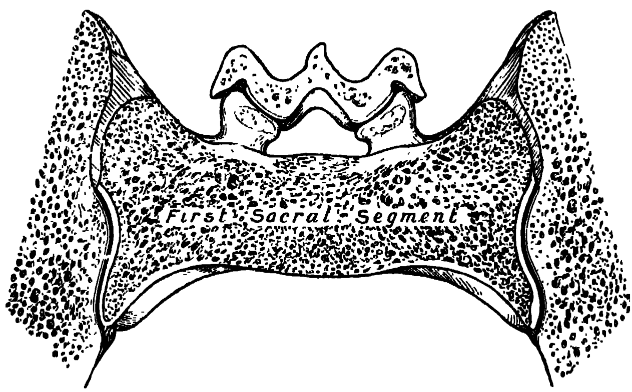
It may be divided into two arches by a vertical plane passing through the acetabular cavities; the posterior of these arches is the one chiefly concerned in the function of transmitting the weight. Its essential parts are the upper three sacral vertebræ and two strong pillars of bone running from the sacro-iliac articulations to the acetabular cavities. For the reception and diffusion of the weight the acetabular cavity is strengthened by two additional bars running towards the pubis and ischium. In order to lessen concussion in rapid changes of distribution of the weight, joints (sacro-iliac articulations) are interposed between the sacrum and the iliac bones; an accessory joint (symphysis pubis) exists in the middle of the anterior arch. The sacrum forms the summit of the posterior arch; the weight transmitted falls on it at the lumbo-sacral articulation and, theoretically, has a component in each of two directions. One component of the force is expended in driving the sacrum downwards and backwards between the iliac bones,

while the other thrusts the upper end of the sacrum downwards and forwards towards the pelvic cavity.

The movements of the sacrum are regulated by its form. Viewed as a whole, it presents the shape of a wedge with its base upwards and forwards. The first component of the force is therefore acting against the resistance of the wedge, and its tendency to separate the iliac bones is resisted by the sacro-iliac and ilio-lumbar ligaments and by the ligaments of the symphysis pubis.

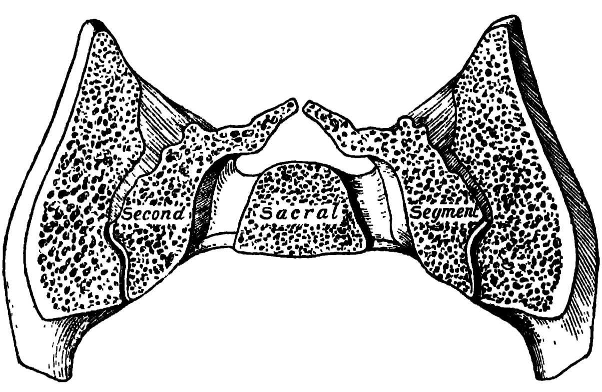
If a series of coronal sections of the sacro-iliac joints be made, it will be found possible to divide the articular portion of the sacrum into three segments: anterior,

Fig. 446.—Coronal section of anterior sacral segment.



middle, and posterior In the *anterior segment* (fig. 446), which involves the first sacral vertebra, the articular surfaces show slight sinuosities and are almost parallel to one another; the distance between their dorsal margins is, however, slightly greater than that between their ventral margins. This segment therefore presents a slight wedge shape with the truncated apex downwards. The *middle segment* (fig. 447) is a narrow band across the centres of the articulations. Its dorsal width is distinctly greater than its ventral, so that the segment is more definitely wedge-shaped, the truncated apex being again directed downwards. Each

Fig. 447.—Coronal section of middle sacral segment.



articular surface presents in the centre a marked concavity from above downwards, and into this a corresponding convexity of the iliac articular surface fits, forming an interlocking mechanism. In the *posterior segment* (fig. 448) the ventral width is greater than the dorsal, so that the wedge form is the reverse of those of the other segments—i.e. the truncated apex is directed upwards. The articular surfaces are only slightly concave.

Dislocation downwards and forwards of the sacrum by the second component of the force applied to it is prevented therefore by the middle segment, which

interposes the resistance of its wedge shape and that of the interlocking mechanism on its surfaces; a rotatory movement, however, is produced by which the anterior segment is tilted downwards and the posterior upwards; the axis of this rotation passes through the dorsal part of the middle segment. The movement of the anterior segment is slightly limited by its wedge form, but chiefly by the posterior sacro-iliac ligaments; that of the posterior segment is checked to a slight extent by its wedge form, but the chief limiting factors are the great and small sacro-sciatic ligaments. In all these movements the effect of the sacro-iliac and ilio-lumbar ligaments and the ligaments of the symphysis pubis in resisting the separation of the iliac bones must be recognised.

FIG. 448.—Coronal section of posterior sacral segment.

During pregnancy the pelvic joints and ligaments are relaxed, and capable therefore of more extensive movements. When the fœtus is being expelled the force is applied to the front of the sacrum. Upward dislocation is again prevented by the interlocking mechanism of the middle segment. As the fœtal head passes the anterior segment the latter is carried upwards, enlarging the antero-posterior diameter of the pelvic inlet; when the head reaches the posterior segment this also is pressed upwards against the resistance of its wedge, the movement only being possible by the laxity of the joints and the stretching of the sacro-sciatic ligaments.

ARTICULATIONS OF THE UPPER EXTREMITY

The articulations of the Upper Extremity may be arranged as follows:

I. Sterno-clavicular.	VI. Wrist.
II. Acromio-clavicular.	VII. Carpal.
III. Shoulder.	VIII. Carpo-metacarpal.
IV. Elbow.	IX. Intermetacarpal.
V. Radio-ulnar.	X. Metacarpo-phalangeal.
XI. Interphalangeal.	

I STERNO-CLAVICULAR ARTICULATION (ARTICULATIO STERNOCLAVICULARIS)

The sterno-clavicular articulation (fig. 449) is regarded by most anatomists as an arthrodial joint; but Cruveilhier considers it to be an articulation by reciprocal reception. Probably the former opinion is correct, the variety of movements which the joint enjoys being due to the interposition of an inter-articular fibro-cartilage between the joint surfaces. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the manubrium sterni, and the cartilage of the first rib. The articular surface of the clavicle is much larger than that of the sternum, and is invested with a layer of cartilage,* which is considerably thicker than that on the latter bone. The ligaments of this joint are:

Capsular.	Interclavicular.
Anterior Sterno-clavicular.	Costo-clavicular (rhomboid).
Posterior Sterno-clavicular.	Interarticular fibro-cartilage.

The **Capsular Ligament** (capsula articularis) completely surrounds the articulation and consists of fibres of varying degrees of thickness and strength. Those in front and behind are of considerable thickness, and form the anterior and posterior sterno-clavicular ligaments; but those above, and especially those below, are thin and scanty, and partake more of the character of areolar than of true fibrous tissue.

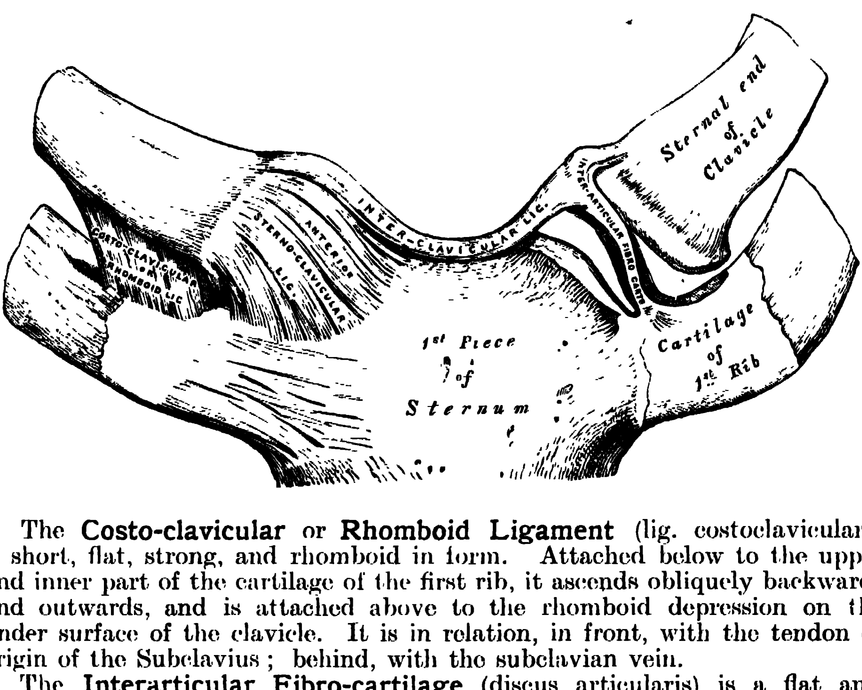
* According to Bruch, the sternal end of the clavicle is covered by a tissue which is fibrous rather than cartilaginous in structure.

The **Anterior Sterno-clavicular Ligament** (lig. sternoclaviculare ant.) is a broad band of fibres, which covers the anterior surface of the articulation; it is attached above to the upper and front part of the inner extremity of the clavicle, and, passing obliquely downwards and inwards, is attached below to the front of the upper part of the manubrium sterni. This ligament is covered by the sternal portion of the Sterno-cleido-mastoid and the integument; behind, it is in relation with the capsule, the interarticular fibro-cartilage and the two synovial membranes.

The **Posterior Sterno-clavicular Ligament** (lig. sternoclaviculare post.) is a similar band of fibres, which covers the posterior surface of the articulation; it is attached above to the upper and back part of the inner extremity of the clavicle, and, passing obliquely downwards and inwards, is attached below to the back of the upper part of the manubrium sterni. It is in relation, in front, with the interarticular fibro-cartilage and synovial membranes; behind, with the Sterno-hyoid and Sterno-thyroid.

The **Interclavicular Ligament** (lig. interclaviculare) is a flattened band, which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to that of the other, and is also attached to the upper margin of the sternum. It is in relation, in front, with the integument; behind, with the Sterno-thyroid muscles.

FIG. 449.—Sterno-clavicular articulation. Anterior view.



The **Costo-clavicular** or **Rhomboid Ligament** (lig. costoclaviculare) is short, flat, strong, and rhomboid in form. Attached below to the upper and inner part of the cartilage of the first rib, it ascends obliquely backwards and outwards, and is attached above to the rhomboid depression on the under surface of the clavicle. It is in relation, in front, with the tendon of origin of the Subclavius; behind, with the subclavian vein.

The **Interarticular Fibro-cartilage** (discus articularis) is a flat and nearly circular disc, interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, near its junction with the sternum; and by its circumference to the interclavicular and anterior and posterior sterno-clavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre. It divides the joint into two cavities, each of which is furnished with a synovial membrane.

Of the two **Synovial Membranes** found in this articulation, the outer is reflected from the sternal end of the clavicle, over the adjacent surface of the fibro-cartilage, and over the cartilage of the first rib; the inner is attached to the margin of the articular surface of the sternum and clothes the adjacent surface of the fibro-cartilage; the latter is the larger of the two.

Movements.—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upwards, downwards, backwards, forwards, as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk. 'The movements attendant on elevation and depression of the shoulder take place between the clavicle and the interarticular fibro-cartilage, the bone rotating upon the ligament on an axis drawn from before backwards through its own articular facet. When the shoulder is moved forwards and backwards, the clavicle, with the interarticular fibro-cartilage, rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, round an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves upon the interarticular fibro-cartilage, and the latter, with the clavicle, rolls upon the sternum.' * Elevation of the shoulder is limited principally by the costo-clavicular ligament; depression, by the interclavicular ligament and interarticular fibro-cartilage. The muscles which *raise* the clavicle, as in shrugging the shoulders, are the upper fibres of the Trapezius, the Levator anguli scapulæ, and the clavicular head of the Sterno-mastoid, assisted to a certain extent by the two Rhomboids, which pull the vertebral border of the scapula backwards and upwards and so raise the clavicle. The *depression* of the clavicle is principally effected by gravity assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn *backwards* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus magnus and Pectoralis minor.

Surface Form.—The sterno-clavicular joint is subcutaneous and its position may be easily ascertained by feeling the enlarged sternal end of the clavicle just external to the long, cord-like, sternal origin of the Sterno-mastoid. If this muscle be relaxed by bending the head forwards, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint.

Applied Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is owing to this, and to the fact that the force of the blow is usually transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint; it may be either forwards, backwards, or upwards. Should it be displaced backwards it may cause pressure on the trachea. The chief point worthy of note, as regards the construction of the joint, in connection with dislocation, is the fact that, owing to the shape of the articular surfaces, and the strength of the joint mainly depending upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

11. ACROMIO-CLAVICULAR ARTICULATION (ARTICULATIO ACROMIO-CLAVICULARIS)

The acromio-clavicular articulation (fig. 450) is an arthrodial joint between the outer extremity of the clavicle and the inner margin of the acromion process of the scapula. Its ligaments are:

Capsular.	Interarticular Fibro-cartilage.
Superior Acromio-clavicular.	Coraco-clavicular { Trapezoid and Conoid.
Inferior Acromio-clavicular.	

The **Capsular Ligament** (capsula articularis) completely surrounds the articular margins, and is specially strong above and below, where it forms the superior and inferior acromio-clavicular ligaments. It consists of fibres arranged parallel to each other and passing between the adjacent borders of the two bones.

The **Superior Acromio-clavicular Ligament** (lig. acromioclaviculare sup.) is a quadrilateral band, which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres,

* Humphry, *On the Human Skeleton*, page 402.

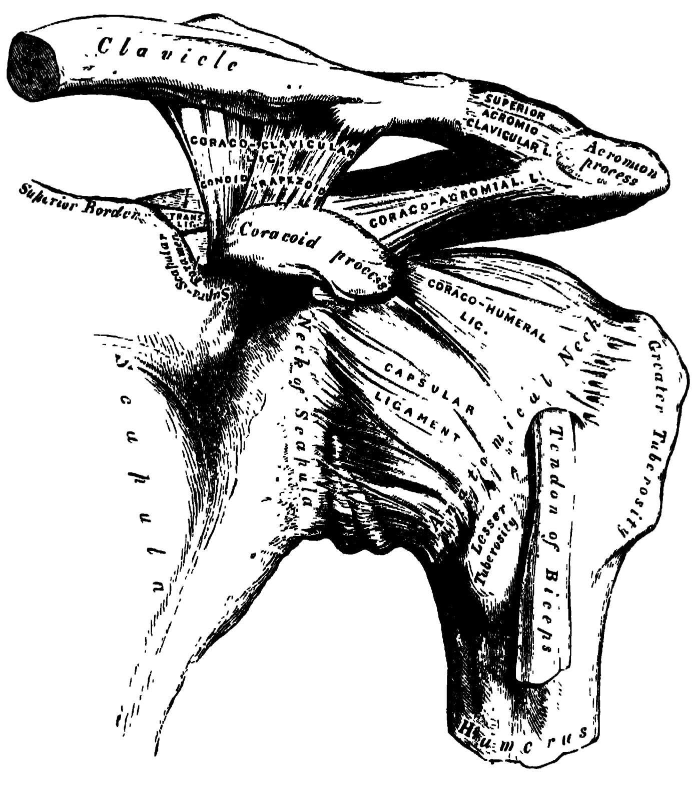
which interlace with the aponeuroses of the Trapezius and Deltoid; below, it is in contact with the interarticular fibro-cartilage when this is present.

The **Inferior Acromio-clavicular Ligament** (lig. acromioclaviculare inf.) is somewhat thinner than the preceding; it covers the under part of the articulation, and is attached to the adjoining surfaces of the two bones. It is in relation, above, in rare cases with the interarticular fibro-cartilage; below, with the tendon of the Supraspinatus.

The **Interarticular Fibro-cartilage** (discus articularis) is frequently absent in this articulation. When it exists, it generally only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely, it completely separates the joint into two cavities.

The **Synovial Membrane.**—There is usually only one synovial membrane in this articulation, but when a complete interarticular fibro-cartilage exists, there are two.

Fig. 450.—The left shoulder-joint, acromio-clavicular articulation, and proper ligaments of scapula.



The **Coraco-clavicular Ligament** (lig. coracoclaviculare) (fig. 450) serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but as it forms a most efficient means of retaining the clavicle in contact with the acromial process, it is usually described with it. It consists of two fasciculi, called the *trapezoid* and *conoid ligaments*.

The *Trapezoid Ligament* (lig. trapezoideum), the anterior and external fasciculus, is broad, thin, and quadrilateral: it is placed obliquely between the coracoid process and the clavicle. It is attached, below, to the upper surface of the coracoid process; above, to the oblique line on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament, the two forming, by their junction, an angle projecting backwards.

The *Conoid Ligament* (lig. conoideum), the posterior and internal fasciculus, is a dense band of fibres, conical in form, with its base directed upwards. It is

attached by its apex to a rough impression at the base of the coracoid process, internal to the preceding; above, by its expanded base, to the conoid tubercle on the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are in relation, in front, with the Subclavius and Deltoid; behind, with the Trapezius.

Movements.—The movements of this articulation are of two kinds: 1. A gliding motion of the articular end of the clavicle on the acromion. 2. Rotation of the scapula forwards and backwards upon the clavicle; the extent of this rotation is limited by the two portions of the coraco-clavicular ligament, the trapezoid limiting rotation forwards and the conoid backwards.

The acromio-clavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Humphry, that if there had been no joint between the clavicle and scapula, the circular movement of the scapula on the ribs (as in throwing the shoulders backwards or forwards) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such positions, and it would have been impossible to give a blow straight forwards with the full force of the arm; that is to say, with the combined force of the scapula, arm, and forearm. 'This joint,' as he happily says, 'is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position, or nearly so.' Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Surface Form.—The position of the acromio-clavicular joint can generally be ascertained by defining the slightly enlarged extremity of the outer end of the clavicle, which projects above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

Applied Anatomy.—The acromio-clavicular joint owes its security mainly to the coraco-clavicular ligament, which limits the amount of movement of the outer end of the clavicle either upwards, backwards, or forwards. Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs upwards: that is to say, the outer end of the clavicle is displaced above the acromion process of the scapula. The displacement is often incomplete, on account of the strong coraco-clavicular ligaments, which remain untorn. The same difficulty exists, as in the sterno-clavicular dislocation, in maintaining the ends of the bone in position after reduction.

LIGAMENTS OF THE SCAPULA

The ligaments of the scapula (fig. 450) are:

Coraco-acromial, Transverse, and Spino-glenoid.

The **Coraco-acromial Ligament** (lig. coracoacromiale) is a strong triangular band, extending between the coracoid and acromion processes. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle; and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed inwards, its anterior fibres forwards and inwards. This ligament, together with the coracoid and acromion processes, forms a vault for the protection of the head of the humerus. It is in relation, above, with the clavicle and under surface of the Deltoid; below, with the tendon of the Supraspinatus muscle, a bursa being interposed. Its outer border is continuous with a dense lamina that passes beneath the Deltoid upon the tendons of the Supra- and Infra-spinatus muscles. The ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as occasionally is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The **Transverse or Suprascapular Ligament** (lig. transversum scapulæ superius) converts the suprascapular notch into a foramen. It is a thin and

flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen; the suprascapular vessels pass over the ligament. The ligament is sometimes ossified.

The **Spino-glenoid Ligament** (lig. transversum scapulæ inferius) consists of a band of fibres, situated on the posterior surface of the neck of the scapula and stretching from the outer border of the spine to the margin of the glenoid cavity. It forms an arch under which the suprascapular vessels and nerve pass as they enter the infraspinous fossa.

III. SHOULDER-JOINT (ARTICULATIO HUMERI)

The shoulder-joint (fig. 450) is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the large hemispherical head of the humerus and the shallow glenoid cavity of the scapula, an arrangement which permits of very considerable movement, while the joint itself is protected against displacement by the tendons which surround it. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use, therefore, is to limit the amount of movement. The joint is protected above by an arch, formed by the coracoid and acromion processes, and the coraco-acromial ligament. The articular surfaces are covered by cartilage: that on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case in the glenoid cavity. The ligaments of the shoulder are:

Capsular.	Gleno-humeral.
Coraco-humeral.	Transverse Humeral.
Glenoid.*	

The **Capsular Ligament** (capsula articularis) completely encircles the articulation, being attached, above, to the circumference of the glenoid cavity beyond the glenoid ligament; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere, and is remarkably loose and lax, and much larger and longer than is necessary to keep the bones in contact, allowing them to be separated from each other more than an inch, an evident provision for that extreme freedom of movement which is peculiar to this articulation. It is strengthened, above, by the Supraspinatus; below, by the long head of the Triceps; behind, by the tendons of the Infraspinatus and Teres minor; and in front, by the tendon of the Subscapularis. The capsular ligament usually presents three openings. One anteriorly, below the coracoid process, establishes a communication between the joint and a bursa beneath the tendon of the Subscapularis muscle. The second, which is not constant, is at the posterior part, where a communication sometimes exists between the joint and a bursal sac under the tendon of the Infraspinatus muscle. The third is seen between the tuberosities of the humerus, for the passage of the long tendon of the Biceps.

The **Coraco-humeral Ligament** (lig. coracohumerale) is a broad band which strengthens the upper part of the capsular ligament. It arises from the outer border of the coracoid process, and passes obliquely downwards and outwards to the front of the great tuberosity of the humerus, being blended with the tendon of the Supraspinatus. This ligament is intimately united to the capsular ligament by its hinder and lower border; but its superior and anterior border presents a free edge, which overlaps the capsular ligament.

Gleno-humeral Ligaments.—In addition to the coraco-humeral ligament, three supplemental bands, which are named the *gleno-humeral ligaments*, strengthen the capsular ligament. These may be best seen by opening the capsule at the back of the joint and removing the head of the humerus. One

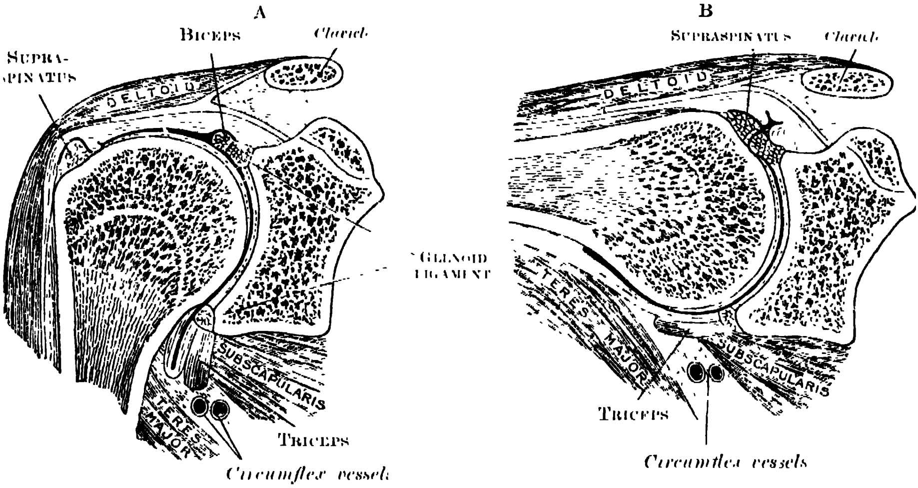
* The long tendon of origin of the Biceps also acts as one of the ligaments of this joint. See the observations on page 372, on the function of the muscles passing over more than one joint.

of them is situated on the inner side of the joint, and passes from the inner edge of the glenoid cavity to the lower part of the lesser tuberosity of the humerus. A second is situated at the lower part of the joint, and passes from the under edge of the glenoid cavity to the under part of the anatomical neck of the humerus. A third is situated at the upper part of the joint, and is fixed above to the apex of the glenoid cavity close to the root of the coracoid process, and passing downwards along the inner edge of the tendon of the Biceps, is attached below to a small depression above the lesser tuberosity of the humerus. In addition to these, the capsule is strengthened externally on its anterior aspect by two bands derived from the tendons of the Pectoralis major and Teres major respectively.

The **Transverse Humeral Ligament** is a broad band of fibrous tissue passing from the lesser to the greater tuberosity of the humerus, and always limited to that portion of the bone which lies above the epiphysial line. It converts the bicipital groove into an osseo-aponeurotic canal, and is the homologue of the strong process of bone which connects the summits of the two tuberosities in the musk ox.

The **Glenoid Ligament** (labrum glenoidale) is a fibro-cartilaginous rim attached round the margin of the glenoid cavity. It is triangular on section,

Fig. 451.—Coronal sections through the shoulder-joint (A) with the arm hanging by the side; (B) with the arm abducted at right angles. (After Henle.)



the thickest portion being fixed to the circumference of the cavity, the free edge being thin and sharp. It is continuous above with the long tendon of the Biceps, which gives off two fasciculi, to blend with the fibrous tissue of the ligament. This ligament deepens the cavity for articulation, and protects the edges of the bone.

The **Synovial Membrane** is reflected from the margin of the glenoid cavity over the glenoid ligament; it is then reflected over the internal surface of the capsular ligament, and covers the lower part and sides of the anatomical neck of the humerus as far as the cartilage covering the head of the bone. The long tendon of the Biceps which passes through the capsular ligament is enclosed in a tubular sheath of synovial membrane, which is reflected upon it at the point where it perforates the capsule, and is continued around it as far as the summit of the glenoid cavity. The tendon of the Biceps thus traverses the articulation, but it is not contained in the interior of the synovial cavity.

Bursæ.—The bursæ in the neighbourhood of the shoulder-joint are the following: (1) A constant bursa is situated between the tendon of the Subscapularis muscle and the capsule of the joint; it communicates with the synovial cavity through an opening in the front of the capsular ligament: (2) a bursa which occasionally communicates with the joint is sometimes found between the tendon

of the Infraspinatus and the capsule: (3) a large bursa exists between the under surface of the Deltoid and the capsule, but does not communicate with the joint; this bursa is prolonged under the acromion process and coraco-acromial ligament, and intervenes between these structures and the capsule of the joint: (4) a large bursa mucosa is situated on the summit of the acromion: (5) a bursa is frequently found between the coracoid process and the capsule of the joint: (6) there is a bursa beneath the Coraco-brachialis: (7) one lies between the Teres major and the long head of the Triceps: (8) one is placed in front of, and another behind, the tendon of the Latissimus dorsi.

The *Muscles* in relation with the joint are, above, the Supraspinatus; below, the long head of the Triceps; in front, the Subscapularis; behind, the Infraspinatus and Teres minor; within, the long tendon of the Biceps. The Deltoid is placed most externally, and covers the articulation on its outer side, as well as in front and behind.

The *Arteries* supplying the joint are articular branches of the anterior and posterior circumflex, and suprascapular.

The *Nerves* are derived from the circumflex and suprascapular.

Movements.—The shoulder-joint is capable of every variety of movement, flexion, extension, abduction, adduction, circumduction, and rotation. The humerus is *flexed* (drawn forwards) by the Pectoralis major, anterior fibres of the Deltoid, Coraco-brachialis, and when the forearm is flexed, by the Biceps; *extended* (drawn backwards) by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and, when the forearm is extended, by the Triceps; it is *abducted* by the Deltoid and Supraspinatus; it is *adducted* by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major, and by the weight of the limb; it is *rotated outwards* by the Infraspinatus and Teres minor; and it is *rotated inwards* by the Subscapularis, Latissimus dorsi, Teres major, Pectoralis major, and the anterior fibres of the Deltoid.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when this latter is supplemented by the glenoid ligament. 2. The looseness of the capsule of the joint. 3. The intimate connection of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the Biceps tendon to the joint.

It is in consequence of the relative sizes of the two articular surfaces, and the looseness of the capsular ligament, that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces, and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, the arm can be carried considerably farther by the movements of the scapula, involving, of course, motion at the acromio- and sterno-clavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint (see pp. 401 to 403). The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown somewhat forwards and outwards, because the margin of the head of the humerus is by no means a true circle: its greatest diameter is from the bicipital groove, downwards, inwards, and backwards, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of this measurement. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoid process, and the coraco-acromial ligament, constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament, and an opening made in it to counteract the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere, an arrangement which 'renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest' (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch, enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate

portions of the capsule, as well as by the interlocking of the bones. Thus it is said that 'abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity; adduction by the tension of the coraco-humeral ligament' (Beaunis et Bouchard). Cleland * maintains that the limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoid ligament fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

The scapula is capable of being moved upwards and downwards, forwards and backwards, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator anguli scapulæ, and the two Rhomboids; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn *backwards* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side, the Deltoid and Supraspinatus can only lift it to a right angle with the trunk, the further elevation of the limb being effected by the Trapezius and Serratus magnus moving the scapula on the wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of this bone compensating to a very great extent for the immobility of the joint.

Cathcart † has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only while passing from the hanging to the horizontal position but also in travelling upwards as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—i.e. the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The intimate union of the tendons of the Supraspinatus, Infraspinatus, Teres minor and Subscapularis muscles with the capsule, converts these muscles into elastic and spontaneously acting ligaments of the joint. It is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonises the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously discussed (see page 372). Next, it strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion process, when the Deltoid contracts; it thus fixes the head of the humerus as the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infra-spinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coraco-acromial ligament, in a curved direction, with its convexity inwards, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Applied Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more

* *Journ. of Anat. and Phys.* No. 1, 1867, p. 85.
† *Ibid.* vol. xviii. 1881

frequently dislocated than any other joint in the body. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily *subglenoid*. The head of the bone does not usually remain in this situation, between the tendons of the Subscapularis and the Triceps, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front of and behind the joint. As the muscles at the back are stronger than those in front, and especially since the long head of the Triceps prevents the bone from passing backwards, dislocation forwards is much more common than backwards. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid.

Fig. 452.—Left elbow-joint, showing anterior and internal ligaments.

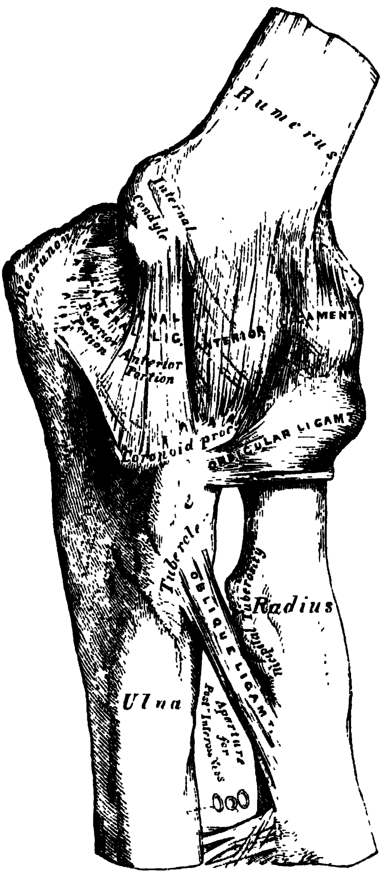


Fig. 453.—Left elbow-joint, showing posterior and external ligaments.

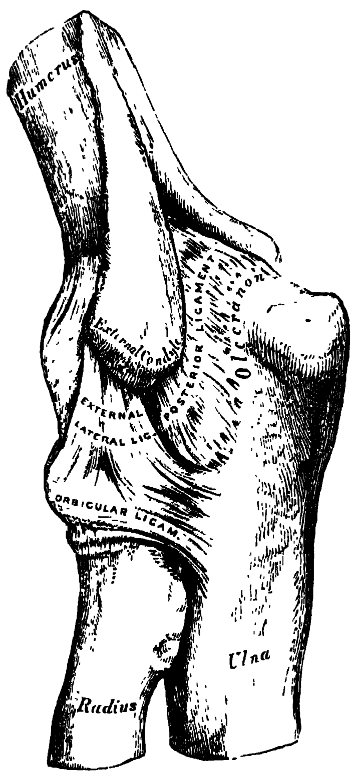


Occasionally, in consequence probably of a greater amount of force being brought to bear on the limb, the head is driven farther inwards, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backwards and remains in the infraspinous fossa, beneath the spine (subspinous).

The shoulder-joint may be the seat of any of those inflammatory affections, either acute or chronic, which attack joints, though perhaps less frequently than some other articulations of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyæmia, or may follow secondarily on acute epiphysitis in infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended, and the contour of the joint rounded. Special projections may occur at the sites of the openings in the capsular ligament. Thus a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis ; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major, from effusion into the diverticulum which runs down the bicipital groove with the tendon of the Biceps. The effusion into the synovial cavity can be best

ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt. In cases of septic synovitis, where incision is required, the opening should be made in front, over the most prominent point of the swelling. After the pus has been evacuated a counter-opening should be made behind, so as to ensure efficient drainage.

Tuberculous arthritis not infrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result, or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteo-arthritis, and may also be affected in gout and rheumatism; or in locomotor ataxy, when it becomes the seat of Charcot's disease.

Ankylosis is occasionally met with in the shoulder-joint as the result of destructive changes. The ankylosis usually takes place with the arm in a dependent position, and any attempt to raise the arm is attended by a rotation of the scapula on the wall of the chest.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation: in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coraco-acromial ligament down the arm for about three inches: this will expose the bicipital groove containing the tendon of the Biceps, which should be hooked out of the way. The capsule is freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus are stripped off with the capsule, without dividing their attachments to the latter. The head of the bone can then be thrust out of the wound and sawn off; or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if carious.

IV. ELBOW-JOINT (ARTICULATIO CUBITI)

The elbow-joint (figs. 452, 453) is a ginglymus or hinge-joint. The trochlea of the humerus is received into the greater sigmoid cavity of the ulna, so as to admit of the movements peculiar to this joint, viz. flexion and extension; while the capitellum of the humerus articulates with the cup-shaped depression on the head of the radius. The articular surfaces are each covered with a thin layer of cartilage, and connected together by a **Capsular Ligament** (capsula articularis), which is especially thickened on its two sides, and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:

Anterior.	Internal Lateral.
Posterior.	External Lateral.

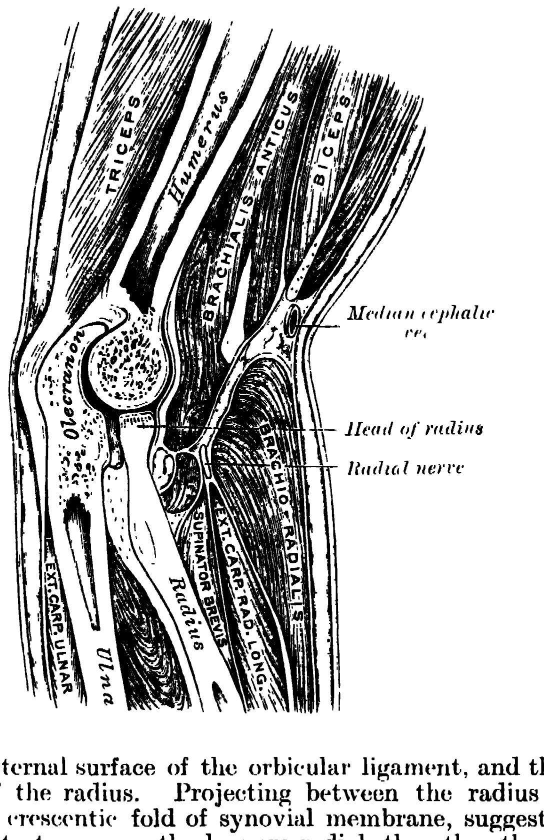
The **Anterior Ligament** (fig. 452) is a broad and thin fibrous layer, which covers the anterior surface of the joint. It is attached to the front of the internal epicondyle and to the front of the humerus immediately above the coronoid and radial fossæ; below, to the anterior surface of the coronoid process of the ulna and to the orbicular ligament (page 413), being continuous on either side with the lateral ligaments. Its superficial fibres pass obliquely from the inner condyle of the humerus outwards to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the Brachialis anticus, except at its outermost part.

The **Posterior Ligament** (fig. 453) is thin and membranous, and consists of transverse and oblique fibres. Above, it is attached to the humerus immediately behind the capitellum and close to the inner margin of the trochlear surface, to the lateral margins of the olecranon fossa, and to the back of the external condyle some little distance from the trochlear surface. Below, it is fixed to the upper and outer margins of the olecranon process, to the posterior part of the orbicular ligament, and to the ulna behind the lesser sigmoid cavity. The transverse fibres form a strong band which bridges across the olecranon fossa; under cover of this band a pouch of synovial membrane and a pad of fat project into the upper part of the fossa when the joint is extended. In the fat are a few scattered fibrous bundles, which pass from

the deep aspect of the transverse band to the upper part of the fossa. This ligament is in relation, behind, with the tendon of the Triceps and the Anconeus.

The **Internal Lateral Ligament** (lig. collaterale ulnare) (fig. 452) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The *anterior portion*, directed obliquely forwards, is attached, above, by its apex, to the front part of the internal epicondyle of the humerus; and, below, by its broad base, to the inner margin of the coronoid process. The *posterior portion*, also of triangular form, is attached, above, by its apex, to the lower and back part of the internal epicondyle; below, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal epicondyle to blend with a *transverse band* of ligamentous tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the Triceps and Flexor carpi ulnaris and the ulnar nerve, and gives origin to part of the Flexor sublimis digitorum.

FIG. 454.—Sagittal section of right elbow-joint taken somewhat obliquely and seen from the radial aspect. (After Braune.)



The **External Lateral Ligament** (lig. collaterale radiale) (fig. 453) is a short and narrow fibrous band, less distinct than the internal, attached, above, to a depression below the external epicondyle of the humerus; below, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the ulna. It is intimately blended with the tendon of origin of the Supinator brevis.

The **Synovial Membrane** is very extensive. It extends from the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossæ on that bone; it is reflected over the anterior, posterior, and lateral ligaments, and forms a pouch between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the circumference of the head of the radius. Projecting between the radius and ulna into the cavity is a crescentic fold of synovial membrane, suggesting the division of the joint into two: one the humero-radial, the other the humero-ulnar.

Between the capsular ligament and the synovial membrane are three masses of fat. The largest, over the olecranon fossa, is pressed into the fossa by the Triceps during flexion; the second, over the coronoid fossa, and the third, over the radial fossa, are pressed into their respective fossæ during extension.

The *Muscles* in relation with the joint are, in front, the Brachialis anticus; behind, the Triceps and Anconeus; externally, the Supinator brevis, and the common tendon of origin of the Extensor muscles; internally, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris (fig. 454).

The *Arteries* supplying the joint are derived from the anastomosis between the superior profunda, inferior profunda, and anastomotic branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar,

and the recurrent branch of the radial. These vessels form a complete anastomotic chain around the joint.

The *Nerves* of the joint are a twig from the ulnar, as it passes between the internal condyle and the olecranon; a filament from the musculo-cutaneous, and two from the median.

Movements.—The elbow-joint comprises three different portions, viz. the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radio-ulnar articulation, described below. All these articular surfaces are enveloped by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take place in the plane of the shaft of the humerus. When the forearm is extended and supinated, the axes of the arm and forearm are not in the same line, the upper portion of the limb forming an obtuse angle with the lower, the hand and forearm being directed outwards. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the trochlear surface of the humerus, with its prominences and depressions accurately adapted to the great sigmoid cavity, prevents any lateral movement. *Flexion* is produced by the action of the Biceps and Brachialis anticus, assisted by the Brachio-radialis and the muscles arising from the internal condyle of the humerus; *extension*, by the Triceps and Anconeus, assisted by the Extensors of the wrist, the Extensor communis digitorum and the Extensor minimi digiti.

The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis and allow of movement in all directions, were it not for the orbicular ligament, by which the head of the radius is bound down firmly to the sigmoid cavity of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise tend to occur, from the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament, the tendon of the Biceps would be liable to pull the head of the radius out of the joint.* The head of the radius is not in complete contact with the capitellum of the humerus in all positions of the joint. The capitellum occupies only the anterior and inferior surfaces of the lower end of the humerus, so that in complete extension a part of the radial head can be plainly felt projecting at the back of the articulation. In full flexion the movement of the radial head is hampered by the compression of the surrounding soft parts, so that the freest rotatory movement of the radius on the humerus (pronation and supination) takes place in semiflexion, in which position the two articular surfaces are in freest and most intimate contact. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint; the limitation of flexion is also aided by the soft structures of the arm and forearm coming into contact.

In any position of flexion or extension, the radius, carrying the hand with it, can be rotated in the upper radio-ulnar joint. The hand is directly articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint by the interarticular fibro-cartilage. Thus, rotation of the head of the radius round an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Surface Form.—If the forearm be slightly flexed, a curved crease or fold with its convexity downwards is seen in the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position

* Humphry, *op. cit.* p. 419.

of the radio-humeral joint can be ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

Applied Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, lateral displacement of the bones is very uncommon; whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, occurs much more frequently. Dislocation backwards takes place when the forearm is in a position of extension, and forwards when in a position of flexion. For, in the extended position, the coronoid process is not locked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forwards. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backwards, while the olecranon, having left the olecranon fossa, is not so efficient in preventing a forward displacement. When lateral dislocation does take place it is generally incomplete. Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation. As a rule, in young persons, the application of any severe violence to a joint is more likely to produce a fracture of bone than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The joint-cavity then becomes distended with fluid, the bulging showing itself principally around the olecranon process, that is to say, on its inner and outer sides and above, in consequence of the laxness of the posterior ligament. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint, or the whole elbow may assume a fusiform appearance. There is not generally much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus. In cases of suppurative synovitis, incisions should be made into the joint on either side of the olecranon, care being taken to avoid wounding the ulnar nerve on the inner side. Chronic synovitis, usually of tuberculous origin, is of common occurrence in the elbow-joint: in such cases the forearm tends to assume the position of semiflexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind that if ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. The elbow-joint is also sometimes affected with osteo-arthritis, but less commonly than some of the larger joints.

Excision of the elbow is principally required for one of three conditions—viz. tuberculous arthritis, injury and its results, or faulty ankylosis—but may be necessary for some other rarer conditions, such as disorganising arthritis after pyæmia and unreduced dislocations. The results of the operation are, as a rule, more favourable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in any of the first three conditions mentioned above. The operation is best performed by a vertical incision down the back of the joint; a straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps. The operator, guarding the soft parts with his thumb-nail, separates them from the bone with the point of his knife. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process; and the prolongation of the Triceps into the deep fascia of the forearm over the Anconeus. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bones turned out and sawn off. The turning out of the ends of the bones is rendered easier by first cutting off the olecranon process with a pair of cutting bone forceps. The section of the humerus should be through the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive movements must be commenced early—that is to say, about the tenth day. It is most important to maintain the continuity of the Triceps with the deep fascia of the forearm, so as to obtain good power of extension in the new joint.

V. RADIO-ULNAR ARTICULATIONS

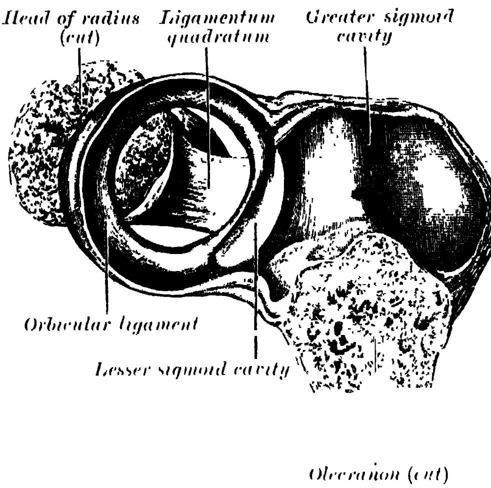
The articulation of the radius with the ulna is effected by ligaments, which connect together both extremities as well as the shafts of these bones. The ligaments may, consequently, be subdivided into three sets: 1, those of the superior radio-ulnar articulation; 2, the middle radio-ulnar ligaments; 3, those of the inferior radio-ulnar articulation.

1. Superior Radio-ulnar Articulation (Articulatio Radioulnaris Proximalis)

This articulation is a trochoid or pivot-joint between the circumference of the head of the radius and the ring formed by the lesser sigmoid cavity of the ulna and the *annular* or *orbicular* ligament.

The **Annular or Orbicular Ligament** (lig. annulare radii) (fig. 455) is a strong band of fibres, which encircles the head of the radius, and retains it in contact with the lesser sigmoid cavity of the ulna. It forms about four-fifths of the osseo-fibrous ring, and is attached to the anterior and posterior margins of the lesser sigmoid cavity; a few of its lower fibres are, however, continued round below the cavity and form at this level a complete fibrous ring. Its upper border blends with the anterior and posterior ligaments of the elbow, while from its lower border a thin loose membrane passes to be attached to the neck of the radius; a thickened band which extends from

Fig. 455.—Orbicular ligament of radius, from above. The head of the radius has been sawn off and the bone dislodged from the ligament.



the lower border of the orbicular ligament below the lesser sigmoid cavity to the neck of the radius is known as the *ligamentum quadratum*. The *outer surface* of the orbicular ligament is strengthened by the external lateral ligament of the elbow, and affords origin to part of the Supinator brevis. Its *inner surface* is smooth, and lined by synovial membrane, which is continuous with that of the elbow-joint.

Movements.—The movements which take place in this articulation are limited to rotatory movements of the head of the radius within the ring formed by the orbicular ligament and the lesser sigmoid cavity of the ulna; rotation forwards being called *pronation*; rotation backwards, *supination*. Supination is performed by the Biceps and Supinator brevis, assisted to a slight extent by the Extensor muscles of the thumb, and, in certain positions, by the Brachio-radialis. Pronation is performed by the Pronator teres and Pronator quadratus, assisted, in some positions, by the Brachio-radialis.

Surface Form.—The position of the superior radio-ulnar joint is marked on the surface by a dimple on the back of the elbow which indicates the position of the head of the radius.

Applied Anatomy.—Dislocation of the head of the radius alone is a not uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downwards in the orbicular ligament, the upper border of which becomes folded over the head of the

radius, between it and the capitellum of the humerus. The forearm becomes fixed in a position of semiflexion, midway between supination and pronation, and great pain is complained of upon any attempt to move the joint. It should be noted that the synovial membrane of the superior radio-ulnar joint is directly continuous with that of the elbow-joint, and, therefore, any septic or tuberculous disease which affects the latter also involves the former joint. The superior radio-ulnar joint is always removed in an excision of the elbow (see p. 412).

2. Middle Radio-ulnar Union

The shafts of the radius and ulna are connected by the

Oblique ligament and the Interosseous membrane.

The **Oblique Ligament** (chorda obliqua) (fig. 452) is a small, flattened, fibrous band, which extends obliquely downwards and outwards, from the outer side of the tubercle of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the interosseous membrane; and it appears to be placed as a substitute for it in the upper part of the interosseous interval. It is sometimes wanting.

The **Interosseous Membrane** (membrana interossea antibrachii) is a broad and thin plane of fibrous tissue descending obliquely downwards and inwards, from the interosseous ridge on the radius to that on the ulna; the lower part of the membrane is attached to the posterior of the two lines into which the interosseous ridge of the radius divides. It is deficient above, commencing about an inch beneath the bicipital tuberosity of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones, and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique ligament an interval exists, through which the posterior interosseous vessels pass. Two or three fibrous bands are occasionally found on the posterior surface of this membrane; they descend obliquely from the ulna towards the radius, and have consequently a direction contrary to that of the other fibres. The membrane is in relation, *in front*, by its upper three-fourths, with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying in the interval between which are the anterior interosseous vessels and nerve; by its lower fourth with the Pronator quadratus; *behind*, with the Supinator brevis, Extensor ossis metacarpi pollicis, Extensor brevis pollicis, Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

3. Inferior Radio-ulnar Articulation (Articulatio Radioulnaris Distalis)

This is a pivot-joint formed between the head of the ulna and the sigmoid cavity on the inner side of the lower end of the radius. The articular surfaces are connected together by the following ligaments:

Anterior Radio-ulnar. Posterior Radio-ulnar.
Interarticular Fibro-cartilage.

The **Anterior Radio-ulnar Ligament** (fig. 456) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

The **Posterior Radio-ulnar Ligament** (fig. 457) extends between corresponding surfaces on the posterior aspect of the articulation.

The **Interarticular Fibro-cartilage** (discus articularis) (fig. 459) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower ends of the ulna and radius firmly together. Its periphery is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of the radius, which separates the sigmoid cavity from the carpal articular surface. Its margins are united to the ligaments of the

wrist-joint. Its *upper surface*, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its *under surface*, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform and inner part of the semilunar. Both surfaces are clothed by synovial membrane: the upper surface, by one peculiar to the radio-ulnar articulation; the under surface, by the synovial membrane of the wrist.

The **Synovial Membrane** (fig. 459) of this articulation has been called, from its extreme looseness, the *membrana sacciformis*; it extends upwards between the radius and the ulna, forming here a very loose *cul-de-sac* (recessus sacciformis). The quantity of synovia which it contains is usually considerable.

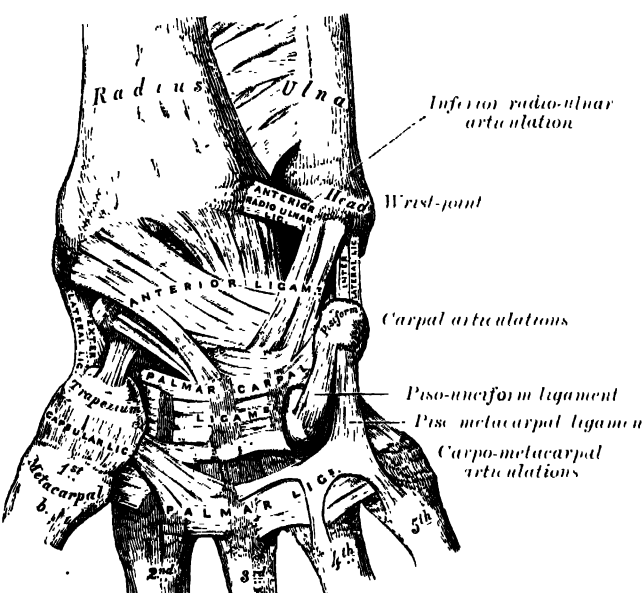
Movements.—The movements in the inferior radio-ulnar articulation are just the reverse of those in the superior radio-ulnar joint. They consist of movements of rotation of the lower end of the radius round an axis which passes through the centre of the head of the ulna. When the radius rotates forwards, *pronation* of the forearm and hand is the result; and when backwards, *supination*. It will thus be seen that in pronation and supination of the forearm and hand the radius describes the segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement the head of the ulna is not stationary, but de cribes a curve in a direction opposite to that taken by the head of the radius. This, however, is not to be regarded as a rotation of the ulna—the curve which the head of this bone describes is due to a combined antero-posterior and lateral movement, the former taking place almost entirely at the elbow-joint, the latter at the shoulder-joint.

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

VI. RADIO-CARPAL OR WRIST JOINT (ARTICULATIO RADIOCARPEA)

The wrist-joint (figs. 456, 457) is a condyloid articulation. The parts entering into its formation are the lower end of the radius and under surface of the interarticular fibro-cartilage above; and the scaphoid, semilunar, and

FIG. 456.—Ligaments of wrist and hand. Anterior view.



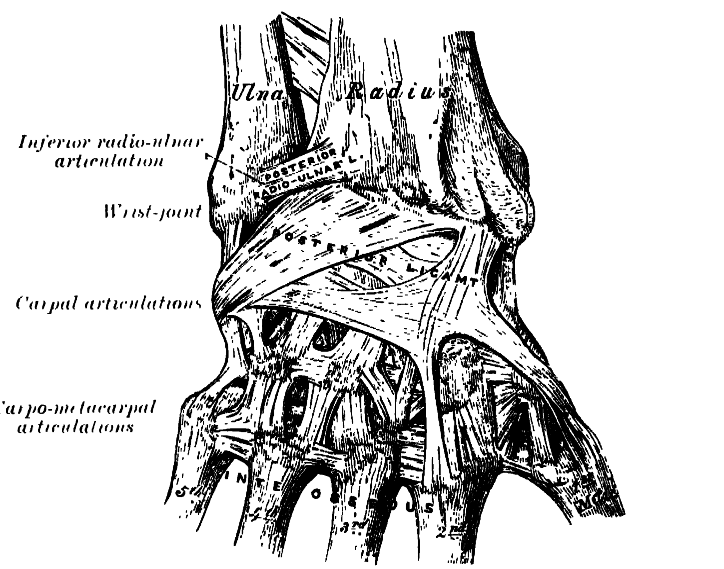
cuneiform bones below. The articular surface of the radius and the under surface of the interarticular fibro-cartilage form together a transversely elliptical concave surface, the *receiving cavity*. The articular surfaces of the scaphoid, semilunar, and cuneiform present a smooth, convex surface, the

condyle, which is received into the concavity above mentioned. All the bony surfaces of the articulation are covered with cartilage, and connected together by a **Capsule**, strengthened by the following ligaments :

Anterior.	Internal lateral.
Posterior.	External lateral.

The **Anterior Ligament** (lig. radiocarpeum volare) (fig. 456) is a broad membranous band, attached above to the anterior margin of the lower end of the radius, to its styloid process and to the front of the lower end of the ulna; its fibres pass downwards and inwards to be inserted into the palmar surfaces of the scaphoid, semilunar, and cuneiform, some of the fibres being continued to the os magnum. In addition to this broad membrane, there is a distinct rounded fasciculus, superficial to the rest, which passes from the base of the styloid process of the ulna to the semilunar and cuneiform. The ligament is perforated by numerous apertures for the passage of vessels, and is in relation, in front, with the tendons of the Flexor profundus digitorum and Flexor longus pollicis ; behind, it is closely adherent to the anterior border of the triangular fibro-cartilage of the inferior radio-ulnar articulation.

FIG. 457.—Ligaments of wrist and hand. Posterior view.



The **Posterior Ligament** (lig. radiocarpeum dorsale) (fig. 457), less thick and strong than the anterior, is attached, above, to the posterior border of the lower end of the radius ; its fibres pass obliquely downwards and inwards, to be attached to the dorsal surfaces of the scaphoid, semilunar, and cuneiform, being continuous with those of the dorsal carpal ligaments. It is in relation, behind, with the Extensor tendons of the fingers ; in front, it is blended with the triangular fibro-cartilage.

The **Internal Lateral Ligament** (lig. collaterale carpi ulnare) (fig. 456) is a rounded cord, attached above to the extremity of the styloid process of the ulna, and dividing below into two fasciculi, one of which is attached to the inner side of the cuneiform, the other to the pisiform and annular ligament.

The **External Lateral Ligament** (lig. collaterale carpi radiale) (fig. 456) extends from the summit of the styloid process of the radius to the outer side of the scaphoid, some of its fibres being prolonged to the trapezium and annular ligament. It has in relation with it the radial artery, which separates the ligament from the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis.

The **Synovial Membrane** (fig. 459) lines the inner surfaces of the ligaments above described, extending from the lower end of the radius and interarticular fibro-cartilage above to the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

The wrist-joint is covered in front by the Flexor, and behind by the Extensor tendons; it is also in relation with the radial and ulnar arteries.

The *Arteries* supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The *Nerves* are derived from the ulnar and posterior interosseous.

Movements.—The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. They will be studied with those of the carpus, with which they are combined.

Fig. 458.—Longitudinal section of the right forearm, hand, and third finger, viewed from the ulnar aspect. (After Braune.)

Surface Form.—On the front of the wrist three transverse furrows may be generally seen: the uppermost is on a level with the styloid process of the ulna; the middle corresponds fairly accurately with the wrist-joint; and the lowest indicates the position of the mid-carpal articulation.

Applied Anatomy.—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movements which take place between the several bones serve to break the jars that result from falls or blows on the hand. Dislocation backwards, which is the more common, simulates to a considerable extent Colles's fracture of the radius, and is liable to be mistaken for it. The differential diagnosis can be easily made by observing the relative positions of the styloid processes of the radius and the ulna. In the natural condition the styloid process of the radius is on a lower level, i.e. nearer the ground, when the arm hangs by the side, than that of the ulna, and this relationship is not disturbed in dislocation. In Colles's fracture, on the other hand, the styloid process of the radius is on the same, or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighbourhood. Chronic inflammation of the wrist is generally tuberculous, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, frequently leads to caries of the carpal bones, and the result is often an ankylosis. A free incision of the joint by a straight posterior cut leads, in some cases, to most satisfactory results.

VII. CARPAL ARTICULATIONS (ARTICULATIONES INTERCARPEÆ)

These articulations may be subdivided into three sets:

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. Articulations of the First or Proximal Row of Carpal Bones

These are arthrodial joints. The ligaments connecting the scaphoid, semilunar, and cuneiform are :

Dorsal, Palmar, and two Interosseous.

The **Dorsal Ligaments,** two in number, are placed transversely behind the bones of the first row ; they connect the scaphoid and semilunar, and the semilunar and cuneiform.

The **Palmar Ligaments,** also two, connect the scaphoid and semilunar, and the semilunar and cuneiform ; they are less strong than the dorsal, and placed very deeply below the Flexor tendons and the anterior ligament of the wrist.

The **Interosseous Ligaments** (fig. 456) are two narrow bundles of fibrous tissue, one connecting the semilunar with the scaphoid, the other joining it to the cuneiform. They are on a level with the superior surfaces of these bones, and their upper surfaces are smooth, and form part of the convex articular surface of the wrist-joint.

The ligaments connecting the pisiform bone are—

Capsular. Two Palmar.

The **Capsular Ligament** is a thin membrane which connects the pisiform to the cuneiform. It is lined with a separate synovial membrane.

The two **Palmar Ligaments** are strong fibrous bands; one, *the piso-unciform ligament* (lig. pisohamatum), connects the pisiform to the unciform, the other, the *piso-metacarpal ligament* (lig. pisometacarpeum), joins the pisiform to the fifth metacarpal bone (fig. 456). These ligaments are, in reality, prolongations of the tendon of the Flexor carpi ulnaris.

2. Articulations of the Second or Distal Row of Carpal Bones

These also are arthrodial joints. The articular surfaces are covered with cartilage, and connected by the following ligaments :

Dorsal, Palmar, and three Interosseous.

The **Dorsal Ligaments,** three in number, extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The **Palmar Ligaments,** also three, have a similar arrangement on the palmar surface.

The three **Interosseous Ligaments,** much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting.

3. Articulations of the Two Rows of Carpal Bones with each other

The joint between the scaphoid, semilunar, and cuneiform on the one hand, and the second row of carpal bones on the other, is named the *mid-carpal joint,* and is made up of three distinct portions : in the centre the head of the os magnum and the superior surface of the unciform articulate with the deep cup-shaped cavity formed by the scaphoid and semilunar, and constitute a sort of ball-and-socket joint. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming gliding joints.

The ligaments are :

Anterior or Palmar.	Internal Lateral.
Posterior or Dorsal.	External Lateral.

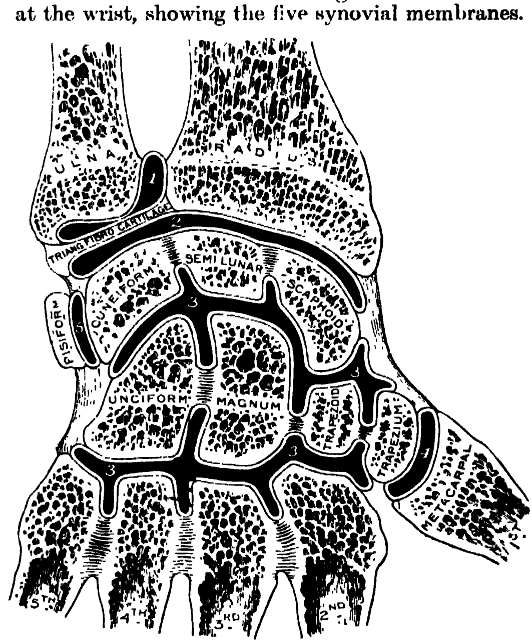
The **Anterior or Palmar Ligament** consists of short fibres, which pass, for the most part, from the palmar surfaces of the bones of the first row to the front of the os magnnm.

The **Posterior** or **Dorsal Ligament** consists of short, irregular bundles of fibres passing between the bones of the first and second rows on the dorsal surface of the carpus.

The **Lateral Ligaments** are very short: one is placed on the radial, the other on the ulnar side of the carpus; the former, the stronger and more distinct, connects the scaphoid and trapezium, the latter the cuneiform and unciform; they are continuous with the lateral ligaments of the wrist-joint. In addition to these ligaments, a slender interosseous band sometimes connects the os magnum and the scaphoid.

The **Synovial Membrane of the Carpus** is very extensive (fig. 459); it passes from the margins of the under surfaces of the scaphoid, semilunar, and cuneiform bones to the margins of the upper surfaces of the bones of the second row. It sends two prolongations upwards—between the scaphoid and semilunar, and the semilunar and cuneiform - and three prolongations downwards between the four bones of the second row. The prolongation between the trapezium and trapezoid, or that between the trapezoid and os magnum, is often continued onwards, owing to the absence of the interosseous ligament, into the carpo-metacarpal joints, sometimes of the four inner metacarpal bones, sometimes of the second and third only. In the latter condition the joint between the unciform and the fourth and fifth metacarpal bones has a separate synovial membrane. The synovial membranes of these joints are prolonged for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and cuneiform.

FIG. 459.—Vertical section through the articulations at the wrist, showing the five synovial membranes.



Movements.—The articulation of the hand and wrist considered as a whole involves four articular surfaces: (*a*) the inferior surfaces of the radius and triangular fibro-cartilage; (*b*) the superior surfaces of the scaphoid, semilunar, and unciform, the pisiform having no essential part in the movement of the hand; (*c*) the S-shaped surface formed by the inferior surfaces of the scaphoid, semilunar, and cuneiform; (*d*) the reciprocal surface formed by the trapezium, trapezoid, os magnum, and unciform. These four surfaces form two joints: (1) the superior or wrist-joint proper; and (2) the inferior or mid-carpal joint.

(1) The articulation between the forearm and carpus is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than of flexion is permitted since the articulating surfaces extend farther on the dorsal than on the palmar surfaces of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. The former is considerably greater in extent than the latter on account of the shortness of the styloid process of the ulna, abduction being soon limited by the contact of the styloid process of the radius with the trapezium. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the combined and consecutive movements of

adduction, extension, abduction, and flexion. No rotation is possible, but the effect of rotation is obtained by the supination and pronation of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; *extension* by the Extensores carpi radialis longior et brevior and the Extensor carpi ulnaris; *adduction* (ulnar flexion), by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion) by the Extensors of the thumb, and the Extensores carpi radialis longior et brevior and the Flexor carpi radialis. When the fingers are extended, flexion of the wrist is performed by the Flexores carpi radialis et ulnaris and extension by the Extensor communis digitorum. When the fingers are flexed, flexion of the wrist is performed by the Flexores sublimis et profundus digitorum, and extension by the Extensores carpi radiales et ulnaris.

(2) The chief movements permitted in the transverse or mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which are the movements most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forwards and backwards on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the os magnum rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

VIII. CARPO-METACARPAL ARTICULATIONS (ARTICULATIONES CARPOMETACARPEÆ)

1. ARTICULATION OF THE METACARPAL BONE OF THE THUMB WITH THE TRAPEZIUM (ARTICULATIO CARPOMETACARPEA POLLICIS)

This is a joint of reciprocal reception, and enjoys great freedom of movement on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, either in the long axis or at right angles to it, one bone appears to be received into a cavity in the other. The joint is surrounded by a capsular ligament.

The **Capsular Ligament** (capsula articularis) is thick but loose, and passes from the circumference of the upper extremity of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest externally and behind, and lined by a separate **synovial membrane.**

Movements.—In the articulation of the metacarpal bone of the thumb with the trapezium the movements permitted are flexion and extension in the plane of the palm of the hand, abduction and adduction in a plane at right angles to the palm, circumduction, and opposition. It is by the movement of opposition that the tip of the thumb is brought into contact with the palmar surfaces of the slightly flexed fingers. This movement is effected through the medium of a small sloping facet on the anterior lip of the saddle-shaped articular surface of the trapezium. The Flexor muscles pull the corresponding part of the articular surface of the metacarpal bone on to this facet, and the movement of opposition is then carried out by the Adductors.

Flexion of this carpo-metacarpal joint is produced by the Flexores longus et brevis pollicis assisted by the Opponens pollicis and the Adductores transversus et obliquus pollicis. Extension is effected mainly by the Extensor ossis metacarpi pollicis, assisted by the Extensores longus et brevis pollicis. Adduction is carried out by the two Adductors; abduction mainly by the Abductor pollicis, assisted by the Extensors.

2. ARTICULATIONS OF THE FOUR INNER METACARPAL BONES WITH THE CARPUS

The joints formed between the carpus and the four inner metacarpal bones are arthrodial joints. The ligaments are:

Dorsal, Palmar, and Interosseous.

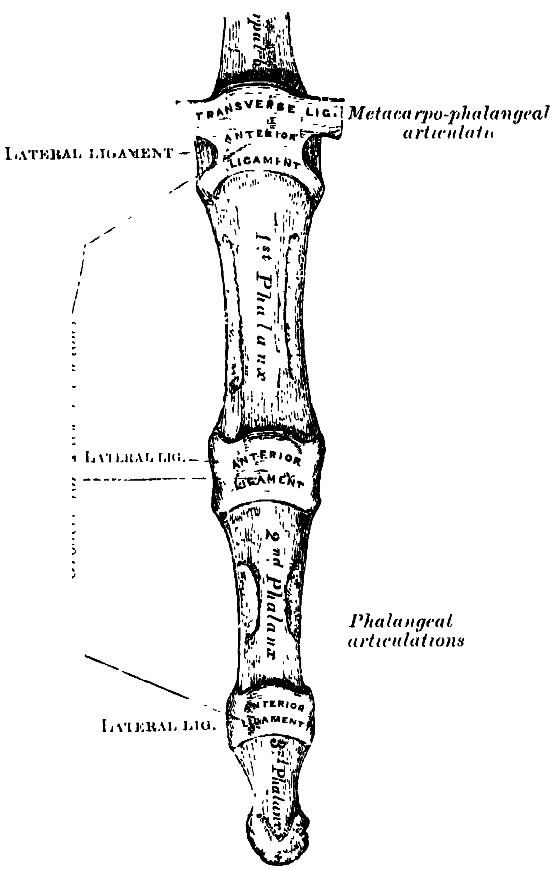
The **Dorsal Ligaments,** the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surfaces. The second metacarpal bone receives two fasciculi, one from the trapezium, the other from

the trapezoid; the third metacarpal receives two, one from the trapezoid, and one from the os magnum; the fourth two, one from the os magnum, and one from the unciform; the fifth receives a single fasciculus from the unciform, and this is continuous with a similar ligament on the palmar surface, forming an incomplete capsule.

The **Palmar Ligaments** have a somewhat similar arrangement on the palmar surface, with the exception of those of the third metacarpal, which are three in number, an external one from the trapezium, situated above the sheath of the tendon of the Flexor carpi radialis; a middle one from the os magnum; and an internal one from the unciform.

The **Interosseous Ligaments** consist of short, thick fibres, which are limited to one part of the carpo-metacarpal articulation; they connect the contiguous inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

Fig. 460.—Articulations of the phalanges.



The **Synovial Membrane** is frequently a continuation of that between the two rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (fig. 459) are thus seen to be five in number. The *first*, the *membrana sacciformis*, passes from the lower end of the ulna to the sigmoid cavity of the radius, and lines the upper surface of the interarticular fibro-cartilage. The *second* passes from the lower end of the radius and interarticular fibro-cartilage above, to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones, and sometimes, in the event of one of the interosseous ligaments being absent, between the bones of the second row to the carpal extremities of the four inner metacarpal bones. The *fourth*, from the margin of the trapezium to the metacarpal bone of the thumb. The *fifth*, between the adjacent margins of the cuneiform and pisiform bones. Occasionally the carpo-metacarpal joints have a separate synovial membrane (see page 419).

Movements.—The movements permitted in the carpo-metacarpal articulations of the fingers are limited to slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus the articulation of the metacarpal bone of the little finger is most movable, then that of the ring-finger; the metacarpal bones of the index and middle fingers are almost immovable.

IX. INTERMETACARPAL ARTICULATIONS (ARTICULATIONES INTERMETACARPEÆ)

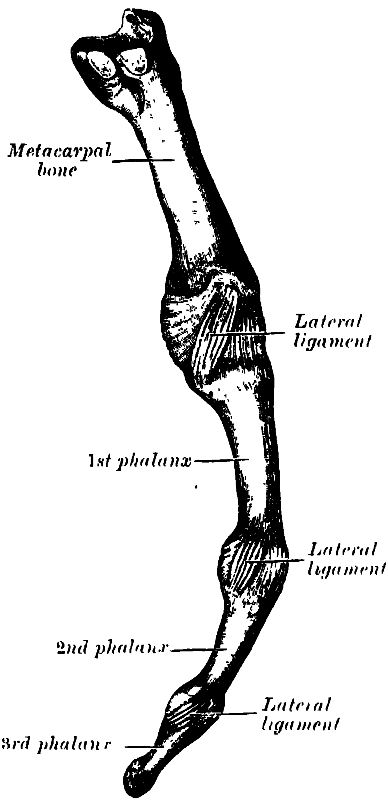
The carpal extremities of the four inner metacarpal bones articulate with one another by small surfaces covered with cartilage, and connected together by dorsal, palmar, and interosseous ligaments.

The **Dorsal** and **Palmar Ligaments** pass transversely from one bone to another on the dorsal and palmar surfaces. The **Interosseous Ligaments** pass between their contiguous surfaces, just beneath their lateral articular facets.

The **Synovial Membrane** between the lateral facets is a reflection from that between the two rows of carpal bones.

The **Transverse Metacarpal Ligament** (fig. 460) is a narrow fibrous band, which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them together. It is blended anteriorly with the anterior (glenoid) ligaments of the metacarpo-phalangeal articulations. To its posterior border is connected the fascia which covers the Interosseous muscles. Its anterior surface is concave where the Flexor tendons pass over it. Behind it the tendons of the Interossei pass to their insertions.

FIG. 461.—Lateral view of metacarpo-phalangeal and interphalangeal joints.



X. METACARPO-PHALANGEAL ARTICULATIONS (ARTICULATIONES METACARPO-PHALANGEÆ) (figs. 460, 461)

These articulations are of the condyloid kind, formed by the reception of the rounded heads of the metacarpal bones into shallow cavities in the extremities of the first phalanges, with the exception of that of the thumb, which presents more of the characters of a ginglymoid joint. The ligaments are—

Anterior and Two Lateral.

The **Anterior Ligaments** (*Glenoid Ligaments* of Cruveilhier) are thick, dense, fibro-cartilaginous structures, placed upon the palmar surfaces of the joints in the intervals between the lateral ligaments, to which they are connected; they are loosely united to the metacarpal bones, but are very firmly attached to the bases of the first phalanges. Their palmar surfaces are intimately blended with the transverse metacarpal ligament, and present grooves for the passage of the Flexor tendons, the sheaths surrounding which are connected to the sides of the grooves. By their deep surfaces, they form part of the articular facets for the heads of the metacarpal bones, and are lined by synovial membranes.

The **Lateral Ligaments** (ligg. collateralia) are strong, rounded cords, placed on the sides of the joints; each is attached by one extremity to the posterior tubercle and adjacent depression on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

Movements.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the movements of abduction and adduction are very limited, and cannot be performed when the fingers are flexed.

XI. INTERPHALANGEAL ARTICULATIONS (ARTICULATIONES DIGITORUM MANUS)

These are hinge joints. The ligaments are:

Anterior. Two Lateral.

The arrangement of these ligaments is similar to those in the metacarpo-phalangeal articulations. The Extensor tendon supplies the place of a posterior ligament.

Movements.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The amount of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

Muscles Acting on the Joints of the Digits

Flexion of the metacarpo-phalangeal joints of the fingers is effected by the Flexores sublimis et profundus digitorum, Lumbricales, and Interossei, assisted in the case of the little finger by the Flexor brevis minimi digiti. Extension of these joints is produced by the Extensor communis digitorum, Extensor indicis and Extensor minimi digiti.

Flexion of the interphalangeal joints of the fingers is accomplished by the Flexor profundus digitorum acting on the first and second joints and by the Flexor sublimis digitorum acting on the first joints. Extension is effected mainly by the Lumbricales and Interossei, the long Extensors having little or no action upon these joints.

Flexion of the metacarpo-phalangeal joint of the thumb is effected by the Flexores longus et brevis pollicis: extension by the Extensores longus et brevis pollicis. Flexion of the interphalangeal joint is accomplished by the Flexor longus pollicis and extension by the Extensor longus pollicis.

Surface Form.—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpo-phalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle.

ARTICULATIONS OF THE LOWER EXTREMITY

The articulations of the Lower Extremity comprise the following:

I. Hip.
II. Knee.
III. Tibio-fibular.
IV. Ankle.
V. Intertarsal.
VI. Tarso-metatarsal.
VII. Intermetatarsal.
VIII. Metatarso-phalangeal.
IX. Interphalangeal.

I. HIP-JOINT (ARTICULATIO COXÆ)

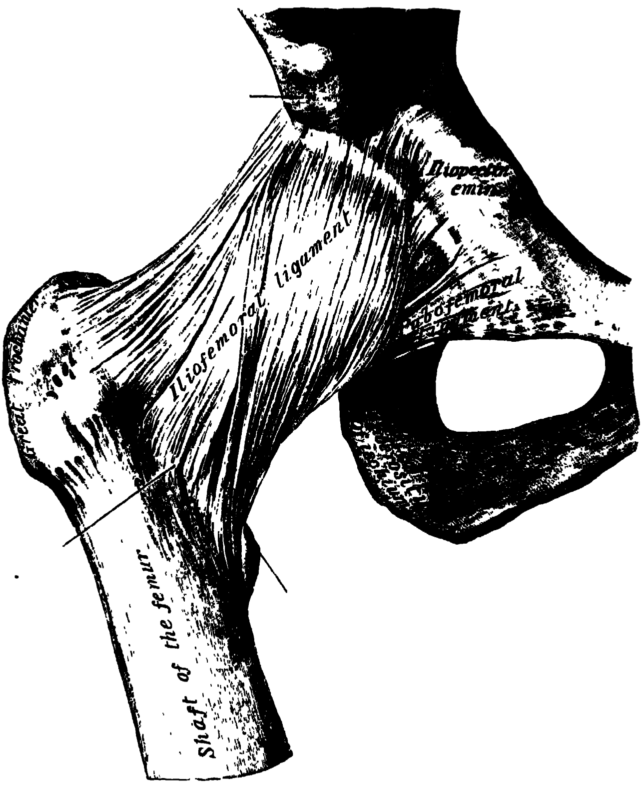
This articulation is an enarthrodial, or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articular cartilage on the head of the femur, thicker at the centre than at the circumference, covers the entire surface with the exception of the depression just below its centre for the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference, and forms an incomplete cartilaginous ring, of a horse-shoe shape, being deficient below, where there is a circular depression, occupied in the recent state by a mass of fat, covered by synovial membrane. The ligaments of the joint are:

Capsular. Teres.
Ilio-femoral. Cotyloid.
Transverse.

The **Capsular Ligament** (capsula articularis), strong and dense, embraces the margin of the acetabulum above, and surrounds the neck of the femur

below. Its *upper circumference* is attached to the rim of the acetabulum, two or three lines external to the cotyloid ligament, above and behind; but in front, it is attached to the outer margin of the ligament, and, opposite to the notch where the margin of the cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. Its *lower circumference* surrounds the neck of the femur, being attached, in front, to the spiral or anterior intertrochanteric line; above, to the base of the neck; behind, to the neck, about half an inch above the posterior intertrochanteric line; below, to the lower part of the neck, close to the lesser trochanter. From this insertion some of the fibres are reflected upwards along the neck as longitudinal bands, termed *retinacula*. The capsule is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular

FIG. 462.—Right hip-joint from the front. (Spalteholz.)

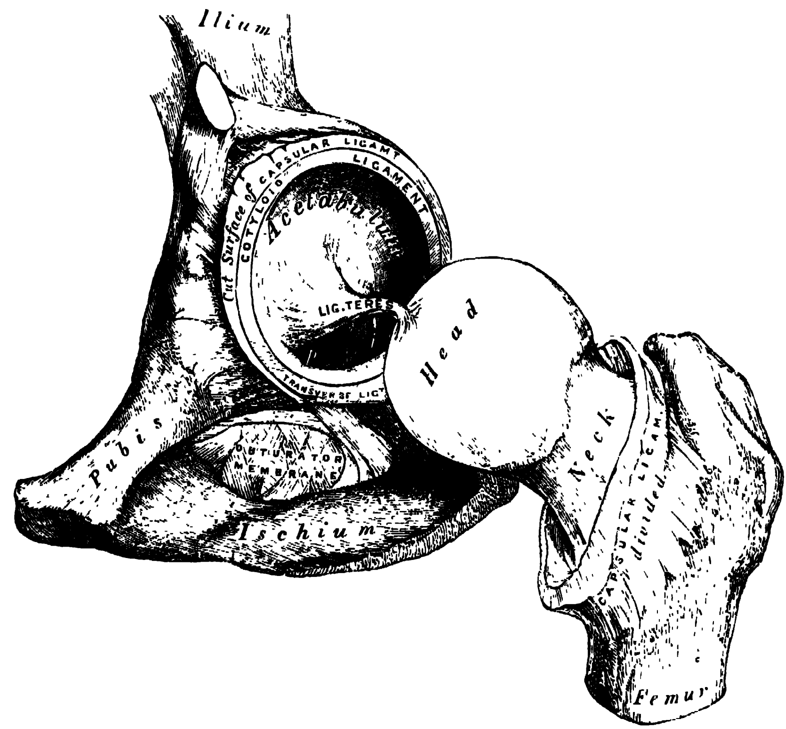


fibres (*zona orbicularis*) are most abundant at the lower and back part of the capsule, and form a sling or collar around the neck of the femur. Anteriorly they blend with the deep surface of the ilio-femoral ligament, and through its medium reach the anterior inferior spine of the ilium. The longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they are reinforced by distinct bands, or accessory ligaments, of which the most important is the *ilio-femoral* (lig. iliofemorale). The other accessory bands are known as the *pubo-femoral* (lig. pubocapsulare), passing from the ilio-pectineal eminence and obturator crest to the front of the capsule, where some of its fibres blend with the lower segment of the ilio-femoral ligament; and the *ischio-capsular* (lig. ischiocapsulare), passing from the ischium, just below the acetabulum, to blend with the circular fibres at the lower part of the joint. The external surface (fig. 442, page 393) is rough, covered by numerous muscles, and separated in front from the Psoas and Iliacus by a synovial bursa, which

not infrequently communicates by a circular aperture with the cavity of the joint. It differs from the capsular ligament of the shoulder in being much less loose and lax, and in not being perforated for the passage of a tendon.

The **Ilio-femoral Ligament** (figs. 462 and 467) is a band of great strength which lies in front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, above, to the lower part of the anterior inferior spine of the ilium; and, dividing below, forms two bands, of which one passes downwards to be inserted into the lower part of the anterior intertrochanteric line; the other passes downwards and outwards to be inserted into the upper part of the same line. Between the two bands is a thinner part of the capsule. In some joints there is no division, and the ligament spreads out into a flat triangular band which is attached below into the whole length of the anterior intertrochanteric line. This ligament is frequently called the Y-shaped ligament of Bigelow; and the outer or upper of the two bands is sometimes described as a separate ligament, under the name of the *ilio-trochanteric ligament.*

FIG. 463.—Left hip-joint laid open.



The **Ligamentum Teres** (lig. teres femoris) is a triangular, somewhat flattened band implanted by its apex into the depression a little behind and below the centre of the head of the femur: its base is attached by three bands, one into either side of the cotyloid notch, where they blend with the transverse ligament, and the third into the surface of the bone outside the notch. It is formed of connective tissue, surrounded by a tubular sheath of synovial membrane. Occasionally only the synovial fold exists, or the ligament may be altogether absent. The ligament is made tense when the hip is semiflexed, and the limb then adducted or rotated outwards; it is, on the other hand, relaxed when the limb is abducted. It has, however, but little influence as a ligament, though it may to a certain extent limit movement.

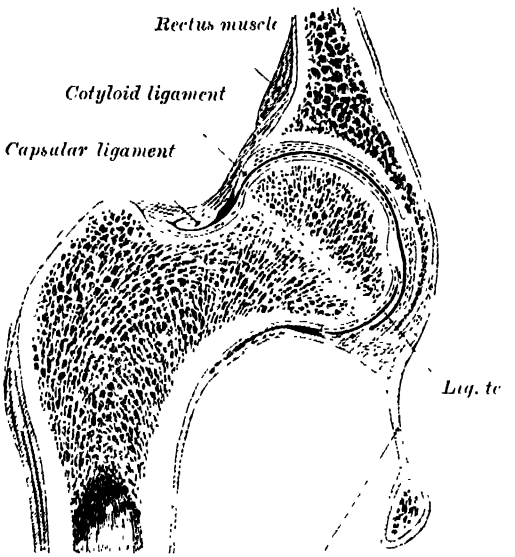
The **Cotyloid Ligament** (labrum glenoidale) is a fibro-cartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the same time it protects the edge of the bone. and fills up the inequalities on its surface. It bridges over the notch as the *transverse ligament,* and thus

forms a complete circle, which closely surrounds the head of the femur and assists in holding it in its place. It is triangular on section, its base being attached to the margin of the acetabulum, and its opposite edge being free and sharp. Its two surfaces are invested by synovial membrane, the external one being in contact with the capsular ligament, the internal one being inclined inwards so as to narrow the acetabulum, and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front, and consists of close compact fibres, which arise from different points of the circumference of the acetabulum, and interlace with each other at very acute angles.

The **Transverse Ligament** (lig. transversum acetabuli) is in reality a portion of the cotyloid ligament, though differing from it in having no cartilage cells among its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum, and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

The **Synovial Membrane** is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum, and is prolonged in the form of a tubular sheath around the ligamentum teres as far as the head of the femur. It sometimes communicates through a hole in the capsular ligament between the inner band of the Y-shaped ligament and the pubo-femoral ligament with a bursa situated on the under surface of the Ilio-psoas.

FIG. 464.—Vertical section through hip-joint. (Henle.)



The *Muscles* in relation with the joint are, in front, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; above, the reflected head of the Rectus and Gluteus minimus, the latter being closely adherent to the capsule; internally, the Obturator externus and Pectineus; behind, the Pyriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris (fig. 465).

The *Arteries* supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The *Nerves* are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the anterior crural supplying the Rectus.

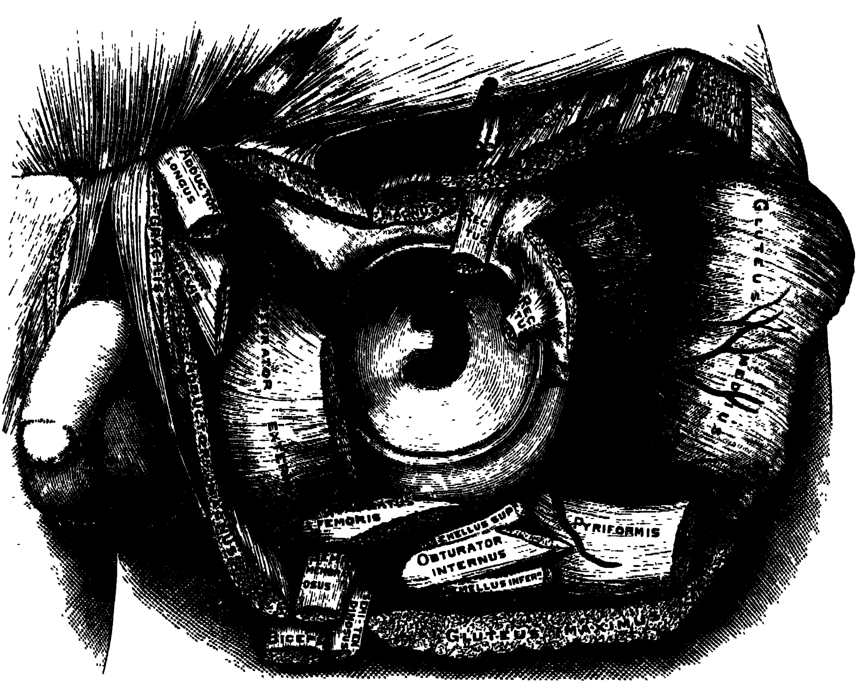
Movements.—The movements of the hip are very extensive, and consist of flexion, extension, adduction, abduction, circumduction, and rotation.

The length of the neck of the femur and its inclinations to the shaft have the effect of converting the angular movements of flexion, extension, adduction, and abduction partially into rotatory movements in the joint. Thus when the thigh is flexed or extended, the head of the femur, on account of the *inward* inclination of the neck, rotates within the acetabulum with only a slight amount of gliding to and fro. The *forward* slope of the neck similarly affects the movements of adduction and abduction. Conversely rotation of the thigh which is permitted by the

upward inclination of the neck, is not a simple rotation of the head of the femur in the acetabulum, but is accompanied by a certain amount of gliding.

The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as has been seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The ilio-femoral ligament is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a

Fig. 465.—Relation of muscles to the capsule of the hip-joint. (From a drawing by F. A. Barton.)

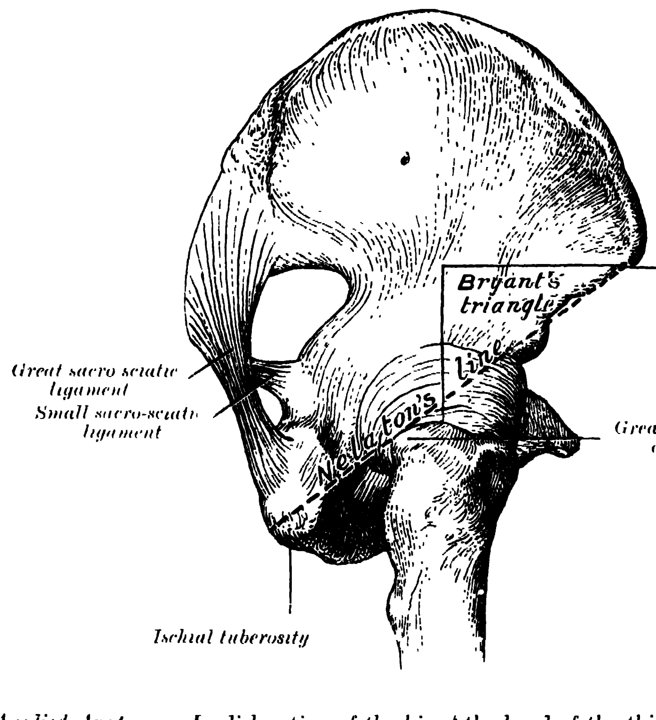


vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and therefore the pelvis tends to fall backwards, but is prevented by the tension of the ilio-femoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. Flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact, when the leg is flexed on the thigh, and by the action of the hamstring muscles when the leg is extended; extension by the tension of the ilio-femoral ligament; adduction by the thighs coming into contact; adduction with flexion by the outer band of the ilio-femoral ligament and the outer part of the capsular ligament; abduction by the inner band of the ilio-femoral ligament and the pubo-femoral band; rotation outwards by the outer band of the ilio-femoral ligament; and rotation inwards by the ischio-capsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are the Psoas, Iliacus, Rectus, Sartorius, Pectineus, Adductores longus et brevis,

and the anterior fibres of the Glutei medius and minimus. *Extension* is mainly performed by the Gluteus maximus, assisted by the hamstring muscles and the ischial head of the Adductor magnus. The thigh is *adducted* by the Adductors magnus, longus and brevis, the Pectineus, the Gracilis, and lower part of the Gluteus maximus, and *abducted* by the Gluteus medius and Gluteus minimus, and the upper part of the Gluteus maximus. The muscles which *rotate* the thigh *inwards* are the Gluteus minimus and the anterior fibres of the Gluteus medius, the Tensor fasciæ femoris and the Ilio-psoas; while those which rotate it *outwards* are the posterior fibres of the Gluteus medius, the Pyriformis, Obturators externus and internus, Gemelli superior and inferior, Quadratus femoris, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

Surface Form.—A line drawn from the anterior superior spine of the ilium to the most prominent part of the tuberosity of the ischium (Nélaton's line) (fig. 466) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; in other words, the upper border of the great trochanter, which touches Nélaton's line, is on a level with the centre of the hip-joint.

FIG. 466.—Nélaton's line and Bryant's triangle.



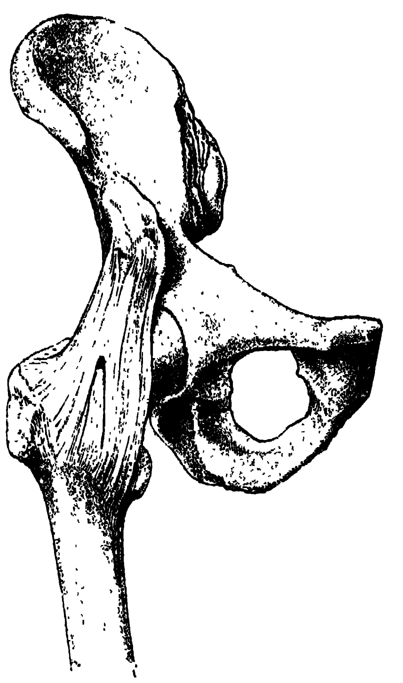
Applied Anatomy.—In dislocation of the hip, 'the head of the thigh-bone may rest at any point around its socket' (Bryant); but whatever position the head ultimately assumes, the primary displacement is generally downwards and inwards, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the ilio-femoral ligament, which is not easily ruptured. When, for instance, the head is forced backwards, this ligament forms a fixed axis, round which the head of the bone rotates, and is thus driven on to the dorsum of the ilium. The ilio-femoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backwards it is tense, and produces inversion of the limb; in the dislocation on to the pubes, it is relaxed, and therefore allows the external rotators to evert the thigh; while in the thyroid dislocation it is tense, and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. Bigelow, however, has endeavoured to show that the Obturator internus is the principal agent in deciding whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium, or in or near the sciatic notch; in both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the displacement on to the dorsum the

head of the bone travels up behind the acetabulum, in front of the muscle ; while in the dislocation into the sciatic notch the head passes behind the muscle, and is prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and it therefore remains in the neighbourhood of the sciatic notch. Bigelow distinguishes these two forms of dislocation by describing them as dislocations backwards, 'above and below' the Obturator internus.

The ilio-femoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as the fulcrum to a lever, of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyæmia, &c. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the ilio-femoral ligament ; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much oftener of a chronic character, and is usually of tuberculous origin. It begins either in the bones or in the synovial membrane ; usually in the former, and probably, in most cases, in the growing, highly vascular tissue in the neighbourhood of the epiphysial cartilage. In this respect it differs very materially from tuberculous arthritis of the knee, where the disease usually commences in the synovial membrane.

Fig. 467.—Hip-joint, showing the ilio-femoral ligament. (After Bigelow.)



In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case, the limb is flexed, abducted, and rotated outwards. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion ; the outer band of the ilio-femoral ligament by abduction ; and the inner band of this ligament and the back of the capsule by rotation outwards. It is, therefore, the position of greatest ease. The condition is not quite obvious at first, upon examining a patient. If the patient is laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be seen that the pelvis is tilted downwards on the diseased side and the limb apparently longer than its fellow, and that the lumbar spine is arched forwards (lordosis) The condition is thus explained: a limb which is flexed and abducted is obviously useless for progression, and in order to overcome the difficulty the patient depresses the affected side of his pelvis, thus producing parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downwards, instead of forwards. In the later stages of the disease the limb becomes flexed and adducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex action by the irritation of the peripheral terminations of this nerve in the inflamed articulation.

Osteo-arthritis is not uncommon in the hip-joint, and is said to be more common in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or advanced life. When much deformity is associated with chronic osteo-arthritis the condition is spoken of as *Arthritis deformans of the hip*, or *Morbus coxæ senilis.* The head of the femur is worn away, and after it often the neck too, until the irregular articular surface comes to lie on the femur between the two trochanters. New formation of bone occurs at its edges, and also at the edges of the acetabulum, which is widened and eroded by a similar chronic process. Pain in the joint, shortening of the limb, and great limitation of movement result, with much creaking and grating when the joint is moved.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis; and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior incision or by a posterior one. The former entails less interference with important structures, especially muscles, than the latter, but permits of less efficient drainage. In these days, however, when the surgeon aims at securing healing of the wound without suppuration, this second desideratum is not of so much importance. In the operation from the front, an incision is made three to four inches in length, starting immediately below and external to the anterior superior spinous process of the ilium, downwards and inwards between the Sartorius and Tensor fasciæ femoris, to the neck of the bone, dividing the capsule at its upper part. A narrow-bladed saw now divides the neck of the femur, and the head of the bone is extracted with sequestrum forceps. All diseased tissue is carefully removed with a sharp spoon or scissors, and the cavity thoroughly flushed out with a hot antiseptic or sterile fluid.

The posterior method consists in making an incision three or four inches long, commencing midway between the top of the great trochanter and the crest of the ilium, and extending down the posterior border of the trochanter. The muscles are detached from the great trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and the bone sawn through just below the top of the trochanter with a narrow saw. The head of the bone is then levered out of the acetabulum. In both operations, if the acetabulum is eroded, it must be freely gouged.

II. KNEE-JOINT (ARTICULATIO GENU)

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: two condyloid joints, one between each condyle of the femur and the corresponding semilunar cartilage and tuberosity of the tibia, and a third between the patella and the femur, partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where, corresponding to these three subdivisions, three synovial membranes are sometimes found, either entirely distinct or only connected together by small communications. This view is further rendered probable by the existence within the joint of the two crucial ligaments, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the ligamentum mucosum would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each lateral joint.

The bones entering into the formation of the knee-joint are the condyles of the femur above, the head of the tibia below, and the patella in front. They are connected together by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

Exterior Ligaments	*Interior Ligaments*
Capsular.	Anterior or External Crucial.

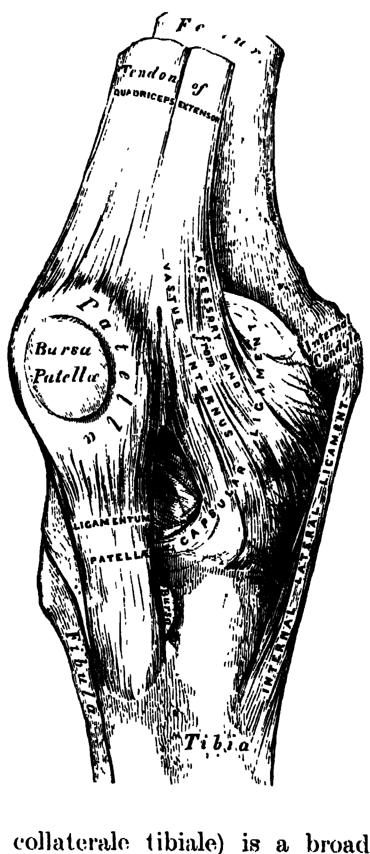
External Lateral.	Coronary.
	Ligamentum mucosum } Processes of Synovial membrane.
	Ligamenta alaria } Processes of Synovial membrane.

The **Capsular Ligament** (capsula articularis) consists of a thin, but strong, fibrous membrane which is strengthened in almost its entire extent by bands inseparably connected with it. Above and in front, beneath the tendon of the Quadriceps extensor muscle, it is so thin that it is usually described as defective. Its chief strengthening bands are derived from the fascia lata and from the tendons surrounding the joint. In front, expansions from the Vasti and from the fascia lata and its ilio-tibial band fill in the intervals between the anterior and lateral ligaments, constituting the *lateral patellar*

ligaments. Behind, the capsular ligament consists of vertical fibres which arise from the condyles and intercondyloid notch of the femur, and are augmented by fibres derived from the tendon of the Semimembranosus, to form the posterior ligament. On the outer side of the joint, a prolongation from the ilio-tibial band fills in the interval between the posterior and the external lateral ligaments, and partly covers the latter. On the inner side, expansions from the Sartorius and Semimembranosus pass upwards to the internal lateral ligament and strengthen the capsule.

The **Anterior Ligament,** or **Ligamentum Patellæ** (fig. 468), is the central portion of the common tendon of the Extensor muscles of the thigh, which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band, about three inches in length, attached, above, to the apex and adjoining margins of the patella and the rough depression on its posterior surface; below, to the tubercle of the tibia; its superficial fibres are continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles pass down on either side of the patella, to be inserted into the upper extremity of the tibia on either side of the tubercle; these portions merge into the capsular ligament, as stated above, forming the lateral patellar ligaments. The posterior surface of the ligamentum patellæ is separated from the synovial membrane of the joint by a large pad (*infrapatellar*) of fat, and from the tibia by a synovial bursa.

FIG. 468.—Right knee-joint. Anterior view.



The **Posterior Ligament** (lig. posticum Winslowii) (fig. 469) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached above to the upper margin of the intercondyloid notch and posterior surface of the femur close to the articular margins of the condyles, and below to the posterior margin of the head of the tibia. Superficial to the main part of the ligament is a strong fasciculus, derived from the tendon of the Semimembranosus and passing from the back part of the inner tuberosity of the tibia obliquely upwards and outwards to the back part of the outer condyle of the femur, where it becomes lost in the general ligament.* The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

The **Internal Lateral Ligament** (lig. collaterale tibiale) is a broad, flat, membranous band, situated nearer to the back than to the front of the joint. It is attached, above, to the inner tuberosity of the femur immediately below the Adductor tubercle; below, to the inner tuberosity and inner surface of the shaft of the tibia. The fibres of the posterior part of the ligament are short, and are inserted into the inner part of the tuberosity of the tibia above the groove for the Semimembranosus muscle. They incline backwards as they descend. The anterior part of the ligament is a flattened band, about four inches in length, which inclines forwards as it descends. It is inserted into the inner surface of the shaft of the tibia about an inch

* This oblique band is sometimes termed the ligamentum posticum Winslowii, in contradistinction to the posterior ligament, which is then regarded as part of the capsular ligament.

and a half below the level of the tuberosity. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semitendinosus muscles, a synovial bursa being interposed. Its *deep surface* covers the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibro-cartilage.

The **External Lateral Ligament** (lig. collaterale fibulare) is a strong, rounded, fibrous cord, attached, above, to the back part of the outer tuberosity of the femur, immediately above the groove for the Popliteus muscle; below, to the outer side of the head of the fibula, in front of the styloid process. Its *outer surface* is covered by the tendon of the Biceps, which divides at its insertion into two parts, separated by the ligament. Passing beneath the ligament are the tendon of the Popliteus muscle, and the inferior external articular vessels and nerve. It has no attachment to the external semilunar fibro-cartilage.

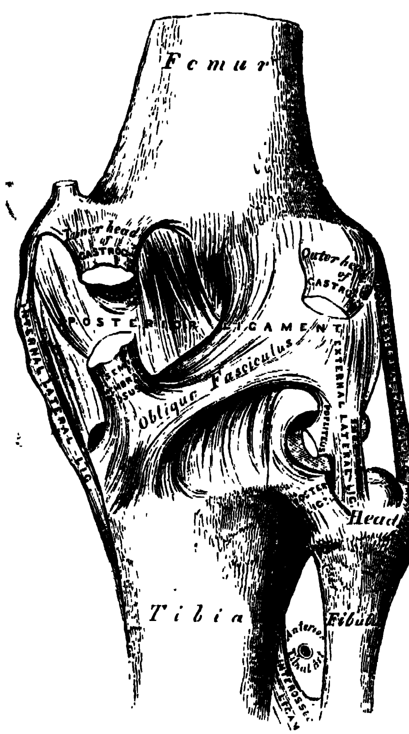


Fig. 469.—Right knee-joint. Posterior view.

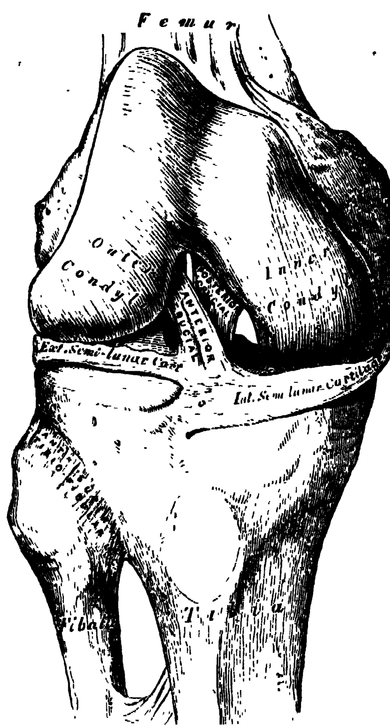

Fig. 470.—Right knee-joint. Showing interior ligaments.

The **Short External Lateral Ligament** is an inconstant bundle of fibres placed behind and parallel with the preceding, attached, above, to the lower and back part of the outer tuberosity of the femur; below, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular ligament, while passing beneath it are the tendon of the Popliteus muscle, and the inferior external articular vessels and nerve.

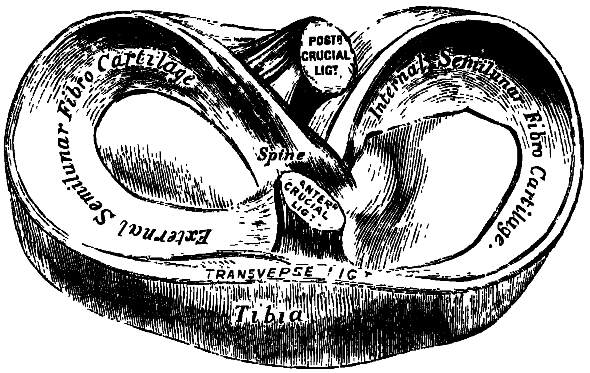
The **Crucial Ligaments** (ligg. cruciata genu) are of considerable strength, situated in the interior of the joint, nearer its posterior than its anterior part. They are called *crucial* because they cross each other somewhat like the lines of the letter X; and have received the names *anterior* and *posterior*, from the position of their attachments to the tibia.

The **Anterior or External Crucial Ligament** (lig. cruciatum anterius) (figs. 470, 471) is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibro-

cartilage; it passes obliquely upwards, backwards, and outwards, and is fixed into the inner and back part of the outer condyle of the femur.

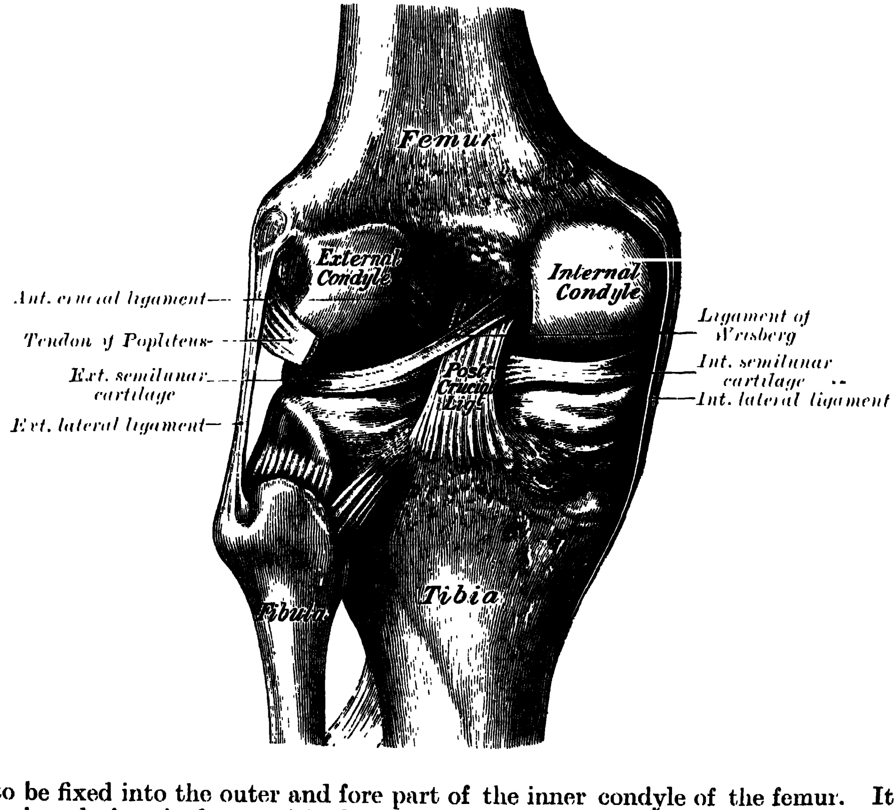
The **Posterior** or **Internal Crucial Ligament** (lig. cruciatum posterius) (figs. 471, 472) is stronger, but shorter and less oblique in its direction, than

FIG. 471.—Head of tibia, with semilunar fibro-cartilages. Seen from above. Right side.



the anterior. It is attached to the back part of the depression behind the spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibro-cartilage; and passes upwards, forwards, and inwards,

FIG. 472.—Left knee-joint from behind, showing interior ligaments.



to be fixed into the outer and fore part of the inner condyle of the femur. It is in relation, in front, with the anterior crucial ligament; behind, with the capsular ligament.

The **Semilunar Fibro-cartilages** (fig. 471) are two crescentic lamellæ, which serve to deepen the surfaces of the head of the tibia for articulation with the condyles of the femur. The peripheral border of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the opposite border is thin, concave, and free. Their upper surfaces are concave, and in relation with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia; both surfaces of the cartilages are smooth, and invested by synovial membrane. Each cartilage covers nearly two-thirds of the periphery of the corresponding articular surface of the tibia.

The **Internal Semilunar Fibro-cartilage** (meniscus medialis) is nearly semicircular in form, a little elongated from before backwards, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is fixed to the depression behind the spine, between the attachments of the external semilunar fibro-cartilage and the posterior crucial ligament.

The **External Semilunar Fibro-cartilage** (meniscus lateralis) forms nearly an entire circle, covering a larger portion of the articular surface than the internal one. It is grooved on its outer side for the tendon of the Popliteus muscle, which separates it from the external lateral ligament. Its extremities, at their insertion, are interposed between the two extremities of the internal semilunar fibro-cartilage; the anterior is attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the posterior is attached behind the spine of the tibia and in front of the posterior extremity of the internal semilunar fibro-cartilage. The anterior attachment of the external semilunar cartilage is twisted on itself so that its free margin looks backwards and upwards, its anterior end resting on a sloping shelf of bone on the front of the external tubercle of the tibial spine. Close to its posterior attachment it gives off a strong fasciculus, the *ligament of Wrisberg*, which passes obliquely upwards and inwards, to be inserted into the inner condyle of the femur, immediately behind the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off which passes forwards to be inserted into the back part of the anterior crucial ligament. The external semilunar fibro-cartilage gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The **Transverse Ligament** (lig. transversum genu) is a band of fibres which passes transversely from the anterior convex margin of the external semilunar fibro-cartilage to the anterior convex margin of the internal semilunar fibro-cartilage; its thickness varies considerably in different subjects, and it is sometimes absent.

The **Coronary Ligaments** (ligamenta coronaria) are merely portions of the capsular ligament, which connect the periphery of each of the semilunar fibro-cartilages with the margin of the head of the tibia.

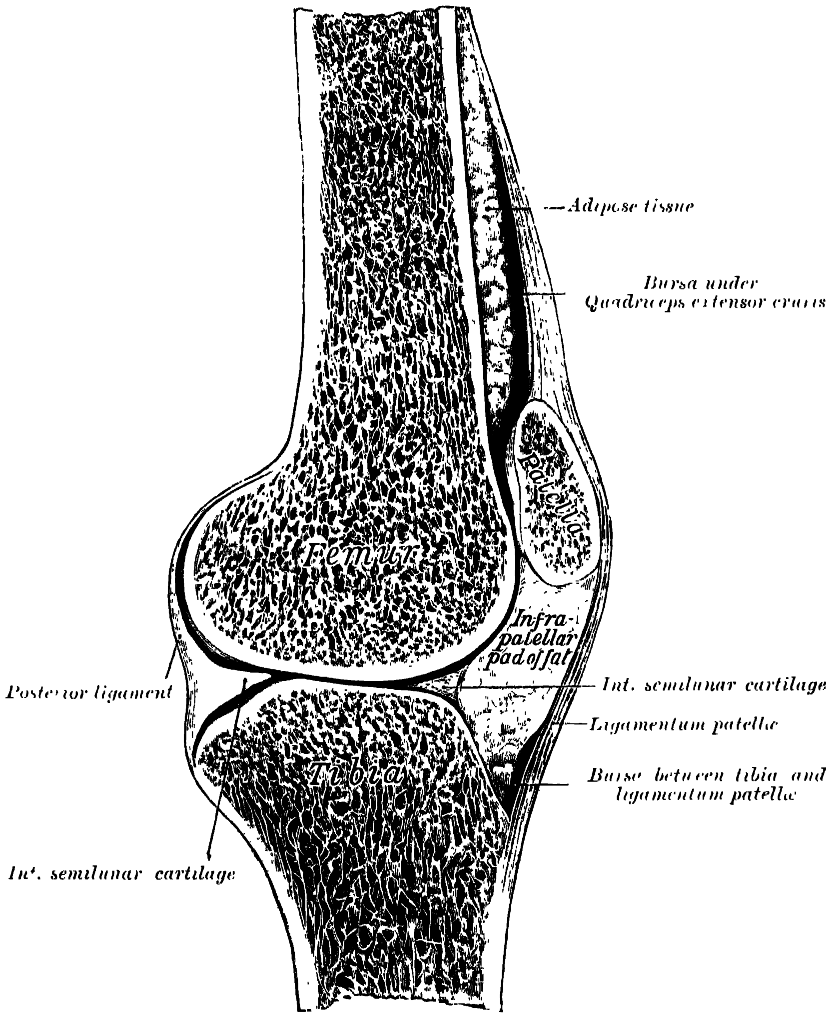
The **Synovial Membrane** of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a short *cul-de-sac* beneath the Quadriceps extensor tendon, on the lower part of the front of the shaft of the femur: this very frequently communicates with a synovial bursa interposed between the tendon and the front of the femur, by an orifice of variable size. The pouch of synovial membrane between the Extensor tendon and front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into it. On either side of the patella, the synovial membrane extends beneath the aponeurosis of the Vastus, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by a considerable quantity of adipose tissue, known as the *infrapatellar pad.* In this situation it sends into the interior of the joint a triangular prolongation, which extends from the anterior part of the joint below the patella to the front of the intercondyloid notch. This fold has been termed the **ligamentum mucosum** (plica synovialis patellaris). It also sends off two fringe-like folds, called the **ligamenta alaria** (plicæ alares) which extend from the sides of the ligamentum mucosum, upwards and laterally between the patella and femur. On either side of the joint, it passes downwards from the femur, lining the

capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and thence along their under surfaces to the tibia. At the back part of the external one it forms a *cul-de-sac* between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments, and lines the inner surfaces of the ligaments which enclose the joint.

Bursæ.—The bursæ about the knee-joint are the following:

In front there are four bursæ: one is interposed between the patella and the skin; another of small size between the upper part of the tibia and the ligamentum patellæ; a third between the lower part of the tuberosity of

FIG. 473.—Sagittal section of right knee-joint.



the tibia and the skin; and a fourth between the anterior surface of the lower end of the femur and the under surface of the Quadriceps extensor cruris, usually communicating with the knee-joint. On the outer side there are four bursæ: (1) one (which sometimes communicates with the joint) between the outer head of the Gastrocnemius and the capsule; (2) one above the external lateral ligament, between it and the tendon of the Biceps; (3) one beneath the external lateral ligament, between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus, between it and the condyle of the femur, which is almost always an extension from the synovial membrane.

On the inner side there are five bursæ : (1) one between the inner head of the Gastrocnemius and the capsule; this sends a prolongation between the tendons of the Gastrocnemius and Semimembranosus and often communicates with the joint ; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semitendinosus ; (3) one beneath the internal lateral ligament, between it and the tendon of the Semimembranosus (this is sometimes only an expansion from the next bursa) ; (4) one beneath the tendon of the Semimembranosus, between it and the head of the tibia ; (5) occasionally there is a bursa between the tendons of the Semimembranosus and Semitendinosus.

Structures around the Joint.—In front, and at the sides, is the Quadriceps extensor ; on the outer side, the tendons of the Biceps and Popliteus and the external popliteal nerve ; on the inner side, the Sartorius, Gracilis, Semitendinosus and Semimembranosus ; behind, an expansion from the tendon of the Semimembranosus, the popliteal vessels, and the internal popliteal nerve, Popliteus, Plantaris, and inner and outer heads of the Gastrocnemius, some lymphatic glands, and fat.

The *Arteries* supplying the joint are the anastomotica magna, a branch of the femoral, the articular branches of the popliteal, the anterior and posterior recurrent branches of the anterior tibial, and the descending branch from the external circumflex of the profunda.

The *Nerves* are derived from the obturator, anterior crural, and external and internal popliteal.

Movements.—The movements which take place at the knee-joint are flexion and extension, and, in certain positions of the joint, internal and external rotation. The movements of flexion and extension at this joint differ from those in a typical hinge-joint, such as the elbow, in that (*a*) the axis round which motion takes place is not a fixed one, but shifts forwards during extension and backwards during flexion ; (*b*) the commencement of flexion and the end of extension are accompanied by rotatory movements associated with the fixation of the limb in a position of great stability. The movement from full flexion to full extension may therefore be described in three phases.

1. In the fully flexed condition the posterior parts of the femoral condyles rest on the corresponding portions of the menisco-tibial surfaces, and in this position a slight amount of simple rolling movement is allowed.

2. During the passage of the limb from the flexed to the extended position a gliding movement is superposed on the rolling, so that the axis, which at the commencement is represented by a line through the inner and outer tuberosities of the femur, gradually shifts forwards. In this part of the movement, the posterior two-thirds of the tibial articular surfaces of the two femoral condyles are involved, and as these have similar curvatures and are parallel to one another, they move forwards equally.

3. The external condyle is brought almost to rest by the tightening of the anterior crucial ligament ; it moves, however, slightly forwards and inwards, pushing before it the anterior part of the external semilunar cartilage. The tibial surface on the internal condyle is prolonged farther forwards than that on the external, and this prolongation is directed outwards. When, therefore, the movement forwards of the condyles is checked by the anterior crucial ligament, continued muscular action causes the internal condyle, dragging with it the semilunar cartilage, to travel backwards and inwards, thus producing an internal rotation of the thigh on the leg. When the position of full extension is reached the outer part of the groove on the external condyle is pressed against the anterior part of the corresponding semilunar cartilage, while the inner part of the groove rests on the articular margin in front of the external tubercle of the tibial spine. Into the groove on the internal condyle is fitted the anterior part of the internal semilunar cartilage, while the anterior crucial ligament and the articular margin in front of the inner tubercle of the tibial spine are received into the fore part of the intercondyloid notch. This third phase by which all these parts are brought into accurate apposition is known as the 'screwing home,' or locking movement of the joint.

The complete movement of flexion is the converse of that described above, and is therefore preceded by an external rotation of the femur which unlocks the extended joint.

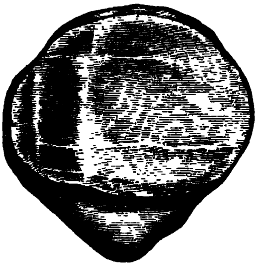
The axes round which the movements of flexion and extension take place are not precisely at right angles to either bone; in flexion, the femur and tibia are in the same plane, but in extension the one bone forms an angle with the other.

In addition to the rotatory movements associated with the completion of extension and the initiation of flexion, rotation inwards or outwards can be effected when the joint is partially flexed. These latter rotatory movements take place mainly between the tibia and the semilunar cartilages, and are freest when the leg is bent at right angles with the thigh.

Movements of Patella.—The articular surface of the patella is indistinctly divided into seven facets—upper, middle, and lower horizontal pairs, and an internal perpendicular facet (fig. 474). When the knee is forcibly flexed, the internal perpendicular facet is in contact with the semilunar surface on the outer part of the internal condyle; this semilunar surface is a prolongation backwards of the inner part of the trochlea. As the leg is carried from the flexed to the extended position, first the uppermost pair, then the middle pair, and lastly the lowest pair of horizontal facets are successively brought into contact with the trochlear surface of the femur. In the extended position, when the Quadriceps extensor is relaxed, the patella lies loosely on the front of the lower end of the femur.

During flexion, the ligamentum patellæ is put upon the stretch, and in extreme flexion so also is the posterior crucial ligament; the lateral and posterior ligaments, and, to a slight extent, the anterior crucial ligament, are relaxed. Flexion is checked during life by the contact of the leg with the thigh. When the knee-joint is fully extended the lateral and posterior ligaments, the anterior crucial ligament, and the inner part of the posterior crucial ligament, are rendered tense; in the act of extending the knee, the ligamentum patellæ is tightened by the Quadriceps extensor, but in full extension with the heel supported it is relaxed. Rotation inwards is checked by the anterior crucial ligament; rotation outwards tends to uncross and relax the crucial ligaments, but is checked by the internal lateral ligament. The main function of the crucial ligaments is to act as a direct bond between the tibia and femur and to prevent the former bone from being carried too far backwards or forwards. They also assist the lateral ligaments in resisting any lateral bending of the joint. The interarticular cartilages are intended, as it seems, to adapt the surface of the tibia to the shape of the femur to a certain extent, so as to fill up the intervals which would otherwise be left in the varying positions of the joint, and to obviate the jars which would be so frequently transmitted up the limb in jumping or by falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface, during kneeling, the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor.

FIG. 474.—Posterior surface of the right patella, showing diagrammatically the areas of contact with the femur in different positions of the knee.



When standing erect in the attitude of 'attention,' the weight of the body falls in front of a line carried across the centres of the knee-joints, and therefore tends to produce over-extension of the articulations; this, however, is prevented by the tension of the anterior crucial, posterior, and lateral ligaments.

Extension of the leg on the thigh is performed by the Quadriceps extensor; *flexion* by the hamstring muscles, assisted by the Gracilis and Sartorius, and by the Gastrocnemius, Popliteus, and Plantaris. *Rotation outwards* is effected by the Biceps, and *rotation inwards* by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis. The Popliteus comes into action especially at the commencement of the movement of flexion of the knee; by its contraction the leg is rotated inwards, or, if the tibia be fixed, the thigh is rotated outwards, and the knee-joint is unlocked.

Surface Form.—The interval between the femur and tibia can always be easily felt. If the limb be extended, it is situated on a slightly higher level than the apex of the patella; but if the limb be slightly flexed, a knife carried horizontally backwards immediately below the apex of the patella would pass directly into the joint. When the knee is semi-flexed, the internal border of the inner condyle of the femur, the upper border of the inner tuberosity of the tibia, and the inner margin of the patella form a triangular depressed area, which coincides with the level of the joint and with the internal semilunar fibro-cartilage. If this cartilage be displaced inwards, a gap will be felt in this situation. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Applied Anatomy.—From a consideration of the construction of the knee-joint, it would at first sight appear to be one of the least secure of any of the joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is considerable; the articular surfaces are but ill-adapted to each other, and the range of motion which it enjoys is great. All these circumstances tend to render the articulation insecure; nevertheless, on account of the powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumatism is a rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated forwards, backwards, inwards, or outwards; or a combination of two of these dislocations may occur, and any of these dislocations may be complete or incomplete.

One or other of the semilunar cartilages may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inwards or outwards: that is to say, either inwards towards the tibial spine, so that the cartilage becomes lodged in the intercondyloid notch; or outwards, so that the cartilage projects beyond the margin of the two articular surfaces. The internal cartilage is much more commonly the one affected.

Acute synovitis, the result of traumatism, is very common in the knee, on account of the superficial position of the joint. When the cavity is distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch, occasionally two inches or more, above the trochlear surface of the femur, and extending a little higher under the Vastus internus than under the Vastus externus. The lower level of the synovial membrane is just above the level of the head of the tibia. Chronic synovitis shows itself principally in the form of pulpy degeneration of the synovial membrane, leading to tuberculous arthritis. The reasons why tuberculous disease of the knee usually commences in the synovial membrane appear to be (*a*) the complex and extensive nature of this sac, and (*b*) the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bones. Syphilitic disease not infrequently attacks the knee-joint. In the tertiary form of the disease, gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilages is almost confined to the knee, though they are occasionally met with in other joints. Many of them occur in cases of osteo-arthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, 'loose' cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

In inflammatory affections of the knee-joint, the position of greatest ease, and therefore the one which is always assumed, is that of slight flexion. In this position there is the most complete relaxation of ligamentous structures, and, therefore, the greatest diminution in the tension caused by the effusion. If this flexed position be maintained for any length of time, it becomes permanent from fibrous adhesions taking place, and the utility of the limb is materially impaired. Attention should therefore be paid by the surgeon to the position of the limb; and by carefully applied splints, with the leg in an extended position, this untoward result should be prevented. In cases of septic synovitis, incisions to evacuate the pus should be made vertically on either side of the patella, between it and the condyles of the femur.

Genu valgum, or knock knee, is a common deformity of childhood. In this condition, owing to changes in and about the joint, the angle between the outer borders of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiæ are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer

tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth, and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. Irregular overgrowth from the inner portion of the epiphysial line takes place, giving rise to apparent enlargement of the inner condyle of the femur, the line of the epiphysis becoming oblique, with a direction downwards and inwards, instead of at right angles to the axis of the bone. If the deformity be marked, an osteotomy of the femur is required to correct it.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practised in cases of disorganisation of the knee from other causes. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed by a horse-shoe incision, starting from one condyle, descending as low as the tubercle of the tibia, and then carried upwards to the other condyle. The bone having been cleared, and in those cases where the operation is performed for tuberculous disease all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysial cartilage will be involved, with disastrous results as regards the growth of the limb. Afterwards a thin slice should be removed from the upper end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge, rather than that a further section of the bones should be made.

The bursæ about the knee-joint are sometimes the seat of enlargement. The prepatellar bursa—i.e. the bursa between the front of the patella and the skin—is frequently affected in individuals who are in the habit of constantly kneeling, and the condition is then known as 'housemaid's knee.' The bursa beneath the Semimembranosus tendon also occasionally becomes enlarged, and forms a fluctuating swelling at the back of the knee. During extension, the swelling is firm and tense; but during flexion it becomes soft, and, as the bursa often communicates with the synovial cavity, the fluid it contains can be made to disappear by pressure when the knee is flexed. Extension of septic processes within the joint is apt to occur along the tendon sheath of the Popliteus muscle, and this may lead to deep-seated suppuration in the popliteal space, often associated with septic thrombosis of the popliteal vein; when this occurs amputation of the limb becomes necessary.

III. ARTICULATIONS BETWEEN THE TIBIA AND FIBULA

The articulations between the tibia and fibula are effected by ligaments which connect both extremities; in addition the shafts of the bones are bound together. The ligaments may consequently be subdivided into three sets: 1. Those of the Superior Tibio-fibular articulation. 2. The Middle Tibio-fibular ligament or interosseous membrane. 3. Those of the Inferior Tibio-fibular articulation.

1. Superior Tibio-fibular Articulation (Articulatio Tibiofibularis)

This articulation is an arthrodial joint. The contiguous surfaces of the bones present flat, oval facets covered with cartilage and connected together by the following ligaments:

Capsular.
Anterior Superior Tibio-fibular. Posterior Superior Tibio-fibular.

The **Capsular Ligament** (capsula articularis) surrounds the articulation, being attached round the margins of the articular facets on the tibia and fibula; it is much thicker in front than behind.

The **Anterior Superior Tibio-fibular Ligament** (lig. capituli fibulæ anterius) (fig. 470) consists of two or three broad and flat bands, which pass obliquely upwards and inwards from the front of the head of the fibula to the front of the outer tuberosity of the tibia.

The **Posterior Superior Tibio-fibular Ligament** (lig. capituli fibulæ posterius) (fig. 469) is a single thick and broad band, which passes upwards and inwards from the back part of the head of the fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.

A **Synovial Membrane** lines the capsule, and at its upper and back part is occasionally continuous with that of the knee-joint.

2. Middle Tibio-fibular Ligament or Interosseous Membrane

An **Interosseous Membrane** (membrana interossea cruris) extends between the interosseous margins of the tibia and fibula, and separates the muscles on

the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres, which for the most part pass downwards and outwards; some few fibres, however, pass in the opposite direction. It is broader above than below. Its upper margin does not quite reach the superior tibio-fibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels to the front of the leg. At its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament, and presents numerous perforations for the passage of small vessels. It is in relation, in front, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; behind, with the Tibialis posticus and Flexor longus hallucis.

3. Inferior Tibio-fibular Articulation (Syndesmosis Tibio-fibulare)

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, and a concave rough surface on the outer side of the tibia. Below, to the extent of about a sixth of an inch, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are:

Anterior Inferior Tibio-fibular.	Transverse Inferior.
Posterior Inferior Tibio-fibular.	Interosseous.

The **Anterior Inferior Tibio-fibular Ligament** (lig. malleoli lateralis anterius) (fig. 476) is a flat, triangular band of fibres, broader below than above, which extends obliquely downwards and outwards between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in front, with the Peroneus tertius, the aponeurosis of the leg, and the integument; behind, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The **Posterior Inferior Tibio-fibular Ligament** (lig. malleoli lateralis posterius), smaller than the preceding, is disposed in a similar manner on the posterior surface of the articulation.

The **Transverse Inferior Ligament** lies under cover of the posterior ligament, and is a strong, thick band of yellowish fibres which passes transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The **Interosseous Ligament** consists of numerous short, strong, fibrous bands, which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. It is continuous, above, with the interosseous membrane.

The **Synovial Membrane** which is associated with the small arthrodial part of this joint is continuous with that of the ankle-joint.

IV. Ankle-joint (Articulatio Talocruralis)

The ankle-joint is a ginglymus, or hinge-joint. The structures entering into its formation are the lower extremity of the tibia and its malleolus, the external malleolus of the fibula, and the transverse ligament, which together form a mortise to receive the upper convex surface of the astragalus and its two lateral facets. The surfaces are connected by a capsule, which in places forms thickened bands constituting the following ligaments:

Capsular.

Anterior.	Internal Lateral.
Posterior.	External Lateral.

The **Capsular Ligament** (capsula articularis) is an imperfect ligamentous structure which surrounds the joint, and is attached, above, to the borders of the articular surface of the tibia; and below, to the astragalus around its

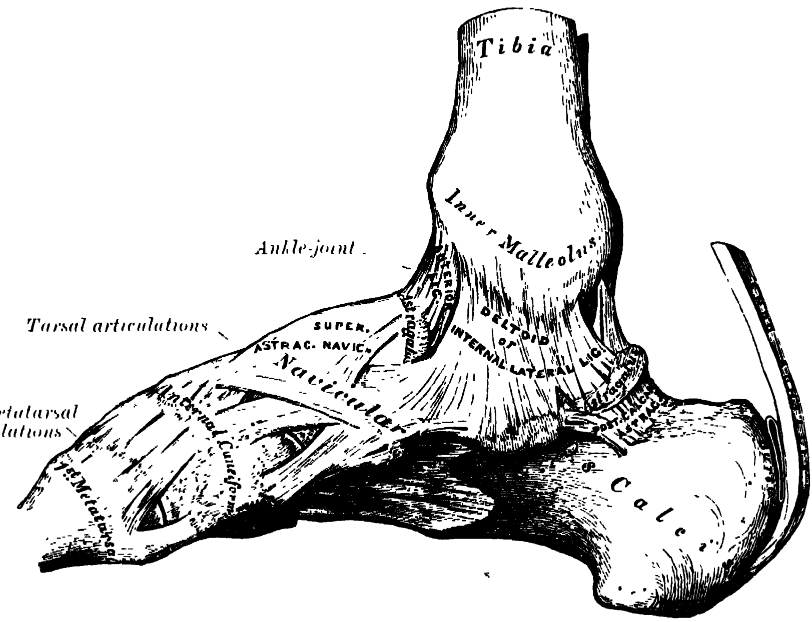
upper articular surface. The parts of which it is composed vary considerably in strength.

The **Anterior Ligament** (fig. 475) is a broad, thin, membranous layer, attached, above, to the anterior margin of the lower extremity of the tibia, below, to the astragalus, in front of its superior articular surface. It is in relation, in front, with the Extensor tendons of the toes, the tendons of the Tibialis anticus and Peroneus tertius, and the anterior tibial vessels and nerve.

The **Posterior Ligament** is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament; below, to the astragalus behind its superior articular facet. Externally, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus, it is stouter than internally.

The **Internal Lateral** or **Deltoid Ligament** (lig. deltoideum) (fig. 475) is a strong, flat, triangular band, attached, above, to the apex and anterior and posterior borders of the inner malleolus. It consists of two sets of fibres,

Fig. 475.—Ankle-joint, tarsal and tarso-metatarsal articulations. Internal view. Right side.



superficial and deep. Of the superficial fibres the most anterior pass forwards to be inserted into the tuberosity of the navicular bone, and immediately behind this they blend with the inner margin of the inferior calcaneo-navicular ligament; the middle descend almost perpendicularly to be inserted into the whole length of the sustentaculum tali of the os calcis; the posterior fibres pass backwards and outwards to be attached to the inner side of the astragalus, and to the prominent tubercle on its posterior surface, internal to the groove for the tendon of the Flexor longus hallucis. The deep fibres are attached, above, to the tip of the inner malleolus, and, below, to the inner surface of the astragalus. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum.

The **External Lateral Ligament** (fig. 476) consists of three fasciculi, taking different directions, and separated by distinct intervals, for which reason it is described by some anatomists as three distinct ligaments.

The *anterior fasciculus* (lig. talofibulare anterius), the shortest of the three, passes from the anterior margin of the external malleolus, forwards and inwards to the astragalus, in front of its external articular facet.

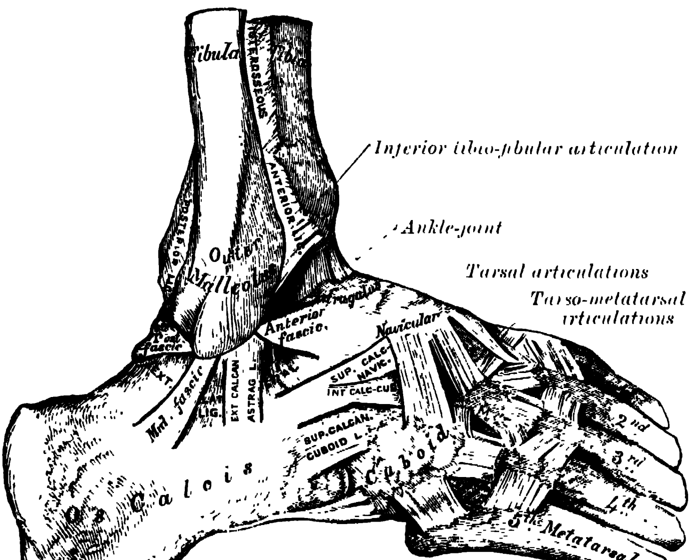
The *posterior fasciculus* (lig. talofibulare posterius), the strongest and most deeply seated, passes inwards from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus immediately external to the groove for the tendon of the Flexor longus hallucis. Its fibres are almost horizontal in direction.

The *middle fasciculus* (lig. calcaneofibulare), the longest of the three, is a narrow, rounded cord, running from the apex of the external malleolus downwards and slightly backwards to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peronei longus et brevis.

The **Synovial Membrane** invests the inner surfaces of the ligaments, and sends a duplicature upwards between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in front, from within outwards, the Tibialis anticus, Extensor proprius hallucis, anterior tibial vessels, anterior tibial nerve, Extensor longus digitorum, and Peroneus tertius; behind, from within outwards, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels, posterior tibial nerve, Flexor longus

Fig. 476.—Ankle-joint, tarsal and tarso-metatarsal articulations. External view. Right side.



hallucis: and, in the groove behind the external malleolus, the tendons of the Peronei longus et brevis.

The *Arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

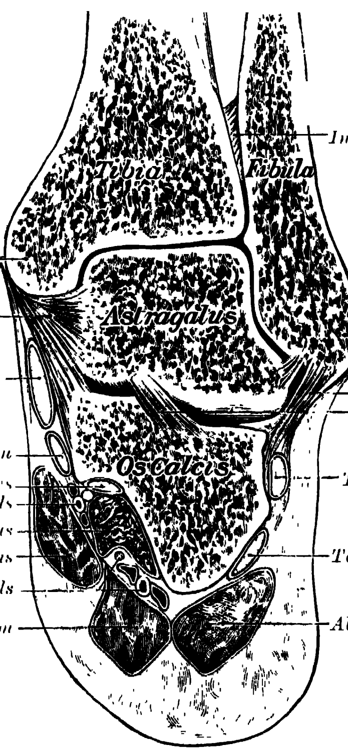
The *Nerves* are derived from the anterior and posterior tibial.

Movements.—When the body is in the erect position, the foot is at right angles to the leg. The movements of the joint are those of dorsiflexion and extension; dorsiflexion consists in the approximation of the dorsum of the foot to the front of the leg, while in extension the heel is drawn up and the toes pointed downwards. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibio-fibular ligaments, and slight bending of the shaft of the fibula. The superior articular surface of the astragalus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight outward rotatory movement of the lower end of the fibula and a stretching of the inferior tibio-fibular ligaments; this outward movement is facilitated by a slight gliding at the superior tibio-fibular

articulation, and possibly also by the bending of the shaft of the fibula. Of the ligaments, the internal lateral is of very great power—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backwards, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forwards, and limits extension of the joint.

The movements of inversion and eversion of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, &c., are mainly effected in the tarsal joints; the joint which enjoys the greatest amount of motion being that between the astragalus and os calcis behind,

FIG. 477.—Coronal section of right ankle-joint and foot.



and the navicular and cuboid in front. This is often called the *transverse* or *medio-tarsal joint*, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the foot upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posticus, Peronei longus et brevis, Flexor longus digitorum, and Flexor longus hallucis; *dorsiflexion*, by the Tibialis anticus, Peroneus tertius, Extensor longus digitorum, and Extensor proprius hallucis.*

Surface Form.—The level of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus. The joint can be felt on either side of the Extensor tendons; and during extension of the foot, the superior facet of the astragalus can be perceived below the anterior border of the lower end of the tibia.

* The student must bear in mind that the Extensor longus digitorum and Extensor proprius hallucis are *extensors* of the toes, but *flexors* of the ankle; and that the Flexor longus digitorum and Flexor longus hallucis are *flexors* of the toes, but *extensors* of the ankle.

Applied Anatomy.—As the ankle-joint is a very strong and powerful articulation, displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of common occurrence, and great force is required to produce it. Nevertheless, dislocation does occasionally occur, both in an antero-posterior and a lateral direction. In the latter, which is the more common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation round an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upwards, is inclined more or less inwards or outwards according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the Tibialis anticus and the internal lateral ligament on the inner side, and between the Peroneus tertius and the external lateral ligament on the outer side. In addition to this, bulging often occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo Achillis.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; or the synovitis may be tuberculous in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence in the synovial membrane, the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed, for two reasons. In the first place, disease of the articulation for which this operation is indicated is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is often of very little use; far less useful, in fact, than it is after Syme's amputation, which is, therefore, a preferable operation in these cases.

V. INTERTARSAL ARTICULATIONS (ARTICULATIONES INTERTARSEÆ)

1. ARTICULATION OF THE OS CALCIS AND ASTRAGALUS (ARTICULATIO TALOCALCANEA)

The articulations between the os calcis and astragalus are two in number—anterior and posterior. Of these, the anterior forms part of the joint between the os calcis, astragalus, and navicular, and will be described as the astragalo-calcaneo-navicular articulation. The posterior or astragalo-calcanean articulation is formed between the posterior and larger facet on the inferior surface of the astragalus, and the external facet on the superior surface of the os calcis. It is an arthrodial joint, and the two bones are connected together by the following ligaments:

Capsular.	Anterior Calcaneo-astragaloid.
External Calcaneo-astragaloid.	Posterior Calcaneo-astragaloid.
Internal Calcaneo-astragaloid.	Interosseous.

The **Capsular Ligament** (capsula articularis) surrounds the two articular surfaces, and consists for the most part of short fibres, which are split up into distinct slips, forming the specially named ligaments of the articulation; between them there is only a weak fibrous investment.

The **External Calcaneo-astragaloid Ligament** (lig. talocalcaneum laterale) (fig. 476) is a short, strong fasciculus, passing from the outer surface of the astragalus, immediately beneath its external facet, to the outer surface of the os calcis. It is placed in front of, but on a deeper plane than, the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

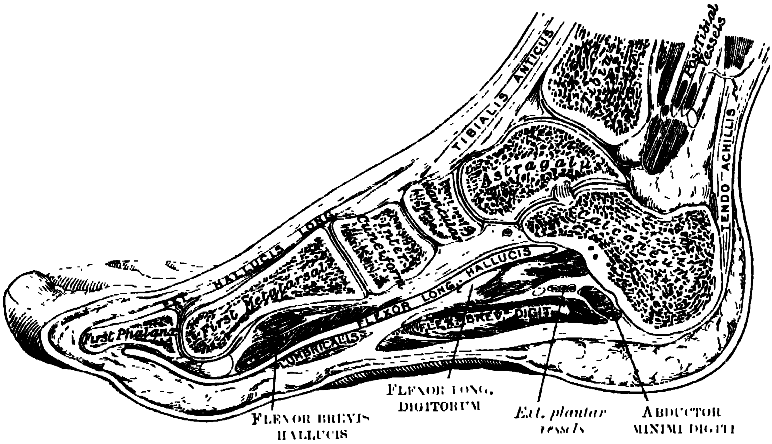
The **Internal Calcaneo-astragaloid Ligament** (lig. talocalcaneum mediale) is a band of fibres connecting the internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneo-navicular ligament.

The **Anterior Calcaneo-astragaloid Ligament** (lig. talocalcaneum anterius) extends from the front and outer surface of the neck of the astragalus to the superior surface of the os calcis. It forms the posterior boundary of the anterior calcaneo-astragaloid joint, and is sometimes described as the *anterior interosseous ligament.*

The **Posterior Calcaneo-astragaloid Ligament** (lig. talocalcaneum posterius) (fig. 475) connects the external tubercle of the astragalus with the upper and inner part of the os calcis ; it is a short band, the fibres of which radiate from their narrow attachment to the astragalus.

The **Interosseous Ligament** (lig. talocalcaneum interosseum) (fig. 477) forms the chief bond of union between the bones. It is, in fact, the united capsular ligaments of the two joints mentioned above, the astragalo-calcaneo-navicular and the astragalo-calcanean, and consists of two partially united layers of fibres, one belonging to the anterior and the other to the posterior joint. It is attached by one extremity to the groove between the articular

Fig. 478.—Sagittal section of the right foot near its inner border, dividing the tibia, astragalus, navicular, internal cuneiform, and first metatarsal bone, and the first phalanx of the great toe. (After Braune.)



facets of the under surface of the astragalus ; by the other, to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

The **Synovial Membrane** (fig. 480) lines the capsule of the joint, and is distinct from the other synovial membranes of the tarsus.

Movements.—The movements permitted between the astragalus and os calcis are limited to gliding of the one bone on the other backwards and forwards and from side to side.

2. Articulation of the Astragalus with the Os Calcis and Navicular (Articulatio Talocalcaneonavicularis)

The articulation between the astragalus and navicular is an arthrodial joint : the rounded head of the astragalus being received into the concavity formed by the posterior surface of the navicular, the anterior articular surface of the calcaneum, and the upper surface of the inferior calcaneo-navicular ligament, which are all directly continuous with each other. There are two ligaments in this joint :

Capsular. Superior Astragalo-navicular.

The **Capsular Ligament** (capsula articularis) consists of a layer of fibres, imperfectly developed except posteriorly, where it becomes greatly increased, and forms, with a part of the capsule of the astragalo-calcanean joint, the strong interosseous ligament which fills in the canal formed by the opposing grooves on the os calcis and astragalus, as above mentioned.

The **Superior Astragalo-navicular Ligament** (lig. talonaviculare dorsale) (fig. 475) is a broad band, which passes obliquely forwards from the neck of the astragalus to the superior surface of the navicular bone. It is weak, and thin

in texture, and covered by the Extensor tendons. The inferior calcaneo-navicular supplies the place of an inferior ligament.

The **Synovial Membrane** lines all parts of the capsule of the joint.

Movements.—This articulation permits of a considerable range of gliding movements; its feeble construction allows occasionally of dislocation of the other bones of the tarsus from the astragalus.

3. Articulations of the Os Calcis with the Cuboid (Articulatio Calcaneocuboidea)

The ligaments connecting the os calcis with the cuboid are five in number:

Capsular

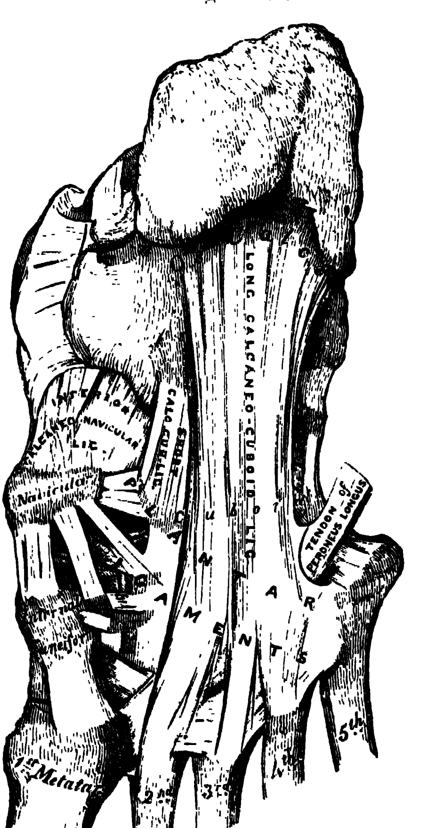
Dorsal { Superior Calcaneo-cuboid. / Internal Calcaneo-cuboid (Interosseous).

Plantar { Long Calcaneo-cuboid. / Short Calcaneo-cuboid.

The **Capsular Ligament** (capsula articularis) is an imperfectly developed layer, containing certain strengthened bands, which form the other named ligaments of the joint.

The **Superior** or **Dorsal Calcaneo-cuboid Ligament** (fig. 476) is a thin but broad fasciculus, which passes between the contiguous surfaces of the os calcis and cuboid, on the dorsal surface of the joint.

Fig. 479.—Ligaments of plantar surface of the right foot.



The **Internal Calcaneo-cuboid (Interosseous) Ligament** (fig. 476) is a short, but thick and strong band of fibres, arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended at its origin with the superior calcaneo-navicular ligament, so as to form with it a V-shaped structure. It is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The **Long Calcaneo-cuboid** or **Long Plantar Ligament** (lig. plantare longum) (fig. 479), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus: it is attached to the under surface of the os calcis, from near the tuberosities to the anterior tubercle; its fibres pass forwards to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being continued onwards to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

The **Short Calcaneo-cuboid** or **Short Plantar Ligament** (lig. calcaneocuboideum plantare) (fig. 479) lies nearer to the bones than the preceding, from which it is separated by a little areolar tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle and the depression in front of it, on the fore part

of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.

Synovial Membrane.—The synovial membrane in this joint is distinct from that of the other tarsal articulations (fig. 480). It lines the inner surface of the capsule.

Movements.—The movements permitted between the os calcis and cuboid are limited to slight gliding movements of the bones upon each other.

The *transverse tarsal* or *medio-tarsal joint* is formed by the articulation of the os calcis with the cuboid, and the articulation of the astragalus with the navicular. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the foot may be slightly flexed or extended, the sole being at the same time carried inwards (inverted) or outwards (everted).

4. The Ligaments connecting the Os Calcis and Navicular

Though these two bones do not directly articulate, they are connected by two ligaments:

Superior or External Calcaneo-navicular.
Inferior or Internal Calcaneo-navicular.

The **Superior** or **External Calcaneo-navicular Ligament** (lig. calcaneonaviculare dorsale) (fig. 476) arises, as already mentioned, with the internal calcaneo-cuboid in the deep hollow between the astragalus and os calcis; it passes forwards from the upper surface of the anterior extremity of the os calcis to the outer side of the navicular bone. These two ligaments resemble the letter Y, being blended together behind but separated in front.

The **Inferior** or **Internal Calcaneo-navicular Ligament** (lig. calcaneonaviculare plantare) (fig. 479) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, and passes forwards and inwards from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the navicular bone. This ligament not only serves to connect the os calcis and navicular, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The *upper surface* presents a fibro-cartilaginous facet, lined by the synovial membrane continued from the anterior calcaneo-astragaloid articulation, and upon this a portion of the head of the astragalus rests. The *under surface* is in contact with the tendon of the Tibialis posticus muscle; its *inner border* is blended with the fore part of the internal lateral ligament of the ankle-joint, thus completing the socket for the head of the astragalus.

Applied Anatomy.—The inferior calcaneo-navicular ligament, by supporting the head of the astragalus, is principally concerned in maintaining the arch of the foot. When it yields, the head of the astragalus is pressed downwards, inwards, and forwards by the weight of the body, and the foot becomes flattened, expanded, and turned outwards, and exhibits the condition known as *flat-foot.* This ligament contains a considerable amount of elastic fibres, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the 'spring' ligament. It is supported, on its under surface, by the tendon of the Tibialis posticus, which spreads out at its insertion into a number of fasciculi, which are attached to most of the tarsal and metatarsal bones. This prevents undue stretching of the ligament, and is a protection against the occurrence of flat-foot, hence muscular weakness is, in most cases, the primary cause of the deformity.

5. The Articulation of the Navicular with the Cuneiform Bones (Articulatio Cuneonavicularis)

The navicular is connected to the three cuneiform bones by:

Dorsal and Plantar ligaments.

The **Dorsal Ligaments** are small, longitudinal bands, arranged as three bundles, one to each of the cuneiform bones. The bundle connecting the navicular with the internal cuneiform is continuous round the inner side of the articulation with the plantar ligament which connects these two bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by processes given off by the tendon of the Tibialis posticus.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

Movements.—Mere gliding movements are permitted between the navicular and cuneiform bones.

6. The Articulation of the Navicular with the Cuboid (Articulatio Cuboideonavicularis)

The navicular bone is connected with the cuboid by:

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** extends obliquely forwards and outwards from the navicular to the cuboid bone.

The **Plantar Ligament** passes nearly transversely between these two bones.

The **Interosseous Ligament** consists of strong transverse fibres, and connects the rough non-articular portions of the lateral surfaces of the two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

7. The Articulation of the Cuneiform Bones with each other (Articulationes Intercuneiformes)

These bones are connected together by:

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligaments** consist of two transverse bands: one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by processes given off from the tendon of the Tibialis posticus.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent cuneiform bones.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the cuneiform bones are limited to a slight gliding upon each other.

8. The Articulation of the External Cuneiform Bone with the Cuboid (Articulatio Cuneocuboidea)

These bones are connected together by:

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** passes transversely between the two bones.

The **Plantar Ligament** has a similar arrangement. It is strengthened by a process given off from the tendon of the Tibialis posticus.

The **Interosseous Ligament** consists of strong transverse fibres which connect the adjacent rough non-articular surfaces of the two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the external cuneiform and cuboid are limited to a slight gliding upon each other.

Nerve-supply.—All the joints of the tarsus are supplied by the anterior tibial nerve.

Applied Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur; though, on account of the spongy character of the bones, they are more frequently broken as the result of violence, than dislocated. When dislocation takes place, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining *in situ* in the tibio-fibular mortise. This constitutes what is known as the *sub-astragaloid* dislocation. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the navicular in front—and may even undergo a rotation, on either a vertical or a horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upwards and downwards, so that the trochlear surface faces to one or the other side. Reduction in these cases is often very difficult or impossible, and the displaced astragalus may then require removal by open operation. Dislocation may also occur at the medio-tarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

VI. TARSO-METATARSAL ARTICULATIONS (ARTICULATIONES TARSOMETATARSEÆ)

These are arthrodial joints. The bones entering into their formation are four tarsal bones, viz. the internal, middle and external cuneiform, and the cuboid, which articulate with the bases of the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiforms resting against the middle cuneiform, and is the most strongly articulated of all the metatarsal bones; the third metatarsal articulates with the external cuneiform; the fourth, with the cuboid and external cuneiform; and the fifth, with the cuboid. The bones are connected by the following ligaments:

Dorsal. Plantar. Interosseous.

The **Dorsal Ligaments** consist of strong, flat bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin band; the second has three dorsal ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The **Plantar Ligaments** consist of longitudinal and oblique bands connecting the tarsal and metatarsal bones, but disposed with less regularity than the dorsal ligaments. Those for the first and second metatarsals are the most strongly marked; the second and third metatarsals receive strong bands, which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsals consist of a few fibres derived from the cuboid.

The **Interosseous Ligaments** are three in number: internal, middle, and external. The *internal* is the strongest of the three, and passes from the outer surface of the internal cuneiform to the adjacent angle of the second metatarsal. The *middle*, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The *external* connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

The **Synovial Membrane** between the internal cuneiform bone and the first metatarsal is a distinct sac. The synovial membrane between the middle and external cuneiforms behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forwards from it, one between the adjacent sides of the second and third and another between those of the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forwards between the fourth and fifth metatarsal bones.

Movements.—The movements permitted between the tarsal and metatarsal bones are limited to slight gliding movements of the bones upon each other.

VII. INTERMETATARSAL ARTICULATIONS (ARTICULATIONES INTERMETATARSEÆ)

The base of the first metatarsal is not connected with the second metatarsal by any ligaments ; in this respect the great toe resembles the thumb.

The bases of the four outer metatarsals are connected by dorsal, plantar, and interosseous ligaments.

The **Dorsal Ligaments** pass transversely between the dorsal surfaces of the adjacent metatarsal bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces.

The **Synovial Membranes** between the second and third, and that between the third and fourth metatarsal bones are part of the great tarsal synovial membrane ; that between the fourth and fifth is a prolongation of the synovial membrane of the cubo-metatarsal joint.

Movements.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

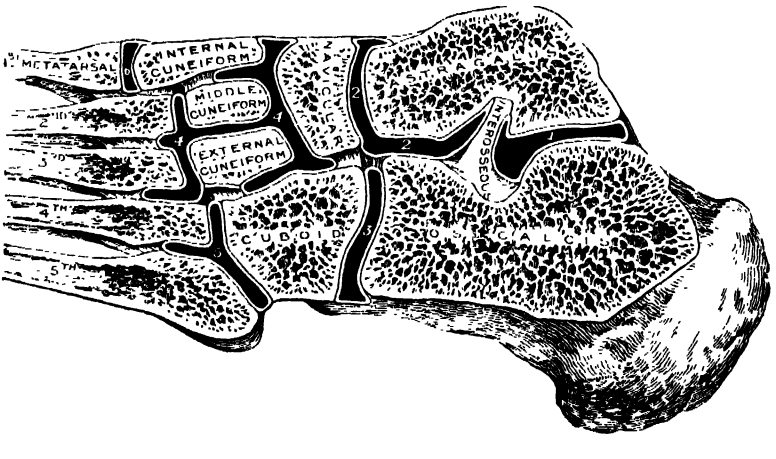
The digital extremities of all the metatarsal bones are connected together by the *transverse metatarsal ligament.*

The **Transverse Metatarsal Ligament** is a narrow band which passes transversely across the anterior extremities of all the metatarsal bones, connecting them together. It is blended anteriorly with the plantar (glenoid) ligaments of the metatarso-phalangeal articulations ; to its posterior border is connected the fascia covering the Interosseous muscles. Its inferior surface is concave where the Flexor tendons run below it ; above it the tendons of the Interosseous muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it is attached to the first digit and connects it with the others.

THE SYNOVIAL MEMBRANES IN THE TARSAL AND METATARSAL JOINTS

The **Synovial Membranes** (fig. 480) found in the articulations of the tarsus and metatarsus are six in number : one for the posterior calcaneo-astragaloid articulation ; a second for the anterior calcaneo-astragaloid and the astragalo-navicular articulations ; a third for the calcaneo-cuboid articulation ; and a fourth for the articulations of the navicular with the

FIG. 480.—Oblique section of the articulations of the tarsus and metatarsus. Showing the six synovial membranes.



three cuneiforms, the three cuneiforms with each other, the external cuneiform with the cuboid, and the middle and external cuneiforms with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other ; a fifth for the internal cuneiform with the metatarsal bone of the great toe ; and a sixth for the

articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial membrane is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

Nerve-supply.—The nerves supplying the tarso-metatarsal joints are derived from the anterior tibial.

VIII. METATARSO-PHALANGEAL ARTICULATIONS (ARTICULATIONES METATARSOPHALANGEÆ)

The metatarso-phalangeal articulations are of the condyloid kind, formed by the reception of the rounded heads of the matatarsal bones into shallow cavities in the extremities of the first phalanges.

The ligaments are :

Plantar. Two Lateral.

The **Plantar Ligaments** (Glenoid ligaments of Cruveilhier) are thick, dense, fibrous structures. They are placed on the plantar surfaces of the joints in the intervals between the lateral ligaments, to which they are connected ; they are loosely united to the metatarsal bones, but very firmly to the bases of the first phalanges. Their plantar surfaces are intimately blended with the transverse metatarsal ligament, and present grooves for the passage of the Flexor tendons, the sheaths surrounding which are connected to the sides of the grooves. Their deep surfaces form parts of the articular facets for the heads of the metatarsal bones, and are lined by synovial membrane.

The **Lateral Ligaments** are strong, rounded cords, placed one on either side of each joint, and attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone, and, by the other, to the contiguous extremity of the phalanx.

The place of a *Dorsal Ligament* is supplied by the Extensor tendon on the back of each joint.

Movements.—The movements permitted in the metatarso-phalangeal articulations are flexion, extension, abduction, and adduction.

IX. INTERPHALANGEAL ARTICULATIONS (ARTICULATIONES DIGITORUM PEDIS)

The articulations of the phalanges are ginglymoid joints.

The ligaments are :

Plantar. Two Lateral.

The arrangement of these ligaments is similar to that in the metatarso-phalangeal articulations : the Extensor tendon supplies the place of a dorsal ligament.

Movements. The only movements permitted in the phalangeal joints are flexion and extension ; these movements are more extensive between the first and second phalanges than between the second and third. The amount of flexion is very considerable, but extension is limited by the plantar and lateral ligaments.

Surface Form.—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the mid-tarsal and the tarso-metatarsal ; the mid-tarsal joint consists of the astragalo-navicular and calcaneo-cuboid articulations. The joint between the astragalus and the navicular lies immediately behind the tubercle of the latter bone. If the foot be grasped and forcibly extended, a rounded prominence, the head of the astragalus, appears on the inner side of the dorsum in front of the ankle-joint, and if a knife were carried downwards, just in front of this prominence and behind the line of the navicular tubercle, it would enter the astragalo-navicular joint. The calcaneo-cuboid joint is situated midway between the external malleolus and the prominent base of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragalo-navicular. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the base of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued inwards, it would pass through the inner side of the head of the first metatarsal bone. The joints between the third and fourth metatarsal bones and the cuboid and external cuneiform are the direct continuation inwards of the previous joint, but their planes are less oblique. The tarso-metatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the navicular bone ; and the joint between the second

metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarso-metatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.

Applied Anatomy.—Gout peculiarly affects the metatarso-phalangeal joint of the big toe, beginning with the deposit of sodium and calcium urates in the cartilage on the bones forming the joint, and slow necrosis of the surrounding tissue. Later the circum-articular fibrous tissue becomes the seat of these gouty deposits, and considerable thickening and deformity may result. The other chief joint-affections, such as rheumatism, gonorrhœal arthritis, tuberculosis, or syphilis, comparatively seldom attack the big toe joint.

Arches of the Foot

In order to allow of its supporting the weight of the body in the erect posture with the least expenditure of material, the foot is constructed of a series of arches which are formed by the tarsal and metatarsal bones, but are strengthened by the ligaments and tendons of the foot.

The main arches are the antero-posterior arches, which may, for descriptive purposes, be regarded as divisible into two types—an inner and an outer. The *inner arch* (see fig. 117, page 363) is made up by the os calcis, the astragalus, the navicular, the three cuneiforms, and the inner three metatarsals. Its summit is at the superior articular surface of the astragalus, and its two extremities or piers, on which it rests in standing, are the tubercles on the inferior surface of the os calcis posteriorly and the heads of the inner three metatarsal bones anteriorly. The chief characteristic of this arch is its elasticity, due to its height and to the number of small joints between its component parts. Its weakest part, i.e. the part where it is most liable to yield from over-pressure, is the joint between the astragalus and navicular, but this portion is braced by the inferior calcaneo-navicular ligament which is elastic and is thus able to quickly restore the arch to its pristine condition when the disturbing force is removed. This ligament is supported internally by blending with the internal lateral ligament of the ankle-joint and inferiorly by the tendon of the Tibialis posticus which is spread out in a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it. The arch is further supported by the plantar fascia, by the small muscles in the sole of the foot, by the tendons of the Tibiales anticus et posticus and Peroneus longus, and by the ligaments of all the articulations involved. The *outer arch* (see fig. 418, page 363) is composed of the os calcis, the cuboid, and the fourth and fifth metatarsals. Its summit is at the calcaneo-astragaloid articulation, and its chief joint is the calcaneo-cuboid, which possesses a special mechanism for locking and allows only a limited movement. The most marked features of this arch are its solidity and its slight elevation; two strong ligaments, the long and short inferior calcaneo-cuboid, together with the outer Extensor tendons and the short muscles of the little toe, preserve its integrity.

While these inner and outer arches may be readily demonstrated as the component antero-posterior arches of the foot, yet the *fundamental longitudinal arch* is contributed to by both, and consists of the os calcis, cuboid, external cuneiform, and third metatarsal: all the other bones of the foot may be removed without destroying this arch.

In addition to the longitudinal arches the foot presents a series of transverse arches. At the hinder part of the metatarsus and the anterior part of the tarsus the arches are complete, but in the middle of the tarsus they present more the characters of half-domes the concavities of which are directed downwards and inwards, so that when the inner borders of the feet are placed in apposition a complete tarsal dome is formed. The transverse arches are strengthened by the interosseous, plantar and dorsal ligaments, by the short muscles of the first and fifth toes (especially the Adductor transversus hallucis), and by the Peroneus longus, whose tendon stretches across between the piers of the arches.

MYOLOGY*

THE Muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures, called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they lie as a flattened layer beneath it, and are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face.

The muscles vary extremely in their form. In the limbs, they are of considerable length, especially the more superficial ones; they surround the bones, and constitute an important protection to the various joints. In the trunk, they are broad, flattened, and expanded, forming the parietes of the cavities which they enclose. Hence the reason of the terms, *long*, *broad*, *short*, &c., used in the description of a muscle.

There is considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some muscles the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyro-hyoid. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at either end; in their actions, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles- e.g. the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of the line of insertion: such is the case in the Pectineus muscle. Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a quill pen, to one side of a tendon which runs the entire length of the muscle. Such muscles are rhomboidal or penniform, as the Peronei. A modification of these rhomboidal muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the middle of the muscle; these are called bipenniform, and an example is afforded in the Rectus femoris. Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincter muscles. The arrangement of the fibres is of considerable importance in respect to the relative strength and range of movement of the muscle. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

The names applied to the various muscles have been derived: 1, from their situation, as the Tibialis, Radialis, Ulnaris, Peroneus; 2, from their direction, as the Rectus abdominis, Obliqui capitis, Transversalis; 3, from their uses, as Flexors,

* The Muscles and Fasciæ are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciæ separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciæ, the special descriptions being given in connection with the different regions.

Extensors, Abductors, &c.; 4, from their shape, as the Deltoid, Trapezius, Rhomboideus; 5, from the number of their divisions, as the Biceps, and Triceps; 6, from their points of attachment, as the Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid.

In the description of a muscle, the term *origin* is meant to imply its more fixed or central attachment; and the term *insertion* the movable point on which the force of the muscle is applied; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face which are attached by one extremity to the bone, and by the other to the movable integument; in the greater number, the muscle can be made to act from either extremity.

In the dissection of the muscles, the student should pay especial attention to the exact *origin*, *insertion*, and *actions* of each, and its more important *relations* with surrounding parts. While accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their actions, it is not to be regarded as conclusive. The action of a muscle deduced from its attachments, or even by pulling on it in the dead subject, is not necessarily its action in the living. By pulling, for example, on the Brachio-radialis in the cadaver the hand may be slightly supinated when in the *prone position* and slightly pronated when in the supine position, but there is no evidence that these actions are performed by the muscle during life. It is impossible for an individual to throw into action any one muscle; in other words, movements, not muscles, are represented in the central nervous system. To carry out a movement a definite combination of muscles is called into play, and the individual has no power either to leave out a muscle from this combination, or to add one to it. One (or more) muscle of the combination is the chief moving force; when this muscle passes over more than one joint other muscles (synergic muscles) come into play to inhibit the movements not required: a third set of muscles (fixation muscles) fix the limb– i.e. in the case of the limb-movements – and also prevent disturbances of the equilibrium of the body generally. As an example, the movement of the closing of the fist may be considered: (1) the prime movers are the Flexores digitorum, Flexor longus pollicis, and the small muscles of the thumb; (2) the synergic muscles are the Extensores carpi, which prevent flexion of the wrist; while (3) the fixation muscles are the Biceps and Triceps, which steady the elbow and shoulder. A further point which must be borne in mind in considering the actions of muscles is that in certain positions a movement can be effected by gravity, and in such a case the muscles acting are the antagonists of those which might be supposed to be in action. Thus in flexing the trunk when no resistance is interposed the Erectores spinæ contract to regulate the action of gravity, and the Recti abdominis are relaxed.*

By a consideration of the action of the muscles, the surgeon is able to explain the causes of displacement in various forms of fracture, and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface-markings they produce, should be carefully remembered, as they form useful guides in the application of ligatures to those vessels.

Applied Anatomy.—Degeneration of muscular tissue is important clinically, and is met with in two main conditions. In one, the degeneration is myopathic, or primary in the muscles themselves; in the other it is neuropathic, or secondary to some lesion of the nervous system—a hæmorrhage into the brain, for example, or injury or inflammation of some part of the spinal cord or peripheral nerves. In either case more or less paralysis and atrophy of the affected muscles result. When the degeneration begins primarily in the muscles, however, it often happens that though the muscle-fibres waste away, their place is taken by fibrous and fatty tissue to such an extent that the affected muscles increase in volume, and actually appear to hypertrophy.

Ossification of muscular tissue as a result of repeated strain or injury is not infrequent. It is oftenest found about the tendon of the Adductor longus and Vastus internus in horsemen, or in the Pectoralis major and Deltoid of soldiers. It may take the form of exostoses firmly fixed to the bone—e.g. 'rider's bone' on the femur (page 573)—or of layers or spicules of bone lying in the muscles or their fasciæ and tendons. Busse states that these bony deposits are preceded by a hæmorrhagic myositis due to injury, the effused blood organising and being finally converted into bone. In the rarer disease, progressive myositis ossificans,

* Consult in this connection the Croonian Lectures (1903) on 'Muscular Movements and their representation in the Central Nervous System,' by Charles E. Beevor, M.D.

there is an unexplained tendency for practically any of the voluntary muscles to become converted into solid and brittle bony masses which are completely rigid.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable length, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior no trace of them. Nerves supplying tendons have special modifications of their terminal fibres, named organs of Golgi (see page 52). The tendons consist principally of a substance which yields gelatin.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white colour, iridescent, glistening, and similar in structure to the tendons. They are only sparingly supplied with blood-vessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles, and, on the other hand, with the movable structures, as the bones, cartilages, ligaments, and fibrous membranes (for instance, the sclera). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscular fibre being distinguishable from that of the tendon only by its striation. But where the muscular fibres join the tendon or aponeurosis at an oblique angle, the former terminate, according to Kölliker, in rounded extremities which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

The *fasciæ* are fibro-areolar or aponeurotic laminæ, of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. The fasciæ have been subdivided, from the situations in which they are found, into two groups, superficial and deep.

The *superficial fascia* is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep fascia, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. In the eyelids and scrotum, where fat is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body; in the groin it is so thick as to be capable of being subdivided into several laminæ. Beneath the fatty layer of the superficial fascia, which is immediately subcutaneous, there is generally another layer of the same structure, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as the superficial epigastric vessels in the abdominal region, the superficial veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymphatic glands. Certain cutaneous muscles also are situated in the superficial fascia, as the Platysma in the neck, and the Orbicularis palpebrarum around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perinæum, and extremities; it is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands, and soles of the feet, forming a fibro-fatty layer, which binds the integument firmly to the underlying structures.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft nidus for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolæ is a bad conductor of heat.

The *deep fascia* is a dense, inelastic, unyielding fibrous membrane, forming sheaths for the muscles, and in some cases affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It forms a strong investment which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciæ are thick in unprotected

situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciæ assist the muscles in their actions, by the degree of tension and pressure they make upon their surfaces; and, in certain situations, where they are strengthened by the presence in them of degenerated muscular fibres which have become converted into fibrous sheets, the degree of tension and pressure is regulated by the associated muscles, as, for instance, by the Tensor fasciæ femoris and Gluteus maximus in the thigh, by the Biceps in the upper and lower extremities, and Palmaris longus in the hand. In the limbs, the fasciæ not only invest the entire limb, but give off septa which separate the various muscles, and are attached beneath to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

The Muscles and Fasciæ may be arranged, according to the general division of the body, into those of the cranium, face, and neck; those of the trunk; those of the upper extremity; and those of the lower extremity.

MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE

The Muscles of the Cranium and Face consist of ten groups, arranged according to the region in which they are situated.

I. Cranial Region.
II. Auricular Region.
III. Palpebral Region.
IV. Orbital Region.
V. Nasal Region.
VI. Maxillary Region.
VII. Mandibular Region.
VIII. Intermaxillary Region.
IX. Temporo-mandibular Region.
X. Pterygo-mandibular Region.

The muscles contained in each of these groups are the following:

I. Cranial Region.
Occipito-frontalis.

II. Auricular Region.
~~Attrahens~~ auriculam.
Attollens auriculam.
Retrahens auriculam.

III. Palpebral Region.
Orbicularis palpebrarum.
Tensor tarsi.
Corrugator supercilii.

IV. Orbital Region.
Levator palpebræ superioris
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus oculi superior.
Obliquus oculi inferior.

V. Nasal Region.
~~Pyramidalis nasi~~.
~~Levator~~ labii superioris alæque nasi.
Dilatator naris posterior.
Dilatator naris anterior.
Compressor naris.
Compressor narium minor.
Depressor alæ nasi.

VI. Maxillary Region.
Levator labii superioris proprius.
~~Levator anguli oris~~.
Zygomaticus major.
Zygomaticus minor.

VII. Mandibular Region.
Levator menti.
~~Depressor labii inferioris~~.
Depressor anguli oris.

VIII. Intermaxillary Region.
Orbicularis oris.
Buccinator.
Risorius.

IX. Temporo-mandibular Region.
Masseter.
Temporal.

X. Pterygo-mandibular Region.
Pterygoideus externus.
Pterygoideus internus.

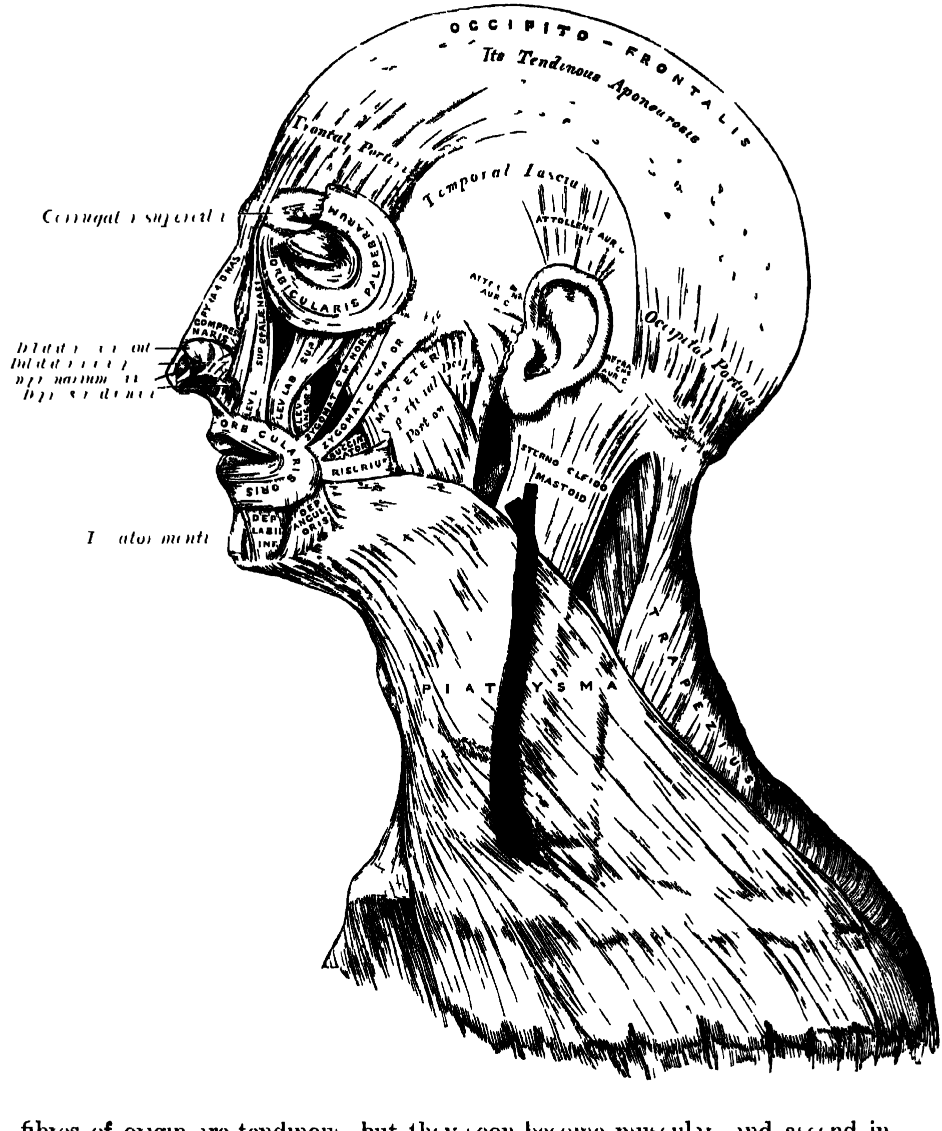
I. Cranial Region

Occipito-frontalis

The superficial fascia in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the Occipito-frontalis and its tendinous aponeurosis; it is continuous, behind, with the superficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

The **Occipito-frontalis** (m. epicranius) (fig. 481) is a broad, musculo-fibrous layer, which covers the whole of one side of the vertex of the skull, from the occiput to the eyebrow. It consists of two muscular bellies, connected by an intervening tendinous aponeurosis, the epicranial aponeurosis. The *occipital portion* (m. occipitalis) is thin, quadrilateral in form, and about an inch and a half in length; it arises from the outer two-thirds of the superior ~~curved~~ line of the occipital bone, and from the mastoid portion of the temporal. Its

FIG. 481.—Muscles of the head, face, and neck.



fibres of origin are tendinous, but they soon become muscular, and ascend in a parallel direction to terminate in the tendinous aponeurosis. The *frontal portion* (m. frontalis) is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader, and its fibres are longer and paler in colour than those of the occipital portion. It has no bony attachments. Its internal fibres are continuous with those of the Pyramidalis nasi. Its middle fibres become blended with the Corrugator supercilii and Orbicularis ~~palpebrarum~~; and the outer fibres are also blended with the latter muscle

over the external angular process. From these attachments the fibres are directed upwards, and join the aponeurosis below the coronal suture. The inner margins of the frontal portions of the two muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The epicranial aponeurosis (*galea aponeurotica*) covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. Behind, it is attached, in the interval between the occipital origins, to the occipital protuberance and highest curved lines of the occipital bone; in front, it forms a short and narrow prolongation between the frontal portions. On either side it gives origin to the Attollens and Attrahens muscles of the pinna; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygoma as a layer of laminated areolar tissue. This aponeurosis is closely connected to the integument by the firm, dense, fibro-fatty layer which forms the superficial fascia: it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the aponeurosis, carrying with it the integument.

7/2 **Nerves.**—The frontal portion is supplied by the temporal branches of the facial nerve; the occipital portion by the posterior auricular branch of the same nerve.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forwards, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backwards. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forwards and backwards. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise: if the action be exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

Applied Anatomy.—From an anatomical point of view, the scalp consists of five layers, viz. the skin, subcutaneous tissue, Occipito-frontalis muscle and its aponeurosis, subaponeurotic connective tissue, and pericranium. But from a surgical standpoint it is better to regard the first three of these structures as a single layer, since they are all intimately fused together, and when torn off in an accident, or turned down as a flap in a surgical operation, remain firmly connected to each other. In consequence of the dense character of the subcutaneous tissue, the amount of swelling which occurs as the result of inflammation is slight; and the edges of a wound which does not involve the Occipito-frontalis muscle or its aponeurosis do not gape. The blood-vessels, also, which lie in this tissue, when wounded, are unable to contract and retract freely; and therefore the hæmorrhage from scalp wounds is often very considerable, but can always be arrested by pressure—a matter of great importance, as it is often very difficult or impossible to pick up with forceps a wounded vessel in the scalp.

The subaponeurotic connective tissue is, from a surgical point of view, of considerable importance. It is loose and lax, and is easily torn through; and hence, when a flap wound occurs in the scalp, this is the tissue which is torn when the flap is separated from the parts beneath. The vessels are therefore torn down with the flap, and there is little risk of sloughing, unless the vitality of the part has been actually destroyed by the injury. In consequence of its loose nature and feeble vitality, any septic inflammation is apt to assume a very diffuse form and spread all over the skull, and, unless relieved by timely incisions may lead to serious complications. Owing to the attachments of the aponeurosis to the zygoma and highest curved line, subaponeurotic effusions sag down in these situations, but do not extend beyond to the zygomatic fossa or into the neck; but anteriorly, where there is no definite attachment to bone, the effusion will pass down over the nose, and into the eyelids. When making incisions into the scalp, care should be taken to avoid the course of the main arteries.

The skin of the scalp is abundantly supplied with sebaceous and sudoriparous glands. The former are sometimes the seat of cystic enlargement, constituting the so-called *sebaceous cysts* or *wens*.

II. Auricular Region (fig. 481)

Attrahens auriculam. Attollens auriculam.
Retrahens auriculam.

These three small muscles are placed immediately beneath the skin around the pinna. In man, in whom the pinna is almost immovable, they are

rudimentary. They are the homologues of large and important muscles in some of the mammalia.

The **Attrahens auriculam** (m. auricularis anterior), the smallest of the three, is thin, fan-shaped, and its fibres are pale and indistinct. It arises from the lateral edge of the aponeurosis of the Occipito-frontalis, and its fibres converge to be inserted into a projection on the front of the helix.

The **Attollens auriculam** (m. auricularis superior), the largest of the three, is thin and fan-shaped. Its fibres arise from the aponeurosis of the Occipito-frontalis, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

The **Retrahens auriculam** (m. auricularis posterior) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Nerves.—The Attrahens and Attollens auriculam are supplied by the temporal branch of the facial nerve; the Retrahens auriculam is supplied by the posterior auricular branch of the same nerve.

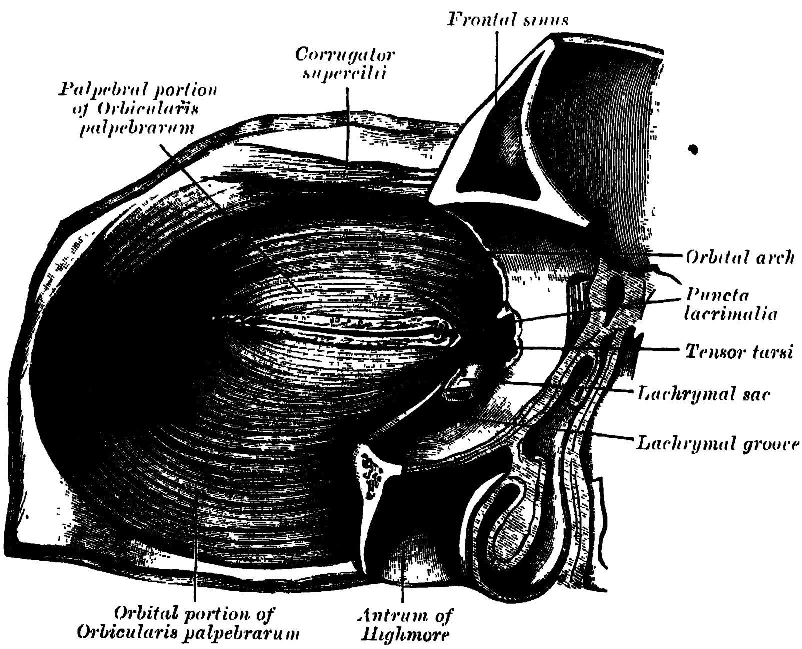
Actions.—In man, these muscles possess very little action: the Attrahens auriculam draws the ear forwards and upwards; the Attollens auriculam slightly raises it; and the Retrahens auriculam draws it backwards.

III. Palpebral Region (figs. 481 and 482)

Orbicularis ~~palpebrarum~~. Tensor tarsi.
Corrugator supercilii.

The **Orbicularis palpebrarum** (m. orbicularis oculi) is a sphincter muscle which surrounds the circumference of the orbit and eyelids. It arises from

Fig. 482.—Left Orbicularis palpebrarum, seen from behind. (From Toldt's Atlas, published by Rebman, Ltd., London.)



the internal angular process of the frontal bone, from the frontal process of the maxilla in front of the lachrymal groove for the nasal duct, and

from the anterior surface and borders of a short tendon, the *tendo oculi*, or *internal tarsal ligament*, placed at the inner angle of the orbit. From this origin, the fibres are directed outwards, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple, and downwards on the cheek. The palpebral portion (pars palpebralis) of the Orbicularis is thin and pale; it arises from the bifurcation of the tendo oculi, forms a series of concentric curves, and is inserted into the external tarsal ligament. The orbital portion (pars orbitalis) is thicker and of a reddish colour: its fibres are well developed, and form complete ellipses. The upper fibres of this portion blend with the Occipito-frontalis and Corrugator supercilii.

The *tendo oculi*, or *internal tarsal ligament*, is a short tendon, about two lines in length and one in breadth, attached to the frontal process of the maxilla in front of the lachrymal groove. Crossing the lachrymal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lachrymal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lachrymal bone. This is the reflected aponeurosis of the tendo oculi.

The *external tarsal ligament* is a much weaker structure than the tendo oculi. It is attached to the margin of the frontal process of the malar bone, and passes inwards to the outer commissure of the eyelid, where it divides into two slips, which are attached to the margins of the respective tarsal plates.

The **Tensor tarsi** or muscle of Horner (pars lacrimalis m. orbicularis oculi) is a small thin muscle, about three lines in breadth and six in length, situated at the inner side of the orbit, behind the tendo oculi and lachrymal sac (fig. 482). It arises from the crest and adjacent part of the orbital surface of the lachrymal bone, and passing across the lachrymal sac, divides into two slips, which cover the lachrymal canals, and are inserted into the tarsal plates internal to the puncta lacrimalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum, from which they are usually considered to be derived; it is occasionally very indistinct.

The **Corrugator supercilii** is a small, narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipito-frontalis and Orbicularis palpebrarum muscles. It arises from the inner extremity of the superciliary ridge; whence its fibres pass upwards and outwards, between the palpebral and orbital portions of the Orbicularis palpebrarum, and are inserted into the deep surface of the skin, opposite the middle of the orbital arch.

Nerves.—The Orbicularis palpebrarum, Corrugator supercilii, and Tensor tarsi are supplied by the facial nerve.

Actions.—The Orbicularis palpebrarum is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inwards towards the inner angle of the orbit, and the eyelids are firmly closed, as in photophobia. When the skin of the forehead, temple, and cheek is thus drawn inwards by the action of the muscle it is thrown into folds, especially radiating from the outer angle of the eyelids, which give rise in old age to the so-called 'crow's feet.' The Levator palpebræ is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe of the eye. Each time the eyelids are closed through the action of the Orbicularis, the tendo oculi becomes tightened, and draws the wall of the lachrymal sac outwards and forwards, so that a vacuum is made in it, and the tears are sucked along the lachrymal canals into it. The Tensor tarsi draws the eyelids and the extremities of the lachrymal canals inwards and compresses them against the surface of the globe of the eye; thus placing them in the most favourable situation for receiving the tears. It serves, also, to compress the lachrymal sac. The Corrugator supercilii draws the eyebrow downwards and inwards, producing the vertical wrinkles of the forehead. It is the 'frowning' muscle, and may be regarded as the principal agent in the expression of suffering.

IV. Orbital Region

Levator palpebræ superioris.	Rectus internus.
Rectus superior.	Rectus externus.
Rectus inferior.	Obliquus oculi superior.

Obliquus oculi inferior.

The **Levator palpebræ superioris** (fig. 483) is thin, flat, and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin

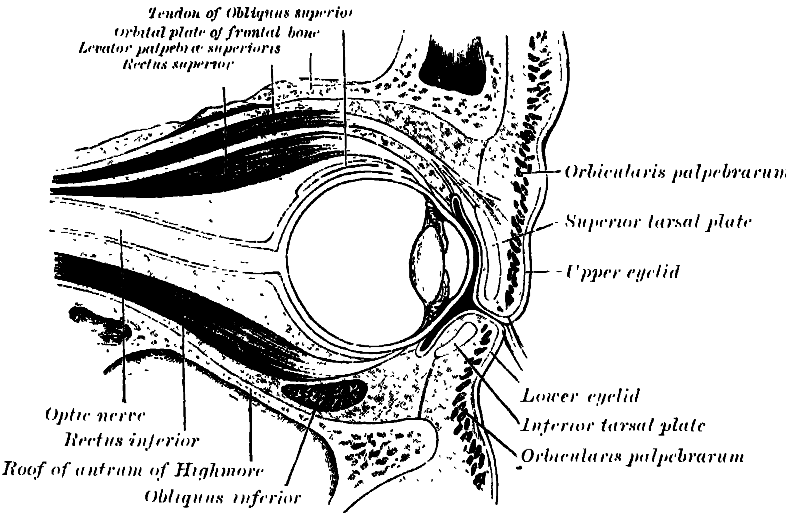


Fig. 483.—Sagittal section of right orbital cavity.

of the Superior rectus. At its origin, it is narrow and tendinous, but soon becomes broad and fleshy, and terminates anteriorly in a wide expansion which splits into three lamellæ. The superficial lamella blends with the

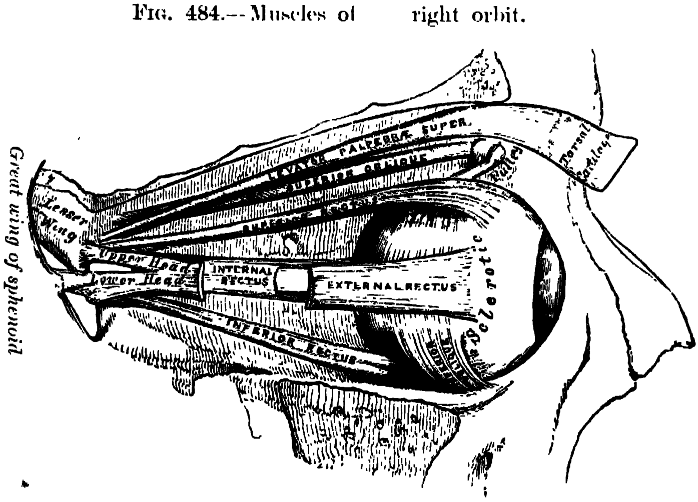

Fig. 484.—Muscles of right orbit.

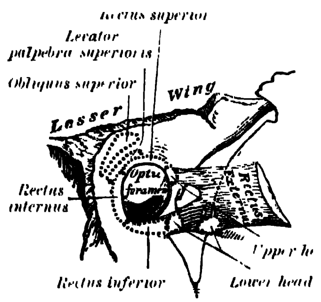
superior palpebral ligament, and is prolonged forwards above the superior tarsal plate to the palpebral part of the Orbicularis palpebrarum, and to the deep surface of the skin of the upper eyelid. The middle lamella, largely made up of non-striped muscular fibres, is inserted into the upper margin

of the superior tarsal plate, whilst the deepest lamella blends with an expansion from the sheath of the Superior rectus, and with it is attached to the superior fornix of the conjunctiva.

The **Four Recti** (fig. 484) arise from a fibrous ring (annulus tendineus communis) which surrounds the upper, inner, and lower margins of the optic foramen and encircles the optic nerve. The ring is completed by a little tendinous bridge prolonged over the lower and inner part of the ~~sphenoidal fissure~~ and attached to a tubercle on the margin of the greater wing of the sphenoid, bounding the sphenoidal fissure (fig. 485). Two specialised parts of this fibrous ring may be made out: a lower, the *ligament* or *tendon of Zinn*, which gives origin to the Inferior rectus, part of the Internal rectus, and the lower head of origin of the External rectus; and an upper, which gives origin to the Superior rectus, the rest of the Internal rectus, and the upper head of the External rectus. This upper band is sometimes termed the *superior tendon of Lockwood*. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion into the sclera, about a quarter of an inch from the margin of the cornea. Between the two heads of the External rectus is a narrow interval, through which pass the two divisions of the third nerve, the nasal branch of the ophthalmic division of the fifth nerve, the sixth nerve, and the ophthalmic vein. Although these muscles present a common origin and are inserted in a similar manner into the sclera, there are certain differences to be observed in them as regards their length and breadth. The Internal rectus is the broadest, the External the longest, and the Superior the thinnest and narrowest.

FIG. 485.—The relative positions of the origins of the muscles of the left eyeball.



The **Obliquus oculi superior** is a fusiform muscle, placed at the upper and inner side of the orbit, internal to the Levator palpebræ. It arises immediately above the inner margin of the optic foramen, above and internal to the origin of the Superior rectus, and, passing forwards to the inner angle of the orbit, terminates in a rounded tendon, which plays in a fibro-cartilaginous ring or pulley attached to the trochlear fossa near the internal angular process of the frontal bone. The contiguous surfaces of the tendon and ring are lined by a delicate synovial membrane, and enclosed in a thin fibrous investment. The tendon is reflected backwards, outwards, and downwards beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into the sclera, behind the equator of the eyeball, the insertion of the muscle lying between the Superior and External recti.

The **Obliquus oculi inferior** is a thin, narrow muscle, placed near the anterior margin of the orbit. It arises from the orbital plate of the maxilla, external to the lachrymal groove. Passing outwards, backwards, and upwards, between the Inferior rectus and the floor of the orbit, and then between the eyeball and the External rectus, it is inserted into the outer part of the sclera between the Superior and External recti, near to, but somewhat behind, the insertion of the Superior oblique.

Nerves.—The Levator palpebræ, Inferior oblique, and the Superior, Inferior and Internal recti are supplied by the third nerve; the Superior oblique, by the fourth; the External rectus, by the sixth.

Actions.—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti are attached to the globe of the eye in such a manner that, acting singly, they will turn its corneal surface either upwards, downwards, inwards, or outwards, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for inasmuch as each passes obliquely outwards and forwards to the eyeball, the elevation or depression of the cornea is accompanied by a certain deviation inwards, with a slight amount of rotation. These latter movements

are corrected by the Oblique muscles, the Inferior oblique correcting the deviation inwards of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External or Internal rectus, on the other hand, produces a purely horizontal movement. If any two contiguous Recti of one eye act together they carry the globe of the eye in the diagonal of these directions, viz. upwards and inwards, upwards and outwards, downwards and inwards, or downwards and outwards. A little consideration will show that sometimes the corresponding Recti of the two eyes act in unison, and at others the opposite Recti act together. Thus, in turning the eyes to the right, the External rectus of the right eye will act in unison with the Internal rectus of the left eye; but if both eyes are directed to an object in the middle line at a short distance, the two Internal recti will act in unison. The movement of circumduction, as in looking round a room, is performed by the successive action of the four Recti. The Oblique muscles rotate the eyeball on its antero-posterior axis, the Superior directing the cornea downwards and outwards, and the Inferior directing it upwards and outwards; these movements are required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of either eye.

Fasciæ of the orbit.—The connective tissue of the orbit is in various places condensed into thin membranous layers, which may be conveniently described as (1) the orbital fascia; (2) the sheaths of the muscles; and (3) the fascia of the eyeball.

(1) The *orbital fascia*. This forms the periosteum of the orbit. It is loosely connected to the bones, and can be readily separated from them. Behind, it is connected with the dura mater by processes which pass through the optic foramen and sphenoidal fissure, and with the sheath of the optic nerve. In front, it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the palpebral fascia. From its internal surface two processes are given off: one to enclose the lachrymal gland, the other to hold the pulley of the Superior oblique muscle in position. A layer of non-striped muscle, the *Orbitalis muscle* of H. Müller, may be seen bridging across the spheno-maxillary fissure.

(2) The *sheaths of the muscles* give off expansions to the margins of the orbit, which limit the action of the muscles.

(3) The *fascia of the eyeball*—Tenon's capsule—will be described with the anatomy of the eyeball.

Applied Anatomy.—The positions and exact points of insertion of the tendons of the Internal and External recti into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide one or other of the muscles for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned inwards, requiring the division of the Internal rectus. In the divergent form, which is more rare, the eye is turned outwards, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: the lids are to be well separated; the eyeball is rotated outwards or inwards, and the conjunctiva raised by a pair of forceps, and incised immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclera; the submucous areolar tissue is then divided, and into the small aperture thus made, a blunt hook is passed upwards between the muscle and the globe, and the tendon of the muscle divided by a pair of blunt-pointed scissors passed between the hook and the globe.

A more recent operation is that of *advancement* in which either the Internal or External rectus (depending on the form of strabismus) is shortened. The muscle is exposed in the same manner; a portion is then cut out of it and the cut ends are sewn together.

V. Nasal Region (fig. 486)

Pyramidalis nasi.
Levator labii superioris alæque nasi.
Dilatator naris posterior.
Dilatator naris anterior.
Compressor naris.
Compressor narium minor.
Depressor alæ nasi.

The [redacted] (m. procerus) is a small pyramidal slip placed over the nasal bone. Its origin is by tendinous fibres from the fascia covering the

lower part of the nasal bone and upper part of the cartilage, where it blends with the Compressor naris, and it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Occipito-frontalis.

The **Levator labii superioris alæque nasi** is a thin triangular muscle, placed by the side of the nose, and extending between the inner margin of the orbit and the upper lip. It arises by a pointed extremity from the upper part of the frontal process of the maxilla, and, passing obliquely downwards and outwards, divides into two slips, one of which is inserted into the cartilage of the ala of the nose; the other is prolonged into the upper lip, blending with the Orbicularis oris and Levator labii superioris proprius.

The **Dilatator naris posterior** is a small muscle, which is placed partly beneath the elevator of the nose and lip. It arises from the margin of the nasal notch of the maxilla, and from the sesamoid cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a thin delicate fasciculus, passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The **Compressor naris** is a small, thin, triangular muscle, arising by its apex from the maxilla, above and a little external to the incisive fossa; its fibres proceed upwards and inwards, expanding into a thin aponeurosis which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Pyramidalis nasi.

The **Compressor narium minor** is a small muscle, attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The **Depressor alæ nasi** is a short radiated muscle, arising from the incisive fossa of the maxilla; its fibres ascend to be inserted into the septum, and back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

Nerves.—All the muscles of this group are supplied by the facial nerve.

Actions.—The Pyramidalis nasi draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The Levator labii superioris alæque nasi draws upwards the upper lip and ala of the nose; its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two Dilatatores enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing, as well as in some emotions, such as anger, they may be noticed to be in violent action. The Depressor alæ nasi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downwards, and thereby constricting the aperture of the nares. The Compressor naris depresses the cartilaginous part of the nose and draws the alæ together.

VI. Maxillary Region (fig. 486)

Levator labii superioris proprius.	Zygomaticus major.
Levator anguli oris.	Zygomaticus minor.

The **Levator labii superioris proprius** is a thin muscle, of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infra-orbital foramen, some of its fibres being attached to the maxilla, others to the malar bone; its fibres converge to be inserted into the muscular substance of the upper lip, between the attachment of the Levator labii superioris alæque nasi and the Levator anguli oris.

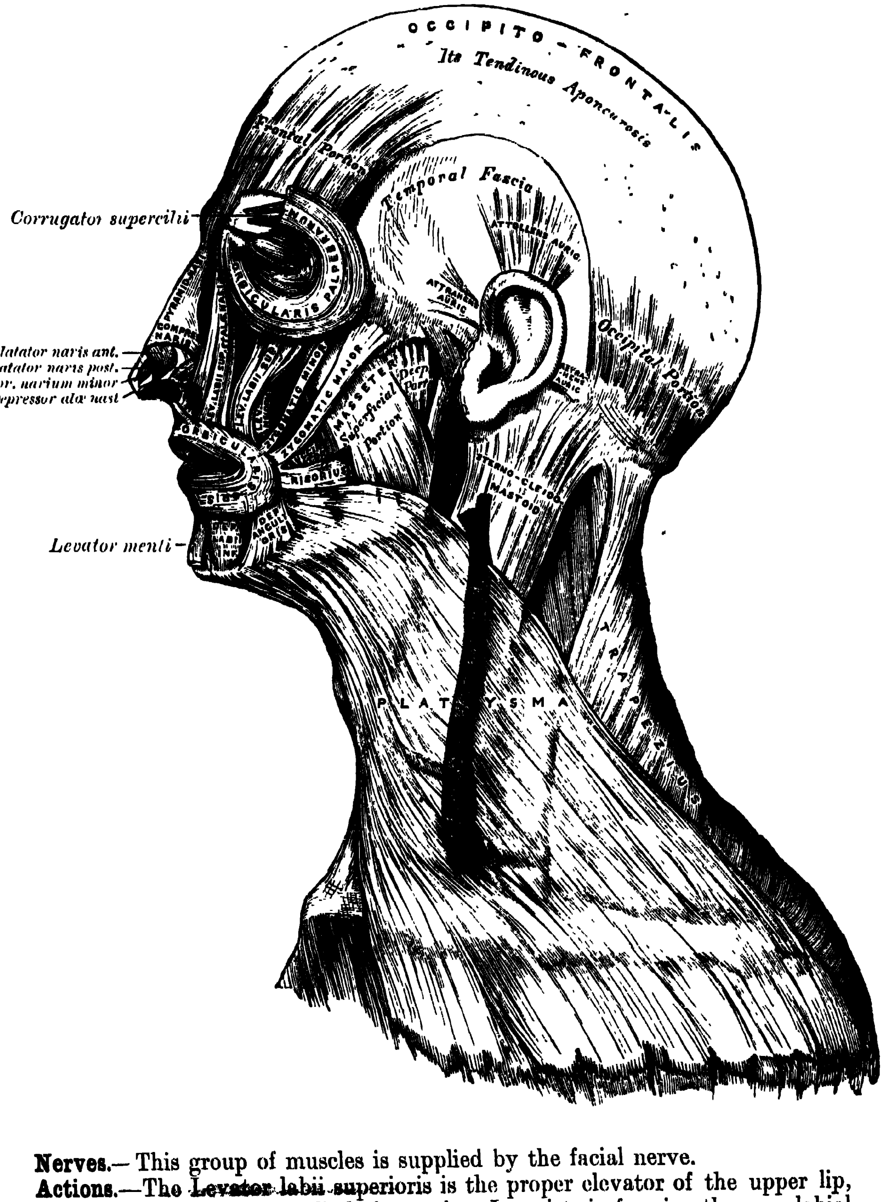
The **Levator anguli oris** (m. caninus) arises from the canine fossa, immediately below the infra-orbital foramen; its fibres incline downwards and a little outwards, to be inserted into the angle of the mouth, intermingling with those of the Zygomaticus major, the Depressor anguli oris, and the Orbicularis oris.

The **Zygomaticus major** is a slender fasciculus, which arises from the malar bone, in front of the zygomatic suture, and descending obliquely down-

wards and inwards, is inserted into the angle of the mouth, where it blends with the fibres of the Levator anguli oris, the Orbicularis oris, and the Depressor anguli oris.

The **Zygomaticus minor** arises from the malar bone, immediately behind the maxillary suture, and passing downwards and inwards, is continuous with the Orbicularis oris at the outer margin of the Levator labii superioris. It lies anterior to the preceding.

Fig. 486.—Muscles of the head, face, and neck.



Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The ~~Levator labii~~ superioris is the proper elevator of the upper lip, carrying it at the same time a little forwards. It assists in forming the naso-labial ridge, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The Levator anguli oris raises the angle of the mouth and assists the Levator labii superioris in producing the naso-labial ridge. The Zygomaticus major draws the angle of the mouth backwards and upwards, as in laughing; while the Zygomaticus minor, being inserted into the outer part of

the upper lip and not into the angle of the mouth, draws it backwards, upwards, and outwards, and thus gives to the face an expression of sadness.

VII. Mandibular Region (fig. 486)

Levator menti.
Depressor labii inferioris.
Depressor anguli oris.

The **Levator menti** (m. mentalis) or Levator labii inferioris is a small conical fasciculus, placed on the side of the frænum of the lower lip. It arises from the incisive fossa, external to the symphysis menti; its fibres descend to be inserted into the integument of the chin.

The **Depressor labii inferioris** (m. quadratus labii inferioris) is a small quadrilateral muscle. It arises from the external oblique line of the mandible, between the symphysis and the mental foramen, and passes obliquely upwards and inwards, to be inserted into the integument of the lower lip, its fibres blending with the Orbicularis oris, and with those of its fellow of the opposite side. It is continuous with the fibres of the Platysma at its origin. This muscle contains much yellow fat intermingled with its fibres.

The **Depressor anguli oris** (m. triangularis) is triangular in shape, arising by its broad base, from the external oblique line of the mandible, whence its fibres pass upwards, to be inserted, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin, and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator menti raises and protrudes the lower lip, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downwards and a little outwards, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist of the Levator anguli oris and Zygomaticus major; acting with the Levator anguli oris, it will draw the angle of the mouth directly inwards.

VIII. Intermaxillary Region

Orbicularis oris. Buccinator. Risorius.

The **Orbicularis oris** (fig. 486) is not a simple sphincter muscle like the Orbicularis palpebrarum, but consists of numerous strata of muscular fibres having different directions and surrounding the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of the Buccinator fibres—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the maxilla passing to the lower lip, and those from the mandible to the upper lip. Other fibres of the muscle, situated at its upper and lower part, pass across the lips from side to side without decussation. Superficial to this stratum is a second, formed on either side by the Levator and Depressor anguli oris muscles, which cross each other at the angle of the mouth; those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addition to these there are fibres from other muscles inserted into the lips, the Levator labii superioris, the Levator labii superioris alæque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane, through the thickness of the lip. Finally there are fibres by which the muscle is connected with the maxillæ and the septum of the nose and with the mandible. In the upper lip these consist of two bands, inner and outer, on each side of

the middle line ; the outer band (*m. incisivus superior*) arises from the alveolar border of the maxilla, opposite the lateral incisor tooth, and arching outwards is continuous at the angle of the mouth with the other muscles inserted into this part ; the inner band (*m. nasolabialis*) connects the upper lip to the back of the septum of the nose. The interval between the two inner bands corresponds with the depression, called the *philtrum*, seen on the lip beneath the septum of the nose. The additional fibres for the lower lip constitute a slip (*m. incisivus inferior*) on either side of the middle line which arises from the mandible, external to the Levator labii inferioris, and arches outwards to the angle of the mouth, to join the Buccinator and the other muscles attached to this part.

The **Buccinator** (fig. 494) is a broad, thin muscle, quadrilateral in form, occupying the interval between the jaws at the side of the face. It arises from the ~~outer surfaces~~ of the ~~alveolar processes~~ of the upper and lower jaws, corre- 1,
sponding to the three molar teeth ; and behind, from the anterior border of the 2
pterygo-mandibular ligament which separates it from the Superior constrictor of the pharynx. The fibres converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the inferior segment; the uppermost and lowermost fibres continue forward uninterruptedly into the corresponding lip without decussation.

Relations.—The Buccinator is in relation by its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the lower jaw, from the Masseter, and from a small portion of the Temporal, and which has been named the *suctorial pad*, because it is supposed to assist in the act of sucking. In front the superficial surface of the Buccinator is in relation with the Zygomatici, Risorius, Levator anguli oris, Depressor anguli oris, and Stenson's duct which pierces it opposite the second molar tooth of the upper jaw ; the facial artery and vein cross it from below upwards ; it is also crossed by the branches of the facial and buccal nerves. The *deep surface* is in relation with the buccal glands and mucous membrane of the mouth.

The *pterygo-mandibular ligament* is a tendinous band, derived from the deep cervical fascia and attached by one extremity to the hamular process of the internal pterygoid plate, and by the other to the posterior extremity of the internal oblique line of the mandible. Its *inner surface* is covered by the mucous membrane of the mouth. Its *outer surface* is separated from the ramus of the mandible by a quantity of adipose tissue. Its *posterior border* gives attachment to the Superior constrictor of the pharynx ; its *anterior border*, to the fibres of the Buccinator (see fig. 494).

The **Risorius** consists of a narrow bundle of fibres, which arises in the fascia over the Masseter muscle and, passing horizontally forwards, is inserted into the skin at the angle of the mouth (fig. 486). It is placed superficial to the Platysma, and is broadest at its outer extremity. This muscle varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve.

Actions.—The Orbicularis oris in its ordinary action produces the direct closure of the lips ; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forwards. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (*buccina*, a trumpet). The Risorius retracts the angles of the mouth, and produces the unpleasant expression which is sometimes seen in tetanus, and is known as 'risus sardonicus.'

IX. Temporo-Mandibular Region

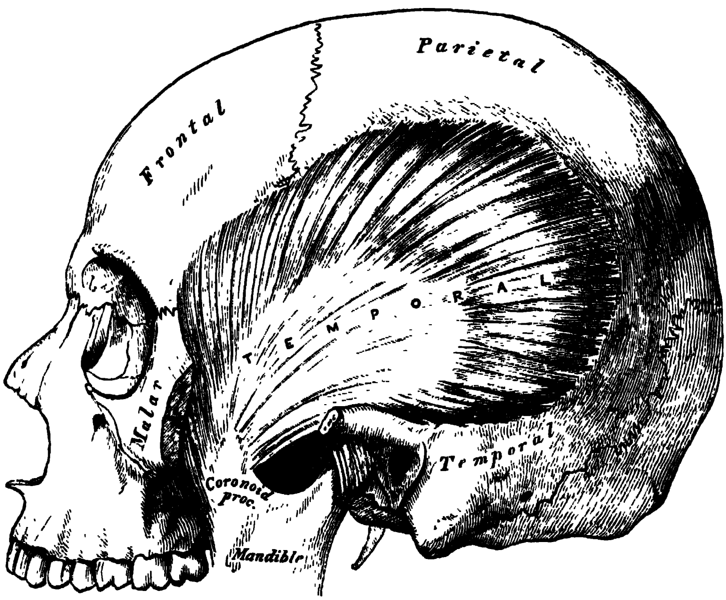
Masseter.	Temporal.

Masseteric fascia.—Covering the Masseter muscle, and firmly connected with it, is a strong layer of fascia, derived from the deep cervical fascia. Above, this fascia is attached to the lower border of the zygoma, and behind it invests the parotid gland, constituting the *parotid fascia*.

The **Masseter** (fig. 486) is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a thick, tendinous aponeurosis from the malar process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch : its fibres pass downwards and backwards, to be inserted into the angle and lower half of the outer surface of the ramus of the mandible. The *deep portion* is much smaller, and more muscular in texture ; it arises from the posterior third of the lower border and the whole of the inner surface of the zygomatic arch ; its fibres pass downwards and forwards, to be inserted into the upper half of the ramus and the outer surface of the coronoid process of the mandible. The deep portion of the muscle is partly concealed, in front, by the superficial portion ; behind, it is covered by the parotid gland. The fibres of the two portions are continuous at their insertion.

Relations.—The Masseter is in relation by its *superficial surface* with the integument, Platysma, Risorius, Zygomatici, the parotid gland and socia parotidis, and with Stenson's duct, and the branches of the facial nerve and the transverse facial vessels which cross it. By its *deep surface*, it is in relation with the insertion of the Temporal muscle, the

FIG. 487.—The Temporal muscle ; the zygoma and Masseter have been removed.



ramus of the mandible, the Buccinator and the long buccal nerve from which it is separated by a mass of fat. The masseteric nerve and artery enter it on its deep surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin*, which projects over the Buccinator muscle, is crossed below by the facial vein.

The **temporal fascia** covers the Temporal muscle. It is a strong, fibrous investment, covered, on its outer surface, by the Attrahens and Attollens auriculam muscles, the aponeurosis of the Occipito-frontalis, and by part of the Orbicularis palpebrarum. The temporal vessels and the auriculo-temporal nerve cross it from below upwards. Above, it is a single layer, attached to the entire extent of the upper temporal ridge ; but below, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital or temporo-malar branch of the superior maxillary nerve, are contained between these two layers. It affords attachment by its inner surface to the superficial fibres of the Temporal muscle.

The **Temporal** (m. temporalis) (fig. 487) is a broad, radiating muscle, situated at the side of the head, and occupying the entire extent of the temporal fossa. It arises from the whole of the temporal fossa (except that portion of it which is formed by the malar bone) and from the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in a tendon, which is inserted into the inner surface, apex, and anterior border of the coronoid process, and the anterior border of the ramus of the mandible, nearly as far forwards as the last molar tooth.

Relations.—The Temporal is in relation by its *superficial surface* with the integument, the Attrahens and Attollens auriculam muscles, the temporal fascia, the superficial temporal vessels, the auriculo-temporal nerve, the temporal branches of the facial and temporo-malar nerves, the aponeurosis of the Occipito-frontalis, the zygoma, and the Masseter. By its *deep surface*, it is in relation with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery, and its deep temporal branches, the deep temporal nerves, and the buccal vessels and nerve. Behind the tendon are the masseteric vessels and nerve. Its anterior border is separated from the malar bone by a mass of fat.

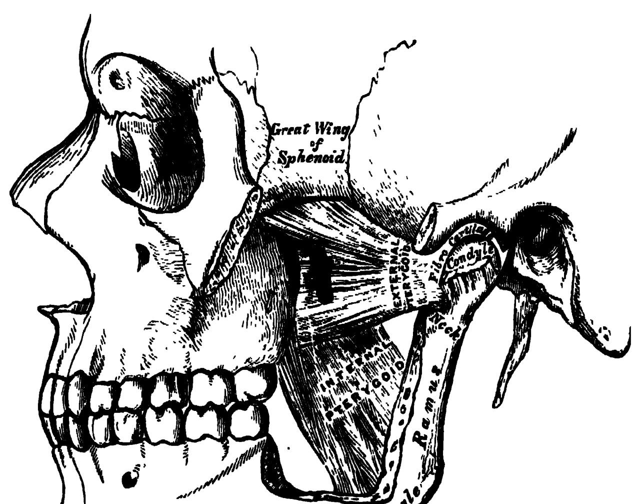
Nerves.—Both muscles are supplied by the inferior maxillary nerve.

X. Pterygo-Mandibular Region (fig. 488)

Pterygoideus externus. Pterygoideus internus.

The **Pterygoideus externus** is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the mandible. It arises by two heads, separated by a slight interval: the *upper* from the inferior portion of the external surface of the greater wing

Fig. 488.—The Pterygoid muscles; the zygomatic arch and a portion of the ramus of the jaw have been removed.



of the sphenoid and from the pterygoid ridge which separates the zygomatic from the temporal fossa; the *lower* from the outer surface of the external pterygoid plate. Its fibres pass horizontally backwards and outwards, to be inserted into a depression in front of the neck of the condyle of the mandible, and into the front of the interarticular fibro-cartilage of the temporo-mandibular articulation.

Relations.—By its *external surface* it is in relation with the ramus of the lower jaw, the internal maxillary artery, which crosses it,* the tendon of the Temporal muscle, and the Masseter. Its *internal surface* rests against the upper part of the Internal pterygoid, the internal lateral ligament, the middle meningeal artery, and the inferior maxillary nerve; by its *upper border* it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its *lower border* it is in relation with the inferior dental and lingual nerves. Through the interval between the two portions of the muscle, the buccal nerve emerges and the internal maxillary artery passes, when the trunk of this vessel lies on the lower part of the muscle (see fig. 488).

The **Pterygoideus internus** is a thick, quadrilateral muscle, and resembles the Masseter in form. It arises from the pterygoid fossa, being attached to the inner surface of the external pterygoid plate, and to the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosities of the palate and maxilla; its fibres pass downwards, outwards, and backwards, to be inserted, by a strong tendinous lamina, into the lower and back part of the inner side of the ramus and angle of the mandible, as high as the dental foramen.

Relations.—By its *external surface* it is in relation with the ramus of the mandible, from which it is separated, at its upper part, by the External pterygoid, the internal lateral ligament, the internal maxillary artery, the inferior dental vessels and nerves, the lingual nerve, and a process of the parotid gland. By its *internal surface* it is in relation with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

Nerves.—These muscles are supplied by the inferior maxillary nerve.

Actions.—The Temporal, Masseter and Internal pterygoid raise the mandible against the maxillæ with great force. The External pterygoids assist in opening the mouth, but their main action is to draw forward the condyles and interarticular cartilages so that the mandible is protruded and the inferior incisors projected in front of the upper; in this action they are assisted by the Internal pterygoids. The mandible is retracted by the posterior fibres of the Temporal. If the Internal and External pterygoids of one side act, the corresponding side of the mandible is drawn forward while the opposite condyle remains comparatively fixed, and lateral movement, such as occurs during the trituration of food, takes place.

Surface Form.—The outline of the muscles of the head and face cannot be traced on the surface, except in the case of two of the masticatory muscles. The muscles of the head are thin, so that the outline of the bone is perceptible beneath them. Those of the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed; but they serve to round off and smooth prominent borders, and to fill up what would be otherwise unsightly angular depressions. Thus, the Orbicularis palpebrarum rounds off the prominent margin of the orbit, and the Pyramidalis nasi fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed skull. In like manner, the labial muscles, converging to the lips, and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones, and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it. Hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of parts, so as to produce the varied expressions with which the face is endowed; these muscles are therefore termed the 'muscles of expression.' The only two muscles in this region which greatly influence surface-form are the Masseter and the Temporal. The Masseter is a quadrilateral muscle, which imparts fulness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fulness, especially marked at the lower part of the muscle. The Temporal muscle is fan-shaped, and fills the temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

* In many cases the artery will be found under cover of the muscle.

MUSCLES AND FASCIÆ OF THE NECK

The muscles of the neck may be arranged into groups, corresponding with the regions in which they are situated.

These groups are nine in number:

I. Superficial Region.
II. Infrahyoid Region.
III. Suprahyoid Region.
IV. Lingual Region.
V. Pharyngeal Region.
VI. Palatal Region.
VII. Anterior Vertebral Region.
VIII. Lateral Vertebral Region.
IX. Muscles of the Larynx.

The muscles contained in each of these groups are the following:

I. Superficial Region.
Platysma.
Sterno-cleido-mastoid.

II. Infrahyoid Region.
Sterno-hyoid.
Sterno-thyroid.
Thyro-hyoid.
Omo-hyoid.

III. Suprahyoid Region.
Digastric.
Stylo-hyoid.
Mylo-hyoid.
Genio-hyoid.

IV. Lingual Region.
Extrinsic.
Genio-hyo-glossus.
Hyo-glossus.
Chondro-glossus.
Stylo-glossus.
Palato-glossus.
Intrinsic.
Superior lingualis.
Inferior lingualis.
Transverse lingualis.
Vertical lingualis

V. Pharyngeal Region.
Inferior constrictor.
Middle constrictor.
Superior constrictor.
Stylo-pharyngeus.
Palato-pharyngeus.
Salpingo-pharyngeus.

VI. Palatal Region.
Levator palati.
Tensor palati.
Azygos uvulæ.
Palato-glossus.
Palato-pharyngeus.
Salpingo-pharyngeus.

VII. Anterior Vertebral Region.
Rectus capitis anticus major.
Rectus capitis anticus minor.
Rectus capitis lateralis.
Longus colli.

VIII. Lateral Vertebral Region.
Scalenus anticus.
Scalenus medius.
Scalenus posticus.

IX. Muscles of the Larynx
Included in the description of the Larynx.

I. Superficial Cervical Region

Platysma. Sterno-cleido-mastoid.

The **superficial cervical fascia** is a thin lamina, which is hardly demonstrable as a separate membrane. It invests the Platysma.

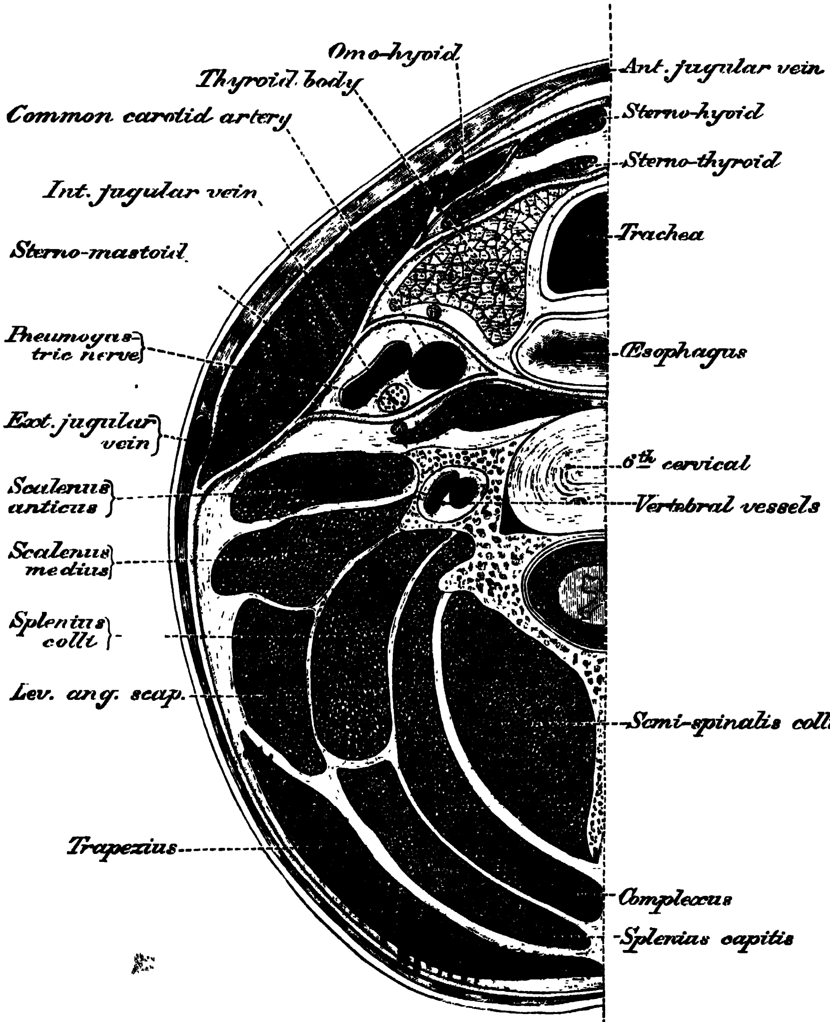
The Platysma (fig. 486) is a broad, thin plane of muscular fibres situated on the side of the neck. It arises by thin, fibrous bands from the fascia covering the upper part of the Pectoralis major and Deltoid; its fibres pass over the clavicle, and proceed obliquely upwards and inwards along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres pass over the mandible, some of them being attached to the bone below the external oblique line, others passing on to be inserted into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles, or to the margin of

the Orbicularis oris. Beneath the Platysma, the external jugular vein may be seen descending from the angle of the mandible to the clavicle.

Actions.—The Platysma produces a slight wrinkling of the surface of the skin of the neck, in an oblique direction, when the entire muscle is brought into action. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth on each side, being one of the chief agents in the expression of melancholy.

The **deep cervical fascia** (fig. 489) lies under cover of the Platysma, and constitutes a complete investment for the neck. It also forms sheaths for

FIG. 489.—Section of the neck at about the level of the sixth cervical vertebra. Showing the arrangement of the deep cervical fascia.



the carotid vessels, and, in addition, is prolonged deeply in the shape of certain processes or lamellæ, which come into close relation with the structures situated in front of the vertebral column.

The investing portion of the fascia is attached behind to the ligamentum nuchæ and to the spine of the seventh cervical vertebra. It forms a thin investment to the Trapezius muscle, and at its anterior border is continued forwards as a rather loose areolar layer, covering the posterior triangle of the neck, to the posterior border of the Sterno-mastoid muscle, where it begins to assume the appearance of a fascial membrane. Along the hinder edge of the

Sterno-mastoid it divides to enclose the muscle, and at the anterior margin again forms a single lamella, which roofs in the anterior triangle of the neck, and reaches forwards to the middle line, to become continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is attached to the symphysis menti and body of the hyoid bone.

Above, the fascia is attached to the superior curved line of the occipital, to the mastoid process of the temporal, and to the whole length of the body of the mandible. Opposite the angle of the mandible the fascia is very strong, and binds the anterior edge of the Sterno-mastoid firmly to that bone. Between the mandible and the mastoid process it ensheathes the parotid gland · the layer which covers the gland extending upwards under the name of the *parotid fascia* to be fixed to the zygomatic arch. From the layer which passes under the parotid a strong band extends upwards to the styloid process, forming the *stylo-mandibular ligament*. Three other bands may be defined: the *spheno-mandibular*, the *pterygo-mandibular* and the *pterygo-spinous ligaments*. The *pterygo-spinous ligament* is a membranous band which stretches across from the upper half of the posterior free border of the external pterygoid plate to the spinous process of the sphenoid. It occasionally ossifies, and produces between its upper border and the base of the skull, an adventitious foramen which transmits the branches of the third division of the fifth nerve to the muscles of mastication.

Below, the fascia is attached to the acromion process, the clavicle, and the manubrium sterni. Some little distance above the last, however, it splits into two layers, superficial and deep. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers is a slit-like interval, the *suprasternal space*, or *space of Burns*. It contains a small quantity of areolar tissue, and sometimes a lymphatic gland, the lower portions of the anterior jugular veins and their transverse connecting branch, and also the sternal heads of the Sterno-mastoid muscles.

The fascia which lines the deep surface of the Sterno-mastoid gives off the following important processes. (1) A process envelops the tendon of the Omo-hyoid, and binds it down to the sternum and first costal cartilage. (2) A strong sheath, the *carotid sheath*, encloses the carotid artery, internal jugular vein, and pneumogastric nerve. (3) The *prevertebral fascia* extends inwards behind the carotid vessels, where it assists in forming their sheath, and passes in front of the prevertebral muscles. It forms the posterior limit of a fibrous compartment, which contains the larynx and trachea, the thyroid gland, and the pharynx and œsophagus. The prevertebral fascia is fixed above to the base of the skull, while below it is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid sheath and along its inner aspect the prevertebral fascia gives off a thin lamina, the *bucco-pharyngeal fascia*, which closely invests the Constrictor muscles of the pharynx, and is continued forward from the Superior constrictor on to the Buccinator. It is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the *retro-pharyngeal space*, is found between them. This space is limited above by the base of the skull, while below it extends behind the œsophagus into the thorax, where it is continued into the posterior mediastinum. The prevertebral fascia is prolonged downwards and outwards behind the carotid vessels and in front of the Scaleni, and forms a sheath for the brachial nerves and subclavian vessels in the posterior triangle of the neck; it is continued under the clavicle as the axillary sheath and is attached to the deep surface of the costo-coracoid membrane. Immediately above and behind the clavicle an areolar space exists between the investing layer and the sheath of the subclavian vessels, and in its upper portion are found the lower part of the external jugular vein, the descending clavicular nerves, the suprascapular and transversalis colli vessels, and the posterior belly of the Omo-hyoid muscle. This space is limited below by the fusion of the costo-coracoid membrane with the anterior wall of the axillary sheath. (4) The *pretracheal fascia* extends inwards in front of the carotid vessels, and assists in forming the carotid sheath. It is further continued behind the depressor muscles of the hyoid bone, and, after enveloping the thyroid body, is prolonged in front of the trachea to meet the corresponding

layer of the opposite side. Above, it is fixed to the hyoid bone, while below it is carried downwards in front of the trachea and large vessels at the root of the neck, and ultimately blends with the fibrous pericardium. This layer is fused on either side with the prevertebral layer, with which it completes the compartment containing the larynx and trachea, the thyroid gland, the pharynx and œsophagus.

Applied Anatomy.—The deep cervical fascia is of considerable importance from a surgical point of view. As will be seen from the foregoing description, it may be divided into three layers: (1) an investing layer; (2) a layer passing in front of the trachea, and forming with the superficial layer a sheath for the depressors of the hyoid bone; (3) a prevertebral layer passing in front of the bodies of the cervical vertebræ, and forming with the second layer a space in which is contained the trachea, œsophagus &c. The investing layer would oppose the extension of abscesses towards the surface, and pus forming beneath it would have a tendency to extend laterally. If the pus be contained in the anterior triangle, it may find its way into the anterior mediastinum, being situated in front of the layer of fascia which passes down into the thorax to become continuous

FIG. 490.—Muscles of the neck. Lateral view.

with the pericardium; but owing to the less density and thickness of the fascia in this situation it most frequently finds its way through it and points above the sternum. Pus forming beneath the second layer would in all probability find its way into the posterior mediastinum. Pus forming behind the prevertebral layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, might extend towards the posterior and lateral part of the neck and point in this situation, or might perforate this layer of fascia and the pharyngeal fascia and point into the pharynx (retro-pharyngeal abscess).

In cases of cut throat the cervical fascia is of considerable importance. When the wound involves only the investing layer the injury is usually trivial, the special danger being injury to the external jugular vein, and the special complication, diffuse cellulitis. But where the second of the two layers is opened up, important structures may be injured, and serious results follow.

The sternal head of origin of the Sterno-mastoid is contained in Burns's space, so that this space is opened in division of this tendon. The lower part of the anterior jugular vein is also contained in the same space.

~~The Sterno-mastoid~~ (m. sternocleidomastoideus) (fig. 490) is a large, thick muscle, which passes obliquely across the side of the neck, being enclosed between the two laminæ of the investing layer of the deep cervical fascia. It is thick and narrow at its central part, but broader and thinner at either extremity. It arises by two heads from the sternum and clavicle. The *sternal portion* is a rounded fasciculus, tendinous in front, fleshy behind, which arises from the upper and anterior part of the manubrium sterni, and is directed upwards, outwards, and backwards. The *clavicular portion* arises from the superior border and anterior surface of the inner third of the clavicle, being composed of fleshy and aponeurotic fibres; it is directed almost vertically upwards. These two portions are separated from one another at their origin by a triangular interval, but become gradually blended, below the middle of the neck, into a thick, rounded muscle which is inserted, by a strong tendon, into the outer surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the outer half of the superior curved line of the occipital bone. The Sterno-mastoid varies much in its extent of attachment to the clavicle: in one case the clavicular may be as narrow as the sternal portion; in another, as much as three inches in breadth. When the clavicular origin is broad, it is occasionally subdivided into numerous slips, separated by narrow intervals. More rarely, the adjoining margins of the Sterno-mastoid and Trapezius have been found in contact.

~~This muscle~~ divides the quadrilateral area of the side of the neck into two triangles, an anterior and a posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck; above, the lower border of the body of the mandible, and an imaginary line drawn from the angle of the mandible to the Sterno-mastoid; behind, the anterior border of the Sterno-mastoid muscle. The apex of the triangle is at the upper border of the sternum. The boundaries of the *posterior triangle* are, in front, the posterior border of the Sterno-mastoid; below, the middle third of the clavicle; behind, the anterior margin of the Trapezius. The apex corresponds with the meeting of the Sterno-mastoid and Trapezius on the occipital bone.*

Relations.—By its *superficial surface* it is in relation with the integument and Platysma, from which it is separated by the external jugular vein, several of the superficial branches of the cervical plexus, and the anterior layer of the deep cervical fascia.[1] By its *deep surface* it is in relation with the sterno-clavicular articulation, the process of the deep cervical fascia which binds the posterior belly of the Omo-hyoid to the sternum and clavicle, the Sterno-hyoid, Sterno-thyroid, Omo-hyoid, posterior belly of the Digastric, Levator anguli scapulæ, Splenius and Scaleni muscles, the common carotid artery, the internal and anterior jugular veins, the origins of the internal and external carotid arteries, the occipital, subclavian, transversalis colli, and suprascapular arteries and veins, the phrenic, pneumogastric, hypoglossal, descendens and communicantes hypoglossi nerves, the spinal accessory nerve which pierces its upper third, the cervical plexus, the upper part of the brachial plexus, parts of the thyroid and parotid glands and their vessels, and the deep lymphatic glands.

Actions.—When only one Sterno-mastoid muscle acts, it draws the head towards the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face towards the opposite side. If the head be fixed, the two muscles assist in elevating the thorax in forced inspiration. Acting together from their sterno-clavicular attachments the muscles will flex the cervical part of the vertebral column.

Nerves.—The Platysma is supplied by the facial nerve; ~~the Sterno-mastoid by the spinal accessory and~~ branches from the anterior ~~primary~~ divisions of the second and ~~third cervical nerves~~.

Surface Form.—The anterior edge of the muscle forms a very prominent ridge beneath the skin and constitutes a guide to the surgeon in making the necessary incisions for ligature of the common or external carotid artery, or of the internal jugular vein.

Applied Anatomy.—The surgical anatomy of the Sterno-mastoid muscle is of importance in connection with the deformity known as *wry-neck*, which is due to a contracted condition of this muscle. The wry-neck may be temporary, as the result of direct

* The anatomy of these triangles will be more fully described with that of the vessels of the neck (p. 640).

irritation of the muscle or of the nerves which supply it, and may occur in acute glandular enlargement, cellulitis of the neck, myositis of the muscle, or cervical caries. It may, however, be permanent, and is then most often due to injury to the muscle during birth, especially in breech presentations; rupture of the muscle and subsequent cicatricial contraction taking place. In these cases, division of the muscle is often necessary to effect a cure, and this may be done either subcutaneously or through an open wound. The subcutaneous method is thus performed: the external jugular and anterior jugular veins having been, if possible, defined, a tenotomy knife is introduced close to the margin of one tendon of origin of the muscle, about half an inch above the clavicle, and the tenotome passed flat behind the tendon and then turned forwards, and the tendon divided from behind forwards while the muscle is put well upon the stretch by an assistant. The other tendon is then divided in a similar manner. In dividing the clavicular origin, it is always desirable to introduce the tenotome along the posterior border, in order to avoid the external jugular vein. The open method is, however, much to be preferred, as being the more effectual and the less dangerous, if precautions are taken to keep the wound aseptic. The tendons of origin are freely exposed by a horizontal incision across the root of the neck and carefully divided; any tense bands of fascia which can be felt should also be divided. The wound is now sutured and dressed, and the head fixed in as straight a position as possible.

There is also a condition coming on in adult life (spasmodic torticollis), which is a very distressing form of functional nervous disease. It begins with tonic or clonic spasm of one of the Sterno-mastoids, which is soon followed by spasm of the Trapezius, particularly its clavicular portion. The Splenius of the opposite side, the Scaleni, Complexi, and Trachelo-mastoids, may all become involved in turn, with secondary contracture of the deep cervical fascia. Operation in these cases often fails to give satisfactory results. Tenotomy of the affected muscles or section of the nerves supplying them may afford temporary relief, but the spasm often returns when the cut nerves or muscles rejoin.

II. Infrahyoid Region (figs. 490, 491)

Sterno-hyoid.	Thyro-hyoid.
Sterno-thyroid.	Omo-hyoid.

The **Sterno-hyoid** (m. sternohyoideus) is a thin, narrow, riband-like muscle, which arises from the posterior surface of the inner extremity of the clavicle, the posterior sterno-clavicular ligament, and the upper and posterior part of the manubrium sterni; passing upwards and inwards, it is inserted, by short, tendinous fibres, into the lower border of the body of the hyoid bone. Below, this muscle is separated from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and from this upwards, lie side by side. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the Rectus abdominis.

The **Sterno-thyroid** (m. sternothyreoideus) is shorter and wider than the preceding muscle, beneath which it is situated. It arises from the posterior surface of the manubrium sterni, below the origin of the Sterno-hyoid, and from the edge of the cartilage of the first rib, and sometimes of the second rib also; and is inserted into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck; and is occasionally traversed by a transverse or oblique tendinous intersection like those in the Rectus abdominis.

The **Thyro-hyoid** (m. thyreohyoideus) is a small, quadrilateral muscle appearing like a continuation of the Sterno-thyroid. It arises from the oblique line on the side of the thyroid cartilage, and passes vertically upwards to be inserted into the lower border of the body and greater cornu of the hyoid bone.

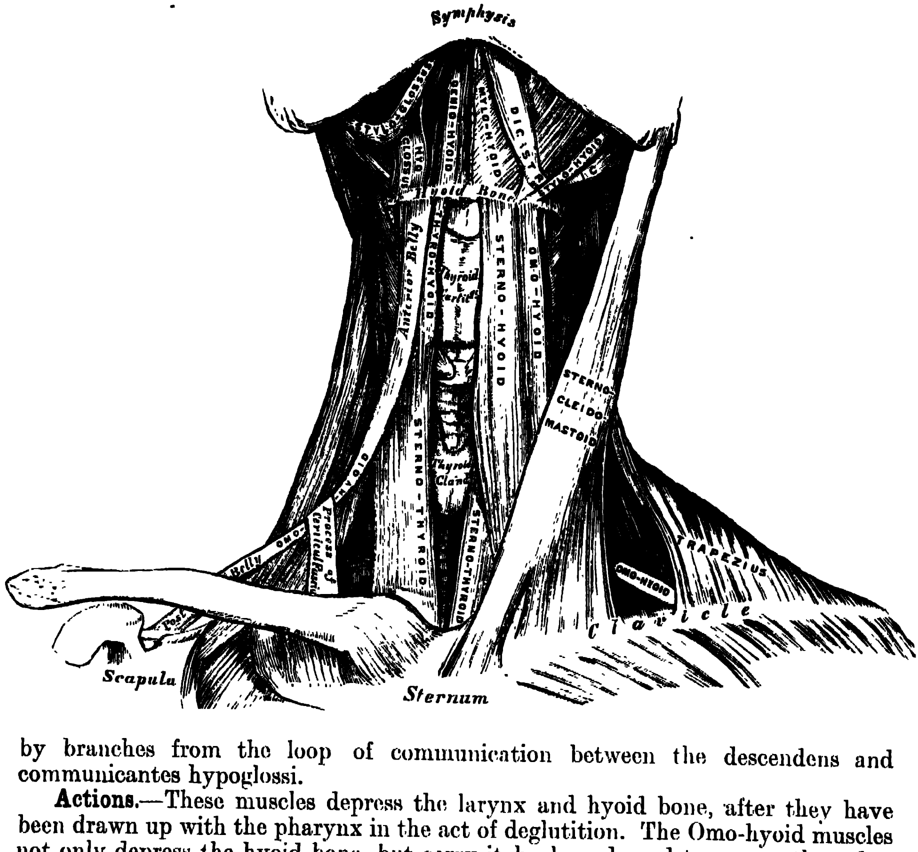
The **Omo-hyoid** (m. omohyoideus) passes across the side of the neck, from the scapula to the hyoid bone. It consists of two fleshy bellies united by a central tendon. It arises from the upper border of the scapula, and occasionally from the transverse ligament which crosses the suprascapular notch, its extent of attachment to the scapula varying from a few lines to an inch. From this origin, the posterior belly forms a flat, narrow fasciculus, which inclines forwards and slightly upwards across the lower part of the neck, being bound down to the clavicle by a fibrous expansion; it then passes behind the Sterno-mastoid muscle, becomes tendinous and changes its direction, forming an obtuse angle. It terminates in the anterior belly, which

passes almost vertically upwards, close to the outer border of the Sterno-hyoid, to be inserted into the lower border of the body of the hyoid bone, just external to the insertion of the Sterno-hyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which sheathes it. This process is prolonged down to be attached to the clavicle and first rib. It is by this means that the angular form of the muscle is maintained.

The posterior belly of the Omo-hyoid divides the posterior triangle of the neck into an upper or *occipital* and a lower or *subclavian* triangle, while its anterior belly divides the anterior triangle into an upper or *carotid* and a lower or *muscular* triangle.

Nerves.—The Thyro-hyoid is supplied by a branch from the hypoglossal nerve; the anterior belly of the Omo-hyoid by the descendens hypoglossi; the Sterno-hyoid, Sterno-thyroid, and posterior belly of the Omo-hyoid, are supplied

FIG. 491.—Muscles of the neck. Anterior view.



by branches from the loop of communication between the descendens and communicantes hypoglossi.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omo-hyoid muscles not only depress the hyoid bone, but carry it backwards and to one or the other side. They are concerned especially in prolonged inspiratory efforts; for by rendering the lower part of the cervical fascia tense they lessen the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. The Thyro-hyoid may act as an elevator of the thyroid cartilage, when the hyoid bone ascends, drawing the thyroid cartilage up behind the hyoid bone. The Sterno-thyroid acts as a depressor of the thyroid cartilage.

III. Suprahyoid Region (figs. 490, 491)

Digastric.	Mylo-hyoid.
Stylo-hyoid.	Genio-hyoid.

The **Digastric** (m. digastricus) consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the

body of the mandible, and extending, in a curved form, from the mastoid process of the temporal to the symphysis menti. The *posterior belly* (venter posterior), longer than the anterior, arises from the digastric groove on the inner side of the mastoid process, and passes downwards, forwards, and inwards. The *anterior belly* (venter anterior) arises from a depression on the inner side of the lower border of the mandible, close to the symphysis, and passes downwards and backwards. The two bellies terminate in the central tendon which perforates the Stylo-hyoid muscle, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined by a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on either side, to be attached to the body and greater cornu of the hyoid bone; this is termed the *suprahyoid aponeurosis*. It forms a strong layer of fascia between the anterior portions of the two muscles, and a firm investment for the deeper muscles of the supra-hyoid region.

The Digastric muscle divides the anterior superior triangle of the neck into smaller triangles: (1) the *submaxillary triangle*, bounded above by the lower border of the body of the mandible and a line drawn from its angle to the mastoid process, below by the posterior belly of the Digastric and the Stylo-hyoid muscles, in front by the anterior belly of the Digastric; (2) the *carotid triangle*, bounded above by the posterior belly of the Digastric and Stylo-hyoid, behind by the Sterno-mastoid, below by the Omo-hyoid; (3) the *suprahyoid* or *submental triangle*, bounded externally by the anterior belly of the Digastric, internally by the middle line of the neck from the hyoid bone to the symphysis menti and inferiorly by the body of the hyoid bone.

Relations.—The Digastric is in relation by its *superficial surface* with the Platysma, Sterno-mastoid, part of the Splenius, ~~Trachelo-mastoid~~, mastoid process, Stylo-hyoid, and the parotid gland. The *deep surface* of the anterior belly lies on the Mylo-hyoid; the deep surface of the posterior belly on the Stylo-glossus, Stylo-pharyngeus, and Hyo-glossus muscles, the external carotid artery and its occipital, lingual, facial, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylo-hyoid** (m. stylohyoideus) is a small, slender muscle, lying in front of, and above, the posterior belly of the Digastric. It arises from the back and outer surface of the styloid process, near the base; and, passing downwards and forwards, is inserted into the body of the hyoid bone, at its junction with the greater cornu, and just above the Omo-hyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

The *stylo-hyoid ligament*.—In connection with the Stylo-hyoid muscle a ligamentous band, the *stylo-hyoid ligament*, may be described. It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and the lesser cornu of the latter. It is often partially ossified, and in many animals forms a distinct bone, the *epihyal*.

The **Mylo-hyoid** (m. mylohyoideus) is a flat, triangular muscle, situated immediately above the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylo-hyoid ridge of the mandible, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass inwards and slightly downwards, to be inserted into the body of the hyoid bone. The middle and anterior fibres are inserted into a median fibrous raphe extending from the symphysis menti to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. This median raphe is sometimes wanting; the muscular fibres of the two sides are then directly continuous with one another.

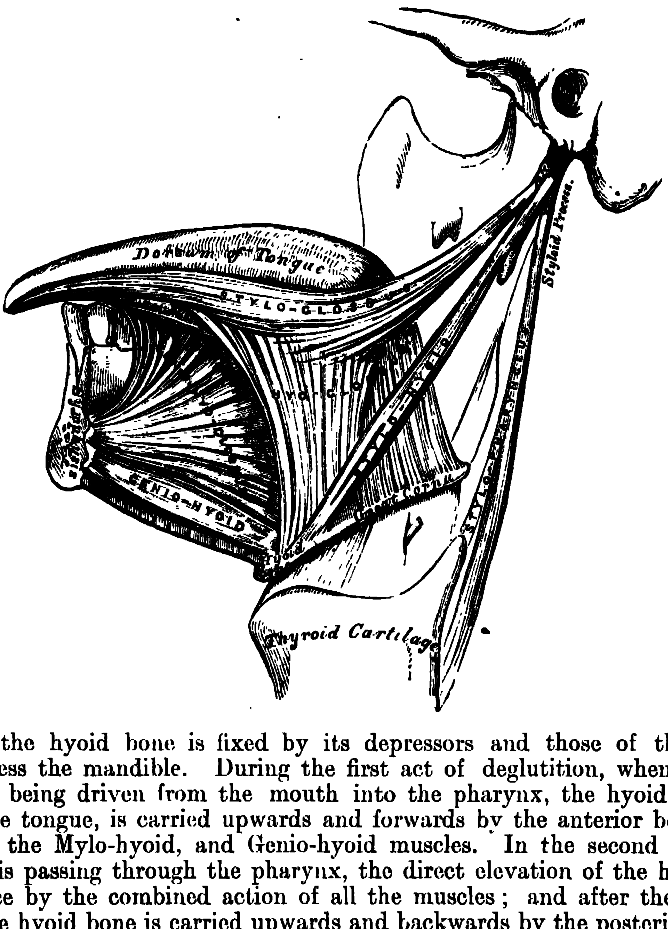
Relations.—The mylo-hyoid is in relation by its *superficial* or *under surface* with the Platysma, the anterior belly of the Digastric, the suprahyoid aponeurosis, the superficial part of the submaxillary gland, the facial and submental vessels, and the mylo-hyoid vessels and nerve. By its *deep* or *superior surface* it is in relation with the Genio-hyoid, part of the Hyo-glossus, and Stylo-glossus muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and Wharton's duct, the sublingual and ranine vessels, and the buccal mucous membrane.

The **Genio-hyoid** (m. geniohyoideus) is a narrow, slender muscle, situated above the inner border of the preceding. It arises from the inferior genial tubercle on the inner side of the symphysis menti, and passes downwards and backwards, to be inserted into the anterior surface of the body of the hyoid bone. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

Nerves.—The Mylo-hyoid and anterior belly of the Digastric are supplied by the mylo-hyoid branch of the inferior dental; the Stylo-hyoid and posterior belly of the Digastric, by the facial; the Genio-hyoid, by the hypoglossal.

Actions.—These muscles perform two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition;

FIG. 492.—Muscles of the tongue. Left side.



or, when the hyoid bone is fixed by its depressors and those of the larynx, they depress the mandible. During the first act of deglutition, when the mass of food is being driven from the mouth into the pharynx, the hyoid bone and with it the tongue, is carried upwards and forwards by the anterior belly of the Digastric, the Mylo-hyoid, and Genio-hyoid muscles. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upwards and backwards by the posterior belly of the Digastric and the Stylo-hyoid, which assist in preventing the return of the food into the mouth.

IV. Lingual Region (fig. 492)

Genio-hyo-glossus. Chondro-glossus.
Hyo-glossus. Stylo-glossus.
Palato-glossus.*

The **Genio-hyo-glossus** (m. genioglossus) has received its name from its triple attachment to the mandible, hyoid bone, and tongue, but its

* The *Palato-glossus*, or *Constrictor isthmi faucium*, although one of the muscles of the tongue, serving to draw its base upwards during the act of deglutition, is more closely associated with the soft palate, both in situation and function; it will, consequently, be described with the muscles of that structure (p. 485).

connection with the hyoid bone is very slight and may be altogether absent. It is a flat, triangular muscle, placed vertically close to the middle line, its apex corresponding with its point of origin from the mandible, its base with its insertion into the tongue and hyoid bone. It arises by a short tendon from the superior genial tubercle on the inner surface of the symphysis menti, immediately above the Genio-hyoid, and from this point spreads out in a fan-like form. The inferior fibres extend downwards, to be attached by a thin aponeurosis to the upper part of the body of the hyoid bone, a few passing between the Hyo-glossus and Chondro-glossus to blend with the Constrictor muscles of the pharynx; the middle fibres pass backwards, and the superior ones upwards and forwards, to enter the whole length of the under surface of the tongue, from the base to the apex. Behind, the muscle is quite distinct from its fellow of the opposite side; the two muscles are separated at their insertions into the under surface of the tongue by a tendinous raphe, which extends through the middle of the organ; in front, they are more or less blended: distinct fasciculi are to be seen passing off from one muscle, crossing the middle line, and intersecting bundles of fibres derived from the muscle on the other side.

The **Hyo-glossus** is a thin, flat, quadrilateral muscle, which arises from the side of the body and whole length of the greater cornu of the hyoid bone, and passes almost vertically upwards to enter the side of the tongue, between the Stylo-glossus and Inferior lingualis. The fibres of this muscle which arise from the body of the hyoid bone are directed upwards and backwards, overlapping those arising from the greater cornu, which are inclined upwards and forwards.

Relations.—The Hyo-glossus is in relation by its *external surface* with the Digastric, the Stylo-hyoid, Stylo-glossus and Mylo-hyoid muscles, the submaxillary ganglion, the lingual and hypoglossal nerves, Wharton's duct, the ranine vein, the sublingual gland, and the deep portion of the submaxillary gland. By its *deep surface* it is in relation with the stylo-hyoid ligament, the Genio-hyo-glossus, Inferior lingualis, and Middle constrictor, the lingual vessels, and the glosso-pharyngeal nerve.

The **Chondro-glossus** is a distinct muscular slip, though it is sometimes described as a part of the Hyo-glossus, from which, however, it is separated by the fibres of the Genio-hyo-glossus, which pass to the side of the pharynx. It is about three-quarters to an inch in length, and arises from the inner side and base of the lesser cornu and contiguous portion of the body of the hyoid bone, and passes directly upwards to blend with the intrinsic muscular fibres of the tongue, between the Hyo-glossus and Genio-hyo-glossus.

A small slip of muscular fibres is occasionally found, arising from the cartilago triticea in the thyro-hyoid ligament; it passes upwards and forwards and enters the tongue with the hindermost fibres of the Hyo-glossus.

The **Stylo-glossus**, the shortest and smallest of the three styloid muscles, arises from the anterior and outer side of the styloid process, near its apex, and from the stylo-mandibular ligament. Passing downwards and forwards between the internal and external carotid arteries, and becoming nearly horizontal in its direction, it divides upon the side of the tongue into two portions: one, longitudinal, enters the side of the tongue near its dorsal surface, blending with the fibres of the Inferior lingualis in front of the Hyo-glossus; the other, oblique, overlaps the Hyo-glossus muscle and decussates with its fibres.

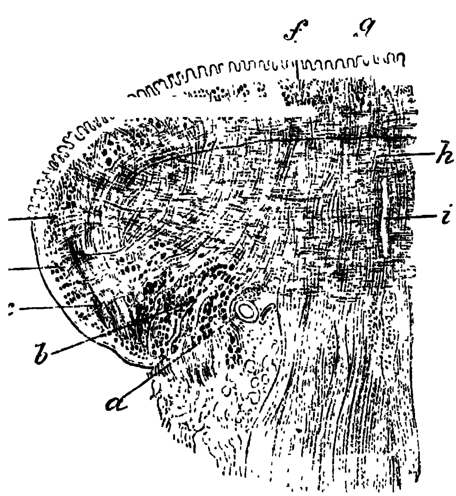
Nerves.—The muscles of this group are supplied by the hypoglossal.

Muscular substance of tongue (fig. 493).—The tongue consists of two symmetrical portions separated from each other in the middle line by a fibrous septum. Its muscular fibres run in various directions, but may be grouped into two sets—extrinsic and intrinsic. The extrinsic muscles are those which have their origin external to, and their terminal fibres contained in, the substance of the organ. They are: the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the superior constrictor of the pharynx (Pharyngo-glossus). The intrinsic are those which are contained entirely within the tongue; they form the greater part of its muscular structure.

Immediately beneath the mucous membrane is a submucous, fibrous layer, into which the muscular fibres which terminate on the surface of the tongue are

inserted. Upon removing this with the mucous membrane, the first stratum of muscular fibres is exposed. This belongs to the group of intrinsic muscles, and has been named the *Superior lingualis*. It consists of a thin layer of oblique and longitudinal fibres, which arise from the submucous fibrous layer, close to the epiglottis, and from the fibrous septum, and pass forwards and outwards to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Genio-hyo-glossus and from the Vertical intrinsic muscle, which will be described later on. Beneath this layer is the second stratum of muscular fibres, derived principally from the extrinsic muscles. In front, it is formed by the fibres derived from the Stylo-glossus, running along the side of the tongue, and sending one set of fibres over the dorsum which runs obliquely forwards and inwards to the middle line, and another set of fibres, on to the under surface of the sides of the anterior part of the tongue, which runs forwards and inwards, between the fibres of the Hyo-glossus, to the middle line. Behind this layer of fibres, derived from the Stylo-glossus, are fibres derived from the Hyo-glossus, together with some few fibres of the Palato-glossus. The Hyo-glossus, entering the side of the under surface of the tongue, between the Stylo-glossus and Inferior lingualis, passes round its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inwards to the septum. It is reinforced by some fibres from the Palato-glossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscular fibres of the tongue is derived from those fibres of the Hyo-glossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the Chondro-glossus. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue. Beneath this layer is the great mass of the intrinsic muscles of the tongue, intersected at right angles by the terminal fibres of one of the extrinsic muscles—the Genio-hyo-glossus. This portion of the tongue is paler in colour and softer in texture than that already described, and is sometimes designated the medullary portion in contradistinction to the firmer superficial part, which is termed the cortical portion. It consists largely of transverse fibres, the *Transverse lingualis*, and of vertical fibres, the *Vertical lingualis*. The Transverse lingualis forms the largest portion of the third layer of muscular fibres of the tongue. The fibres arise from the median septum, and pass outwards to be inserted into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palato-glossus and the Superior constrictor of the pharynx. These Transverse extrinsic fibres, however, run in the opposite direction, passing inwards towards the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Genio-hyo-glossus and partly from intrinsic fibres, the Vertical lingualis. The fibres derived from the Genio-hyo-glossus enter the under surface of the tongue on either side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on either side of the middle line. The Vertical lingualis is found only at the borders of the fore part of the tongue, external to the fibres of the Genio-hyo-glossus. Its fibres extend from the upper to the under surface of the organ, decussating with the fibres of the other muscles,

Fig. 493.—Coronal section of tongue, showing intrinsic muscles. (Altered from Krause.)



a. Lingual artery. b. Inferior lingualis, cut through. c. Fibres of Hyo-glossus. d. Oblique fibres of Stylo-glossus. e. Insertion of Transverse lingualis. f. Superior lingualis. g. Papillæ of tongue. h. Vertical fibres of Genio-hyo-glossus intersecting Transvers lingualis. i. Septum.

and especially with the Transverse lingualis. The fourth layer of muscular fibres of the tongue consists partly of extrinsic fibres derived from the Stylo-glossus, and partly of intrinsic fibres, the *Inferior lingualis*. At the sides of the under surface of the organ are some fibres derived from the Stylo-glossus; as this muscle runs forwards at the side of the tongue, it gives off fibres which pass forwards and inwards between the fibres of the Hyo-glossus and form an inferior oblique stratum which joins in front with the anterior fibres of the Inferior lingualis. The Inferior lingualis is a longitudinal band, situated on the under surface of the tongue, and extending from the base to the apex of the organ. Behind, some of its fibres are connected with the body of the hyoid bone. It lies between the Hyo-glossus and the Genio-hyo-glossus; in front of the Hyo-glossus it comes into relation with the Stylo-glossus, with the fibres of which it blends. It is in relation by its under surface with the ranine artery.

Applied Anatomy.—The fibrous septum which exists between the two halves of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the organ. If the mucous membrane be divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphe, without any appreciable hæmorrhage, and the diseased half can then be removed.

Actions.—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The Genio-hyo-glossi, by means of their posterior fibres, draw the base of the tongue forwards, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole of these two muscles acting along the middle line of the tongue draw it downwards, so as to make it concave from side to side, forming a channel along which fluids may pass towards the pharynx, as in sucking. The Hyo-glossi depress the tongue, and draw down its sides, so as to render it convex from side to side. The Stylo-glossi draw the tongue upwards and backwards. The Palato-glossi draw the base of the tongue upwards. The intrinsic muscles are mainly concerned in altering the shape of the tongue, whereby it becomes shortened, narrowed from side to side, or curved in different directions; thus, the Superior and Inferior linguales tend to shorten the tongue, but the former, in addition, turn the tip and sides upwards so as to render the dorsum concave, while the latter pull the tip downwards and cause the dorsum to become convex. The Transverse lingualis narrows and elongates the tongue, and the Vertical lingualis flattens and broadens it. The complex arrangement of the muscular fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds; and Macalister states 'there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages.'

V. Pharyngeal Region (fig. 494)

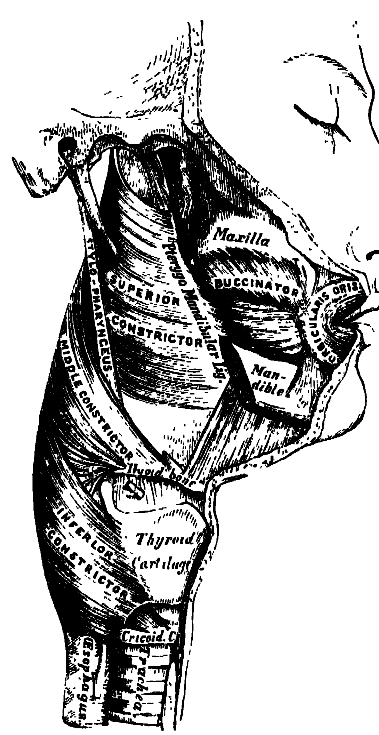
Inferior constrictor.	Superior constrictor.
Middle constrictor.	Stylo-pharyngeus.
Palato-pharyngeus.	(See next section.)
Salpingo-pharyngeus.	

The **Inferior constrictor** (m. constrictor pharyngis inferior), the thickest of the three constrictors, arises from the sides of the cricoid and thyroid cartilages. To the cricoid cartilage it is attached in the interval between the Crico-thyroid muscle in front, and the articular facet for the inferior cornu of the thyroid cartilage behind. To the thyroid cartilage it is attached to the oblique line on the side of the ala, to the cartilaginous surface behind it, nearly as far as its posterior border, and to the inferior cornu. From these attachments the fibres spread backwards and inwards, to be inserted into the fibrous raphe in the posterior median line of the pharynx. The inferior fibres are horizontal, and continuous with the circular fibres of the œsophagus; the rest ascend, increasing in obliquity, and overlap the Middle constrictor.

Relations.—The Inferior constrictor is covered by a thin membrane which surrounds the entire pharynx (bucco-pharyngeal fascia). *Behind*, it is in relation with the vertebral column and the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sterno-thyroid muscle; by its *internal surface*, with the Middle constrictor, the Stylo-pharyngeus, Palato-pharyngeus, the pharyngeal aponeurosis and mucous membrane of the pharynx. The internal laryngeal nerve and the laryngeal branch of the superior thyroid artery run near the upper border, and the inferior or recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery pass beneath the lower border of this muscle, before they enter the larynx.

The **Middle constrictor** (m. constrictor pharyngis medius) is a flattened, fan-shaped muscle, smaller than the preceding. It arises from the whole length of the upper border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylo-hyoid ligament. The fibres diverge from their origin: the lower ones descending beneath the Inferior constrictor, the middle fibres passing transversely, and the upper fibres ascending and overlapping the Superior constrictor. The muscle is inserted into the posterior median fibrous raphe, blending in the middle line with the one of the opposite side.

FIG. 494.—Muscles of the pharynx. External view.



Relations.—This muscle is separated from the Superior constrictor by the glosso-pharyngeal nerve and the Stylo-pharyngeus and stylo-hyoid ligament; and from the Inferior constrictor by the internal laryngeal nerve and laryngeal branch of the superior thyroid artery. *Behind*, it lies on the prevertebral fascia, the Longus colli, and the Rectus capitis anticus major. *On its outer side* it is in relation with the carotid vessels, the pharyngeal plexus, and some lymphatic glands. Near its origin it is covered by the Hyo-glossus, from which it is separated by the lingual vessels. It lies upon the Superior constrictor, the Stylo-pharyngeus, the Palato-pharyngeus, the pharyngeal aponeurosis, and the mucous membrane of the pharynx.

The **Superior constrictor** (m. constrictor pharyngis superior) is a quadrilateral muscle, thinner and paler than the other Constrictors, and situated at the upper part of the pharynx. It arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process, from the pterygo-mandibular ligament, from the alveolar process of the mandible above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue. From these points the fibres curve backwards, to be inserted into the median raphe, being also prolonged by means of an aponeurosis to the pharyngeal spine on the basilar process of the occipital bone. The superior fibres arch beneath the Levator palati and the Eustachian tube. The interval between the upper border of the muscle and the base of the skull is deficient in muscular fibres, and closed by the pharyngeal aponeurosis; it is known as the *sinus of Morgagni*.

Relations.—The Superior constrictor is in relation by its *outer surface* with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the internal jugular vein and pharyngeal venous plexus, and the glosso-pharyngeal, pneumogastric, spinal accessory, hypoglossal, lingual, and sympathetic nerves, the Middle constrictor and Internal pterygoid muscles, the styloid process, the stylo-hyoid ligament, and the Stylo-pharyngeus. By its *internal surface* it is in relation

with the Palato-pharyngeus, the tonsil, the pharyngeal aponeurosis and mucous membrane of the pharynx. Its *lower border* is separated from the Middle constrictor of the pharynx by the Stylo-pharyngeus muscle and the glosso-pharyngeal nerve.

The **Stylo-pharyngeus** is a long, slender muscle, cylindrical above, broad and thin below. It arises from the inner side of the base of the styloid process, passes downwards along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane. Some of its fibres are lost in the Constrictor muscles, while others, joining with the Palato-pharyngeus, are inserted into the posterior border of the thyroid cartilage. The glosso-pharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

Nerves.—The Constrictors are supplied by branches from the pharyngeal plexus, the Inferior constrictor by additional branches from the external and recurrent laryngeal nerves, and the Stylo-pharyngeus by the glosso-pharyngeal nerve.

Actions.—When deglutition is about to be performed, the pharynx is drawn upwards and dilated in different directions, to receive the food propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upwards and outwards, and so increase its transverse diameter; its breadth in the antero-posterior direction is increased by the larynx and tongue being carried forwards in their ascent. As soon as the bolus is received in the pharynx, the elevator muscles relax, the pharynx descends, and the Constrictors contract upon the bolus, and convey it gradually downwards into the œsophagus.

VI. Palatal Region (fig. 495)

Levator palati.	Palato-glossus.
Tensor palati.	Palato-pharyngeus.
Azygos uvulæ.	Salpingo-pharyngeus.

The **Levator palati** (m. levator veli palatini) is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous portion of the temporal bone, and from the inner surface of the cartilaginous portion of the Eustachian tube. After passing above the upper concave margin of the Superior constrictor, it spreads out in the soft palate, its fibres extending obliquely downwards and inwards, as far as the middle line, where they blend with those of the opposite side.

The **Tensor palati** (m. tensor veli palatini) is a broad, thin, riband-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal portion. The vertical portion arises by a flat lamella from the scaphoid fossa at the base of the internal pterygoid plate, from the spine of the sphenoid, and from the outer side of the cartilaginous portion of the Eustachian tube. Descending vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, it terminates in a tendon, which winds round the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle. Between the hamular process and the tendon is a small bursa. The tendon or horizontal portion then passes inwards, and is inserted into a broad aponeurosis, the *palatine aponeurosis*, and into the transverse ridge on the horizontal portion of the palate bone.

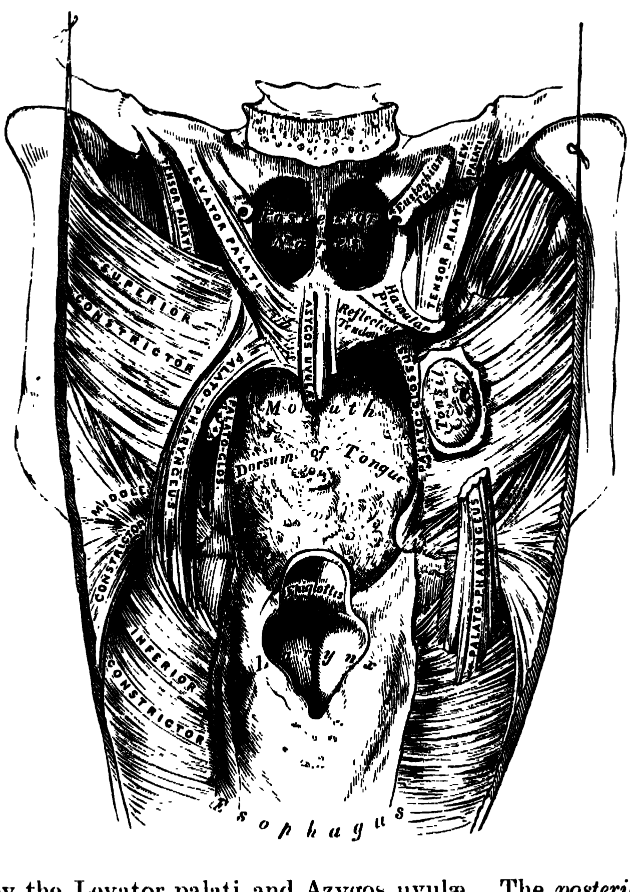
Palatine aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

The **Azygos uvulæ** (m. uvulæ) is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi, placed one on either side of the median line of the soft palate. Each muscle arises from the posterior nasal spine of the palate bone, and from the contiguous tendinous aponeurosis of the soft palate, and descends to be inserted into the uvula.

The **Palato-glossus** (m. glossopalatinus) is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the fauces. It arises from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side, and passing downwards, forwards, and outwards in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transverse lingualis.

The **Palato-pharyngeus** (m. pharyngopalatinus) is a long, fleshy fasciculus narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the fauces. It is separated from the Palato-glossus by an angular interval, in which the tonsil is lodged. It arises from the soft palate by an expanded fasciculus, which is divided into

FIG. 495.--Muscles of the soft palate. The pharynx is laid open from behind.



two parts by the Levator palati and Azygos uvulæ. The *posterior fasciculus* lies in contact with the mucous membrane, and joins with the corresponding muscle in the middle line; the *anterior fasciculus*, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing outwards and downwards behind the tonsil, the Palato-pharyngeus joins the Stylo-pharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly, to decussate with the muscle of the opposite side.

The **Salpingo-pharyngeus.**—This muscle arises from the inferior part of the Eustachian tube near its orifice; it passes downwards and blends with the posterior fasciculus of the Palato-pharyngeus.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order: viz. the posterior fasciculus of the Palato-pharyngeus, covered by a continuation of the mucous membrane of the floor of the nasal fossæ; the Azygos uvulæ; the Levator palati; the anterior fasciculus of the Palato-pharyngeus; the aponeurosis of the Tensor palati, and the Palato-glossus covered by a continuation of the oral mucous membrane.

Nerves.—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the bulbar portion of the spinal accessory through the pharyngeal plexus.*

Actions.—During the *first stage* of deglutition, the bolus is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx, and carried forwards under it. During the second stage the entrance to the larynx is closed, not, as was formerly supposed, by the folding backwards of the epiglottis over it, but, as Anderson Stuart has shown, by the drawing forward of the arytenoid cartilages towards the cushion of the epiglottis—a movement produced by the contraction of the External thyro-arytenoid, the Arytenoid and the Aryteno-epiglottidean muscles.

The bolus after leaving the tongue passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance; † then the Palato-glossi muscles, the constrictors of the fauces, contract behind it; the soft palate is slightly raised by the Levator palati, and made tense by the Tensor palati; and the Palato-pharyngei, by their contraction, pull the pharynx upwards over the bolus, and come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented from passing into the naso-pharynx; at the same time, the Palato-pharyngei form an inclined plane, directed obliquely downwards and backwards, along the under surface of which the bolus descends into the lower part of the pharynx. The Salpingo-pharyngei raise the upper and lateral parts of the pharynx—i.e. those parts which are above the points where the Stylo-pharyngei are attached to the pharynx.

Applied Anatomy.—After the operation for the closure of a cleft in the palate, the palate muscles, especially the Tensor and Levator palati, have a tendency to retard the healing process by active traction upon the line of suture. To obviate this, it is necessary to divide them. This is best done by making longitudinal incisions, on either side, parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

Paralysis of the soft palate is a common sequel of diphtheria; it gives rise to regurgitation of fluids through the nose.

VII. Anterior Vertebral Region (fig. 496)

Rectus capitis anticus major.	Rectus capitis lateralis.
Rectus capitis anticus minor.	Longus colli.

The **Rectus capitis anticus major** (m. longus capitis), broad and thick above, narrow below, appears like a continuation upwards of the Scalenus anticus. It arises by four tendinous slips, from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and ascends, converging towards its fellow of the opposite side, to be inserted into the basilar process of the occipital bone.

The **Rectus capitis anticus minor** (m. rectus capitis anterior) is a short, flat muscle, situated immediately behind the upper part of the preceding. It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process, and passing obliquely upwards and inwards, is inserted into the basilar process immediately behind the preceding muscle.

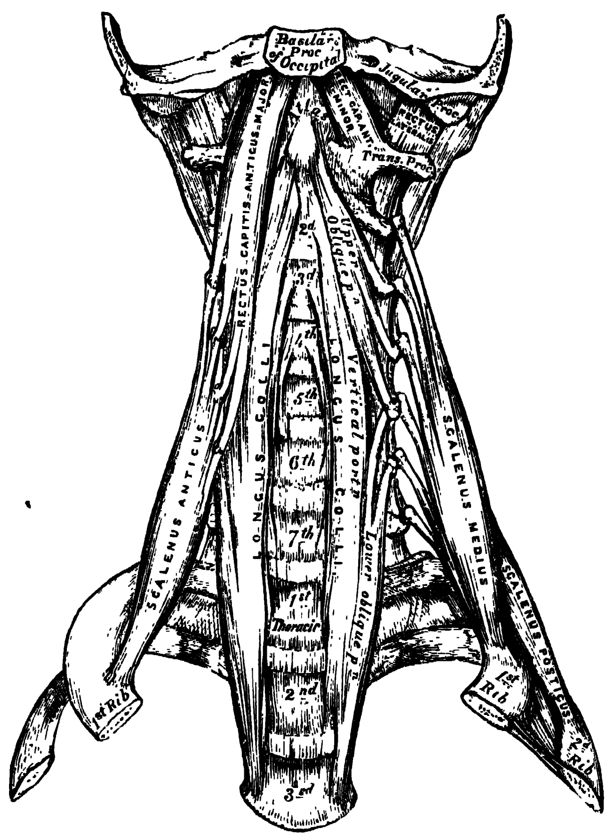
The **Rectus capitis lateralis** is a short, flat muscle, which arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

* 'The Innervation of the Soft Palate,' by Aldren Turner, *Journal of Anatomy and Physiology*, vol. xxiii. p. 523.

† Walton (quoted by Anderson Stuart) maintains that the epiglottis is not essential to the deglutition even of liquids.

The **Longus colli** is a long, flat muscle, situated on the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is broad in the middle, narrow and pointed at each extremity, and consists of three portions, a superior oblique, an inferior oblique, and a vertical portion. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ; and, ascending obliquely inwards, is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The *inferior oblique portion*, the smallest part of the muscle, arises from the front of the bodies of the first two or three thoracic vertebræ; and, ascending obliquely outwards, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The *vertical portion* lies directly on the front of the spine; it arises,

FIG. 496.—The prevertebral muscles.



below, from the front of the bodies of the upper three thoracic and lower three cervical vertebræ, and is inserted into the front of the bodies of the second, third, and fourth cervical vertebræ above.

Nerves.—The Rectus capitis anticus minor and the Rectus lateralis are supplied from the loop between the first and second cervical nerves; the Rectus capitis anticus major by branches from the second, third, and fourth cervical; the Longus colli by branches from the second to the seventh cervical nerves.

Actions.—The Rectus capitis anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backwards. These muscles also serve to flex the head, and from their obliquity, rotate it, so as to turn the face to one or the other side. The Rectus lateralis, acting on one side, bends the head laterally. The Longus colli flexes and slightly rotates the cervical portion of the spine.

VIII. Lateral Vertebral Region (fig. 496)

Scalenus anticus. Scalenus medius.
Scalenus posticus.

The **Scalenus anticus** (m. scalenus anterior) is a cone-shaped muscle, situated deeply at the side of the neck, behind the Sterno-mastoid. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and descending, almost vertically, is inserted by a narrow, flat tendon into the scalene tubercle on the inner border of the first rib, and also into the upper surface of the rib between the grooves for the subclavian artery and vein. The lower part of this muscle separates the subclavian artery and vein: the latter being in front, and the former, with the brachial plexus, behind.

Relations.—*In front* of the Scalenus anticus are the clavicle, the Subclavius, Sterno-mastoid, and Omo-hyoid muscles, the transversalis colli, the suprascapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve. By its *posterior surface*, it is in relation with the cords of the brachial plexus, the subclavian artery, and the pleura, which separate it from the Scalenus medius. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebræ, between the attachments of the Scalenus anticus and Longus colli, lies the ascending cervical branch of the inferior thyroid artery.

The **Scalenus medius** (m. scalenus medius), the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebræ, and descending along the side of the vertebral column, is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the Scalenus anticus by the subclavian artery below, and the cervical nerves above. The posterior thoracic nerve, or nerve of Bell, is formed in the substance of the Scalenus medius and emerges from it. The nerve to the Rhomboids also pierces it.

Relations.—The Scalenus medius is in relation by its *anterior surface* with the Sterno-mastoid; it is crossed by the clavicle, the Omo-hyoid muscle, subclavian artery, and the cervical nerves. To its *outer side* are the Levator anguli scapulæ and the Scalenus posticus.

The **Scalenus posticus** (m. scalenus posterior), the smallest of the three Scaleni, arises, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebræ, and diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus magnus. This is the most deeply placed of the three Scaleni, and is occasionally blended with the Scalenus medius.

Nerves.—The Scaleni are supplied by branches from the second to the seventh cervical nerves.

Actions.—The Scaleni muscles, when they take their fixed points from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed points from below, they bend the spinal column to one or other side. If the muscles of both sides act, lateral movement is prevented, but the spine is slightly flexed.

Surface Form.—The muscles in the neck, with the exception of the Platysma, are invested by the deep cervical fascia. The *Platysma* does not influence surface form unless it is in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. The *Sterno-mastoid* is the most important muscle of the neck as regards its surface form. If the muscle be put into action by drawing the chin downwards and to the opposite shoulder, its surface form will be plainly outlined. The sternal origin will stand out as a sharply defined ridge, while the clavicular origin will present a flatter and less prominent outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick rounded anterior border gradually becoming less marked above. When the muscle is at rest its anterior border is still visible, forming an oblique rounded ridge, terminating below in the sharp outline of the sternal head. The posterior border of the muscle does not show above

the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sterno-clavicular joint. It is an important surface-marking in the operation of ligature of the common carotid artery. Between the sternal and clavicular heads is a slight depression, most marked when the muscle is in action, which overlies the lower part of the internal jugular vein. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped depression, the *suprasternal notch*, more pronounced below, and less so above, where the Sterno-hyoid and Sterno-thyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the *Digastric* to a certain extent influences surface form. It corresponds to a line drawn from the symphysis menti to the side of the body of the hyoid bone, and renders this part of the hyo-mental region convex. In the posterior triangle of the neck, the posterior belly of the *Omo-hyoid*, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

MUSCLES AND FASCIÆ OF THE TRUNK

The Muscles of the Trunk may be arranged in four groups, corresponding with the regions in which they are situated.

I. The Back.
II. The Thorax.
III. The Abdomen.
IV. The Pelvis.
V. The Perinæum.

1. Muscles of the Back

The muscles of the back are very numerous, and may be subdivided into five layers.

First Layer

Trapezius.
Latissimus dorsi.

Second Layer

Levator anguli scapulæ.
Rhomboideus minor.
Rhomboideus major.

Third Layer

Serratus posticus superior.
Serratus posticus inferior.
Splenius capitis.
Splenius colli. cervicis

Fourth Layer

Sacral and Lumbar Regions

Erector spinæ. Sacrospinalis

Thoracic Region.

Ilio-costalis.
Musculus accessorius ad ilio-costalem.
Iliocostalis dorsi
Longissimus dorsi.
Spinalis dorsi.

Cervical Region

Cervicalis ascendens. Iliocosta
Transversalis cervicis. Longissi
Trachelo-mastoid. Longissimc
Complexus. Semispinalis c
Biventer cervicis.
Spinalis colli.

Fifth Layer

Semispinalis dorsi.
Semispinalis colli.
Multifidus spinæ.
Rotatores spinæ.
Interspinales.
Extensor coccygis.
Intertransversales.
Rectus capitis posticus major.
Rectus capitis posticus minor.
Obliquus capitis inferior.
Obliquus capitis superior.

First Layer

Trapezius. Latissimus dorsi.

The **superficial fascia** forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the general superficial fascia. The **deep fascia** is a dense fibrous layer, attached above to the superior curved line of the occipital bone; in the middle line it is attached to the ligamentum nuchæ, and to the spinous processes and supraspinous ligaments of all the vertebræ below the seventh cervical; laterally, in the neck it is continuous with the deep cervical fascia; over the shoulder it is attached to the spine of the scapula and the

acromion process, and is continued downwards over the Deltoid muscle to the arm; on the thorax it is continuous with the deep fascia of the axilla and chest, and on the abdomen with that covering the abdominal muscles; below, it is attached to the crest of the ilium.

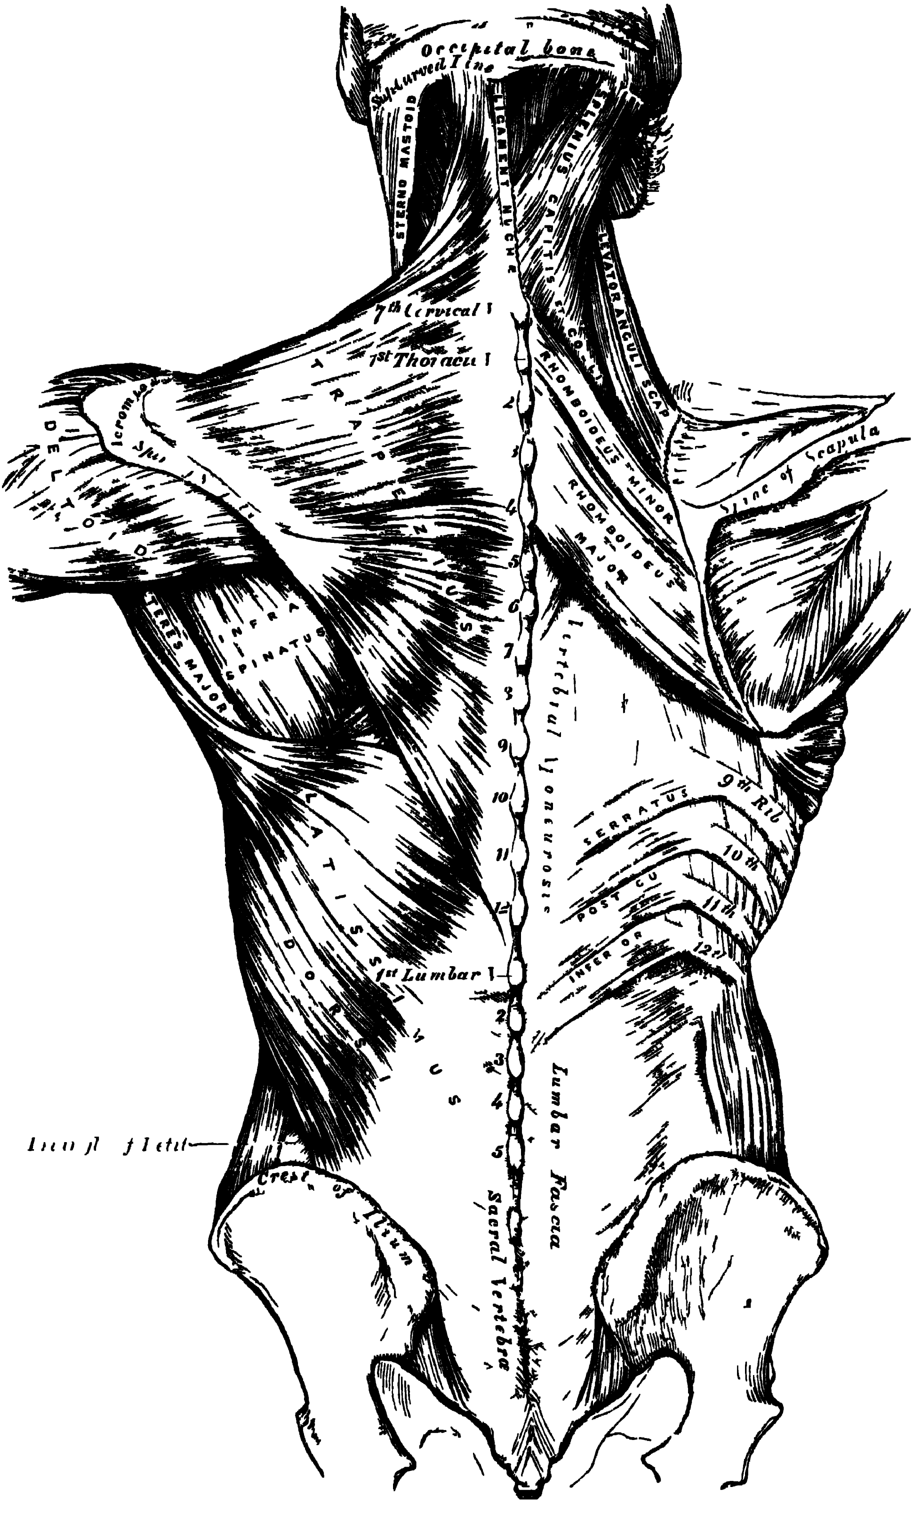
The Trapezius (fig. 497) is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. **It arises** from the external occipital protuberance and the inner third of the superior curved line of the occipital bone, from the ligamentum nuchæ, the spinous process of the seventh cervical, and the spinous processes of all the thoracic vertebræ, and from the corresponding portion of the supraspinous ligament. From this origin, the superior fibres proceed downwards and outwards, the inferior upwards and outwards, and the middle horizontally; the superior fibres are inserted into the posterior border of the outer third of the clavicle; the middle fibres into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in an aponeurosis, which glides over the smooth triangular surface on the inner extremity of the crest of the spine, to be inserted into a tubercle at the apex of this smooth triangular surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin and insertion. At its occipital origin, it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance of aponeurosis. At the middle of its origin from the spines of the vertebræ, it is connected to the bones by means of a broad semi-elliptical aponeurosis; this occupies the space between the sixth cervical and the third thoracic vertebræ, and forms, with the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle arises by numerous short tendinous fibres. The two Trapezius muscles together resemble a trapezium, or diamond-shaped quadrangle: two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the last thoracic vertebra.

The clavicular insertion of this muscle varies in extent: it sometimes advances as far as the middle of the clavicle, and may occasionally become blended with the posterior edge of the Sterno-mastoid, or overlap it.

The Latissimus dorsi (fig. 497) is a broad, flat muscle, which covers the lumbar and the lower half of the thoracic regions, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. **It arises** by tendinous fibres from the spinous processes of the six inferior thoracic vertebræ and from the posterior layer of the lumbar fascia (see page 493), by which it is attached to the spines of the lumbar and sacral vertebræ, to the supraspinous ligament, and to the posterior part of the crest of the ilium. It also arises by muscular fibres from the external lip of the crest of the ilium external to the margin of the Erector spinæ, and from the three or four lower ribs by fleshy digitations, which are interposed between similar processes of the External oblique muscle (fig. 502, page 507). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upwards, and the lower vertically upwards, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and usually receives a few fibres from it. The muscle curves around the lower border of the Teres major, and is twisted upon itself, so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It terminates in a short quadrilateral tendon, about three inches in length, which passes in front of the tendon of the Teres major, and is inserted into the bottom of the bicipital groove of the humerus; its insertion extending higher on the humerus than that of the tendon of the Pectoralis major. The lower border of the tendon of this muscle is united with that of the Teres major, the surfaces of the two being separated near their insertions by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. The muscle at its insertion gives off an expansion to the deep fascia of the arm.

A muscular slip, the *axillary arch*, varying from 3 to 4 inches in length, and from ¼ to ¾ of an inch in breadth, occasionally arises from the upper edge of the Latissimus

FIG 497 —Muscles of the back On the left side, the first layer is exposed, on the right side, the second layer and part of the third



dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coraco-brachialis, or the fascia over the Biceps. The position of this abnormal slip is a point of interest in its relation to the axillary artery, as it crosses the vessel just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It may be easily recognised by the transverse direction of its fibres. Struthers found it, in 8 out of 105 subjects, occurring seven times on both sides.

There is usually a fibrous slip which passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps. This is occasionally muscular, and is the representative of the *Dorso-epitrochlearis* muscle of apes.

The outer margin of the Latissimus dorsi is separated below from the External oblique muscle of the abdomen by a small triangular interval, the base of which is formed by the crest of the ilium, and its floor by the Internal oblique. This is known as the *triangle of Petit* (trigonum lumbale), and is sometimes the site of a lumbar hernia. Another triangle of practical importance is situated behind the scapula. It is bounded above by the Trapezius, below by the Latissimus dorsi, and externally by the vertebral border of the scapula; the floor is partly formed by the Rhomboideus major. If the scapula be drawn forwards by folding the arms across the chest, and the trunk bent forwards, a part of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation. The space is therefore known as the *triangle of auscultation.*

Nerves.—The Trapezius is supplied by the spinal accessory, and by branches from the third and fourth cervical nerves; the Latissimus dorsi by the sixth, seventh, and eighth cervical nerves through the middle or long subscapular nerve.

Second Layer (fig. 497)

Levator anguli scapulæ. Rhomboideus minor.
Rhomboideus major.

The **Levator anguli scapulæ** (m. levator scapulæ) is situated at the back part and side of the neck. It arises by tendinous slips from the transverse processes of the atlas and axis and from the posterior tubercles of the transverse processes of the third and fourth cervical vertebræ; these tendons, becoming fleshy, are united to form a flat muscle, which passes downwards and backwards, and is inserted into the posterior border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine.

The **Rhomboideus minor** arises from the lower part of the ligamentum nuchæ and the spinous processes of the seventh cervical and first thoracic vertebræ. Passing downwards and outwards, it is inserted into the base of the triangular smooth surface at the root of the spine of the scapula. This small muscle is usually separated from the Rhomboideus major by a slight interval.

The **Rhomboideus major** is situated immediately below the preceding, the adjacent margins of the two being occasionally united. It arises by tendinous fibres from the spinous processes of the second, third, fourth, and fifth thoracic vertebræ and the supraspinous ligament, and is inserted into a narrow tendinous arch, attached above to the lower part of the triangular surface at the root of the spine, below, to the inferior angle, the arch being connected to the border of the scapula by a thin membrane. When the arch extends, as it occasionally does, only a short distance, the muscular fibres are inserted into the scapula itself.

Nerves.—The Rhomboid muscles are supplied by a branch from the fifth cervical nerve; the Levator anguli scapulæ by the third and fourth cervical nerves, and frequently by a branch from the nerve to the Rhomboids.

Actions.—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachments. The whole of the Trapezius when in action retracts the scapula and braces back the shoulder; if the head be fixed, the upper part of the Trapezius will elevate the point of the shoulder, as in supporting weights; when the lower fibres are brought into action they assist in depressing the bone. The middle and lower fibres of the muscle rotate the scapula, causing elevation of the acromion process. If the shoulders be fixed, the Trapezii, acting together, will draw the head directly backwards; or if only one act, the head is drawn to the corresponding side.

The Latissimus dorsi, when it acts upon the humerus, depresses it, draws it backwards, and at the same time rotates it inwards. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm be fixed, the muscle may act in various ways upon the trunk: thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms be fixed, the two muscles may assist the Abdominal and great Pectoral muscles in suspending and drawing the whole trunk forwards, as in climbing or walking on crutches.

The Levator anguli scapulæ raises the superior angle of the scapula, assisting the Trapezius in bearing weights or in shrugging the shoulders. If the shoulder be fixed, the Levator anguli scapulæ inclines the neck to the corresponding side and rotates it in the same direction. The Rhomboid muscles carry the inferior angle backwards and upwards, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboideus major acting especially on the lower angle of the scapula, through the tendinous arch by which it is inserted. The Rhomboid muscles, acting together with the middle and inferior fibres of the Trapezius, will retract the scapula.

THIRD LAYER (fig. 497)

Serratus posticus superior. Serratus posticus inferior.

Splenius { Splenius capitis.
Splenius colli.

The **Serratus posticus superior** is a thin, flat, quadrilateral muscle, situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the lower part of the ligamentum nuchæ, from the spinous processes of the last cervical and upper two or three thoracic vertebræ and from the supraspinous ligament. Inclining downwards and outwards, it becomes muscular, and is inserted, by four fleshy digitations, into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

The **Serratus posticus inferior** is situated at the junction of the thoracic and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a wide interval. It arises by a thin aponeurosis from the spinous processes of the last two thoracic and upper two or three lumbar vertebræ, and from the supraspinous ligament. Passing obliquely upwards and outwards, it becomes fleshy, and divides into four flat digitations, which are inserted into the lower borders of the lower four ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbar fascia.

The **vertebral fascia** is a thin, fibrous lamina, extending along the whole length of the back part of the thoracic region, serving to bind down the long extensor muscles of the back which support the vertebral column and head, and to separate them from those muscles which connect the vertebral column to the upper extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached in the median line to the spinous processes of the thoracic vertebræ; externally, to the angles of the ribs; and below, to the upper border of the Serratus posticus inferior and to the portion of the lumbar fascia which gives origin to the Latissimus dorsi; above, it passes beneath the Serratus posticus superior and the Splenius, and blends with the deep fascia of the neck.

The **lumbar fascia** or **aponeurosis** (fig. 498), which may be regarded as the posterior aponeurosis of the Transversalis abdominis muscle, consists of three laminæ, which are attached as follows: the posterior layer, to the spines of the lumbar and sacral vertebræ and the supraspinous ligament; the middle, to the tips of the transverse processes of the lumbar vertebræ and the intertransverse ligaments; the anterior, to the roots of the lumbar transverse processes. The posterior layer is continued above as the vertebral fascia, while inferiorly it is fixed to the outer lip of the iliac crest. With this layer are blended the aponeurotic origin of the Serratus posticus inferior and part of that of the Latissimus dorsi. The middle layer is attached above to the last rib, and below to the iliac crest; the anterior layer is fixed below to the

ilio-lumbar ligament and iliac crest; while above it is thickened to form the external arcuate ligament of the Diaphragm, and stretches from the tip of the last rib to the transverse process of the first or second lumbar vertebra. These three layers, together with the vertebral column, enclose two spaces, the posterior of which is occupied by the Erector spinæ muscle, and the anterior by the Quadratus lumborum.

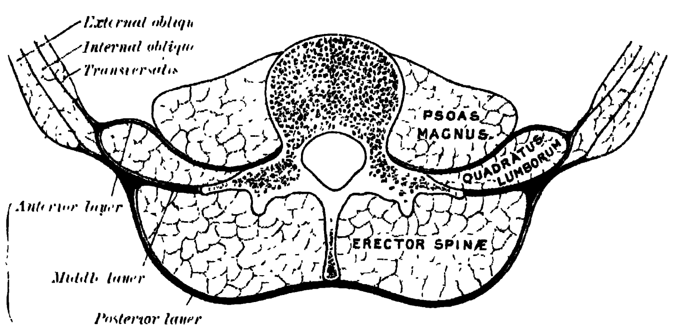
The **Splenius** is a broad sheet situated at the back of the neck and upper part of the thoracic region. At its origin, it is a single muscle, which arises by tendinous fibres, from the lower half of the ligamentum nuchæ, from the spinous processes of the last cervical and upper six thoracic vertebræ, and from the supraspinous ligament. From this origin the fleshy fibres proceed obliquely upwards and outwards, forming a broad flat muscle, which divides as it ascends, into two portions, the Splenius capitis and Splenius colli.

The **Splenius capitis** (m. splenius capitis) is inserted, under cover of the Sterno-mastoid, into the mastoid process of the Temporal bone, and into the rough surface on the occipital bone just below the outer third of the superior curved line.

The **Splenius colli** (m. splenius cervicis) is inserted, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the upper two or three cervical vertebræ.

Nerves.—The Splenius is supplied by the external branches of the posterior primary divisions of the middle and lower cervical nerves; the Serratus posticus superior is supplied by branches from the upper three or four intercostal nerves;

Fig. 498.—Diagram of a transverse section of the posterior abdominal wall, to show the three layers of the lumbar aponeurosis.



the Serratus posticus inferior by branches from the ninth, tenth, and eleventh intercostal nerves.

Actions.—The Serrati are respiratory muscles. The Serratus posticus superior elevates the ribs and is therefore an inspiratory muscle. The Serratus posticus inferior draws the lower ribs downwards and backwards, and thus elongates the thorax; it also fixes the lower ribs, thus assisting the inspiratory action of the Diaphragm and resisting the tendency which it has to draw the lower ribs upwards and forwards. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral fascia. The Splenii of the two sides, acting together, draw the head directly backwards, assisting the Trapezius and Complexus; acting separately, they draw the head to one side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

Fourth Layer

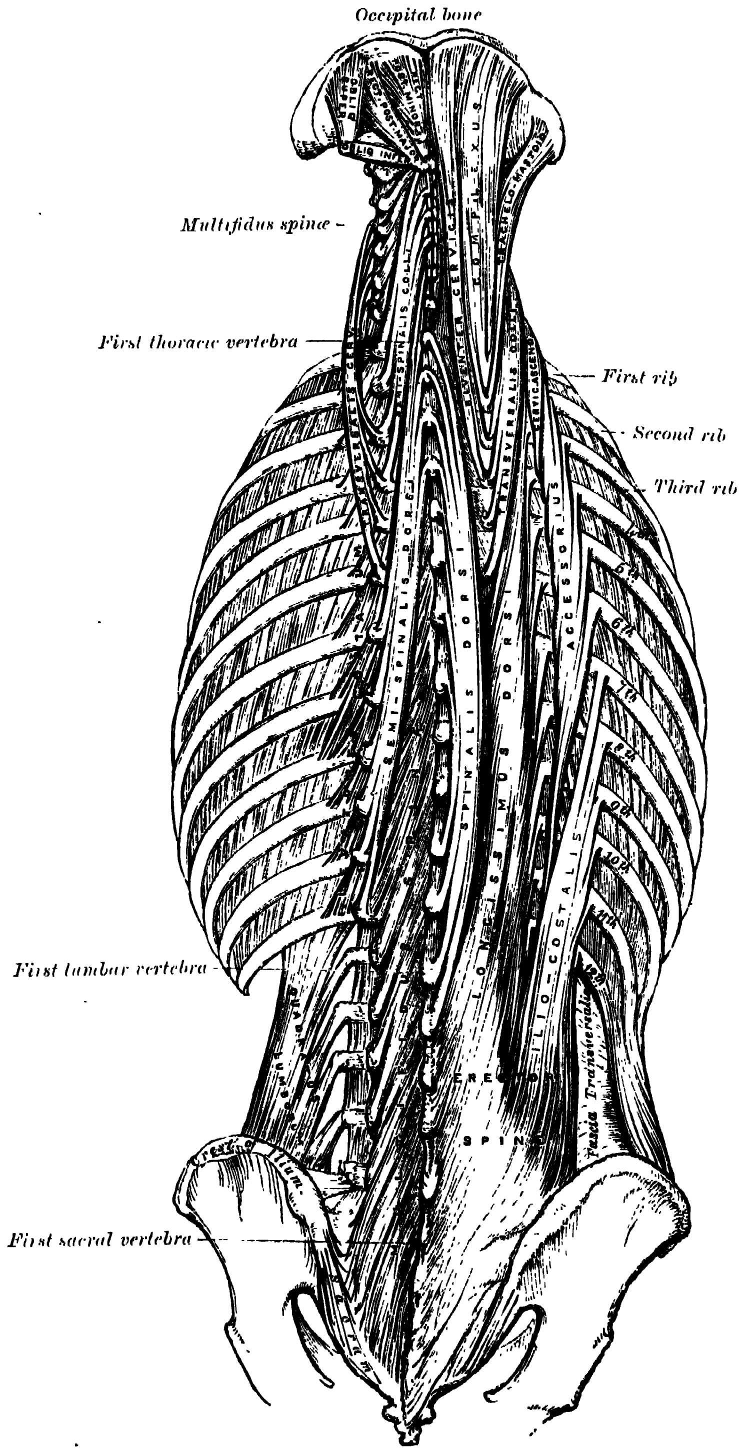
1. Erector spinæ.

a. Outer Column.	*b. Middle Column.*	*c. Inner Column.*
Ilio-costalis.	Longissimus dorsi.	Spinalis dorsi.
Musculus accessorius.	Transversalis cervicis.	
Cervicalis ascendens.	Trachelo-mastoid.	

2. Complexus.

The **Erector spinæ** (m. sacrospinalis) (fig. 499), and its prolongations in the thoracic and cervical regions, fill up the groove on either side of the

Fig. 499.—Muscles of the back. Deep layers.



vertebral column. They are covered in the lumbar region by the lumbar fascia, in the thoracic region by the Serrati and the vertebral fascia, and in the cervical region by a layer of cervical fascia continued beneath the Trapezius and the Splenius. This large muscular and tendinous mass varies in size and structure at different parts of the vertebral column. In the sacral region it is narrow and pointed, and at its origin chiefly tendinous in structure. In the lumbar region it becomes enlarged, and forms a thick fleshy mass. In the thoracic region it is subdivided into three columns, which gradually diminish in size as they ascend to be inserted into the vertebræ and ribs. The outer and middle columns are each subdivided from below upwards into three parts, viz. the outer into *Ilio-costalis*, *Musculus accessorius*, and *Cervicalis ascendens*; the middle into *Longissimus dorsi*, *Transversalis cervicis*, and *Trachelo-mastoid*. The inner column is the shortest and weakest, and is named the *Spinalis dorsi*.

The Erector spinæ arises from the anterior surface of a very broad and thick tendon, which is attached, internally, to the spines of the sacrum, to the spinous processes of the lumbar and the eleventh and twelfth thoracic vertebræ, and the supraspinous ligament; externally, to the back part of the inner lip of the crest of the ilium, and to the lateral crests of the sacrum, where it blends with the great sacro-sciatic and posterior sacro-iliac ligaments. Some of its fibres are continuous with the fibres of origin of the Gluteus maximus. The muscular fibres form a large fleshy mass, bounded in front by the transverse processes of the lumbar vertebræ, and by the middle lamella of the lumbar fascia.

The **Ilio-costalis** (m. iliocostalis lumborum), the external portion of the Erector spinæ, is inserted, by six or seven flattened tendons, into the inferior borders of the angles of the lower six or seven ribs.

The **Musculus accessorius** (m. iliocostalis dorsi) arises by flattened tendons from the upper borders of the angles of the lower six ribs internal to the tendons of insertion of the Ilio-costalis; these become muscular, and are inserted into the upper borders of the angles of the upper six ribs and into the back of the transverse process of the seventh cervical vertebra.

The **Cervicalis ascendens** (m. iliocostalis cervicis) is situated on the inner side of the Accessorius; it arises from the angles of the third, fourth, fifth, and sixth ribs, and is inserted into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

The **Longissimus dorsi** is the middle and largest portion of the Erector spinæ. In the lumbar region, where it is as yet blended with the Ilio-costalis, some of its fibres are attached to the whole length of the posterior surfaces of the transverse processes and the accessory processes of the lumbar vertebræ, and to the middle layer of the lumbar fascia. In the thoracic region it is inserted, by rounded tendons, into the tips of the transverse processes of all the thoracic vertebræ, and by fleshy processes into the lower nine or ten ribs between their tubercles and angles.

The **Transversalis cervicis** (m. longissimus cervicis), placed on the inner side of the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the upper four or five thoracic vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ from the second to the sixth inclusive.

The **Trachelo-mastoid** (m. longissimus capitis) lies on the inner side of the Transversalis cervicis, between it and the Complexus muscle. It arises by tendons from the transverse processes of the upper four or five thoracic vertebræ, and the articular processes of the lower three or four cervical. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the mastoid process, beneath the Splenius capitis and Sterno-mastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.

The **Spinalis dorsi** is situated at the inner side of the Longissimus dorsi, with which it is intimately blended, and arises by three or four tendons from the spinous processes of the first two lumbar and the last two thoracic vertebræ: these, uniting, form a small muscle which is inserted by separate tendons into the spinous processes of the upper thoracic vertebræ, the number varying

from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The *Spinalis colli* is an inconstant muscle, which arises from the lower part of the ligamentum nuchæ, the spine of the seventh cervical, and sometimes from the spines of the first and second thoracic vertebræ, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebræ below it.

The **Complexus** (m. semispinalis capitis) is a broad, thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis cervicis and Trachelo-mastoid. It arises by a series of tendons from the tips of the transverse processes of the upper six or seven thoracic and the seventh cervical vertebræ, and from the articular processes of the three cervical above this. The tendons, uniting, form a broad muscle, which passes obliquely upwards and inwards, and is inserted into the innermost depression between the two curved lines of the occipital bone. This muscle is traversed about its middle by an imperfect tendinous intersection. The term *Biventer cervicis* is given to the inner portion of the Complexus; this portion is usually separated from the rest of the muscle, and consists of two fleshy bellies connected by an intervening tendon.

Fifth Layer

The fifth layer, or rather group, of muscles comprises the

Semispinalis dorsi.	Extensor coccygis.
Semispinalis colli.	Intertransversales.
Multifidus spinæ.	Rectus capitis posticus major.
Rotatores spinæ.	Rectus capitis posticus minor.
Interspinales.	Obliquus capitis inferior.

Obliquus capitis superior.

The **Semispinalis dorsi** (fig. 499) consists of thin, narrow, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of small tendons from the transverse processes of the lower thoracic vertebræ, from the sixth to the tenth inclusive, and is inserted, by five or six tendons, into the spinous processes of the upper four thoracic and lower two cervical vertebræ.

The **Semispinalis colli** (m. semispinalis cervicis), thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six thoracic vertebræ, and is inserted into the cervical spinous processes, from the axis to the fifth inclusive. The fasciculus connected with the axis is the largest, and is chiefly muscular in structure.

The **Multifidus spinæ** (m. multifidus) consists of a number of fleshy and tendinous fasciculi, which fill up the groove on either side of the spinous processes of the vertebræ, from the sacrum to the axis. In the sacral region, these fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, from the aponeurosis of origin of the Erector spinæ, from the inner surface of the posterior superior spine of the ilium, and from the posterior sacro-iliac ligaments; in the lumbar region, from the mamillary processes; in the thoracic region, from the transverse processes; and in the cervical region, from the articular processes of the four lower vertebræ. Each fasciculus, passing obliquely upwards and inwards, is inserted into the whole length of the spinous process of one of the vertebræ above. These fasciculi vary in length: the most superficial, the longest, pass from one vertebra to the third or fourth above; those next in order pass from one vertebra to the second or third above; while the deepest connect two contiguous vertebræ.

The **Rotatores spinæ** (mm. rotatores) are found only in the thoracic region of the vertebral column, beneath the Multifidus spinæ; they are eleven in number on either side. Each muscle is small and somewhat quadrilateral in form; it arises from the upper and back part of the transverse process, and is inserted into the lower border and outer surface of the lamina of the vertebra above, the fibres extending inwards as far as the root of the spinous process. The first is found between the first and second thoracic vertebræ; the last,

between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on either side of the interspinous ligament. In the *cervical region* they are most distinct, and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the last cervical and the first thoracic. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *thoracic region*, they are found between the first and second vertebræ, and sometimes between the second and third; and below, between the eleventh and twelfth. In the *lumbar region*, there are four pairs of these muscles in the intervals between the five lumbar vertebræ. There is also occasionally one in the interspinous space, between the last thoracic and first lumbar, and one between the fifth lumbar and the sacrum.

The **Extensor coccygis** is a slender muscular fasciculus, which is not always present; it extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last segment of the sacrum, or first piece of the coccyx, and passes downwards to be inserted into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebræ of the lower animals.

The **Intertransversales** are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are most developed, consisting of rounded muscular and tendinous fasciculi, and are placed in pairs, passing between the anterior and the posterior tubercles respectively of the transverse processes of two contiguous vertebræ, and separated from one another by the anterior primary division of the cervical nerve, which lies in the groove between them. In this region there are seven pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first thoracic vertebræ. In the *thoracic region* they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper thoracic vertebræ, but between the transverse processes of the lower three thoracic vertebræ, and between the transverse processes of the last thoracic and the first lumbar, they are muscular in structure. In the *lumbar region* they are arranged in pairs, on either side of the vertebral column; one set occupying the entire interspace between the transverse processes of the lumbar vertebræ, the *Intertransversales laterales*; the other set, *Intertransversales mediales*, passing from the accessory process of one vertebra to the mamillary process of the vertebra below.*

The **Rectus capitis posticus major** (m. rectus capitis posterior major) arises by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the outer part of the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upwards and outwards, they leave between them a triangular space, in which are seen the Recti capitis postici minores.

The **Rectus capitis posticus minor** (m. rectus capitis posterior minor), the smallest of the four muscles in this region, is of a triangular shape; it arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is inserted into the inner part of the inferior curved line of the occipital bone and the surface between it and the foramen magnum.

The **Obliquus capitis inferior**, the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes outwards and slightly upwards, to be inserted into the lower and back part of the transverse process of the atlas.

The **Obliquus capitis superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding. It passes obliquely upwards and inwards, and is inserted into the occipital bone, between the two curved lines, external to the Complexus.

* The student is referred to an article on the morphology of the human intertransverse muscles, by J. Dunlop Lickley; *Journal of Anatomy and Physiology*, vol. xxxix. 1904.

The Suboccipital triangle.—Between the two Oblique muscles and the Rectus capitis posticus major a triangular interval exists, the *suboccipital triangle*. This triangle is bounded, above and internally, by the Rectus capitis posticus major; above and externally, by the Obliquus capitis superior; below and externally, by the Obliquus capitis inferior. It is covered in by a layer of dense fibro-fatty tissue, situated beneath the Complexus muscle. The floor is formed by the posterior occipito-atlantal ligament, and the posterior arch of the atlas. It contains the vertebral artery running in a deep groove on the upper surface of the posterior arch of the atlas, and the posterior primary division of the suboccipital nerve.

Nerves.—The fourth and fifth layers of the muscles of the back are supplied by the posterior primary divisions of the spinal nerves.

Actions.—When both the Spinales dorsi contract, they extend the thoracic portion of the vertebral column; when only one contracts, it helps to bend it to one side. The Erector spinæ, comprising the Ilio-costalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the column in the erect posture; it also serves to bend the trunk backwards when it is required to counterbalance the influence of any weight at the front of the body—as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the vertebral column being drawn backwards, by the counterbalancing action of the Erector spinæ muscles. The muscles which form the continuation of the Erector spinæ upwards steady the head and neck, and fix them in the upright position. If the Ilio-costalis and Longissimus dorsi of one side act, they serve to draw down the chest and vertebral column to the corresponding side. The Cervicales ascendentes, taking their fixed points from the cervical vertebræ, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversales cervicis, when both muscles act, taking their fixed points from below, bend the neck backwards. The Trachelo-mastoids, when both muscles act, taking their fixed points from below, bend the head backwards; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti draw the head backwards. The Rectus capitis posticus major, owing to its obliquity, rotates the cranium, with the atlas, round the odontoid process, turning the face to the same side. The Multifidus spinæ acts successively upon the different parts of the column: thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the thoracic region, and so on throughout the entire length of the column; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the erect posture is preserved without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The Multifidus spinæ, besides preserving the erect position of the column, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the Obliquus externus abdominis. The Complexi draw the head directly backwards; if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The Superior oblique draws the head backwards and to its own side. The Inferior oblique rotates the atlas, and with it the cranium, round the odontoid process, turning the face to the same side. The Semispinales, when the muscles of the two sides act together, help to extend the vertebral column; when the muscles of only one side act, they rotate the thoracic and cervical parts of the column, turning the body to the opposite side. The Interspinales by approximating the spinous process help to extend the column. The Intertransversales approximate the transverse processes, and help to bend the column to one side. The Rotatores spinæ assist the Multifidus spinæ to rotate the vertebral column, so that the front of the trunk is turned to the side opposite to that from which the muscles act.

Surface Form.—The surface forms produced by the muscles of the back are numerous and difficult to analyse unless they are considered in systematic order. The most superficial layer influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The *Trapezius* at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior

border forms the posterior boundary of the posterior triangle of the neck, and presents a slight ridge which passes downwards and forwards from the occiput to the junction of the middle and outer thirds of the clavicle. The inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth thoracic vertebra. In like manner, the *Latissimus dorsi* softens down and obscures the underlying structures at the lower part of the back and side of the chest. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forwards and upwards to the posterior border of the axilla, where together with the Teres major it forms a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The *Levator anguli scapulæ* reveals itself as an elevation, running downwards and outwards, from the transverse processes of the upper cervical vertebræ to the angle of the scapula, covered over and toned down by the overlying Trapezius. The *Rhomboidei* produce, when in action, a vertical eminence between the vertebral border of the scapula and the spinal furrow, varying in intensity according to the condition of contraction or relaxation of the Trapezius muscle, by which they are for the most part covered. The lowermost part of the Rhomboideus major is uncovered by the Trapezius and forms on the surface an oblique ridge running upwards and inwards from the inferior angle of the scapula. The *Splenii* by their divergence serve to broaden out the upper part of the back of the neck and produce a fulness in this situation. In the loin, the *Erector spinæ*, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the spinal furrow, and tapers below to a point on the posterior surface of the sacrum. In the back it forms a flattened plane which gradually becomes lost on passing upwards.

Applied Anatomy.—In cases of tuberculous caries of the vertebral bodies, and in other diseases affecting the vertebral column, rigidity of the spinal muscles is one of the earliest and most constant symptoms. A child with commencing spinal disease always maintains the affected portion of the column in a state of absolute rigidity, to prevent the inflamed structures from being moved against each other; this is one of the best examples of nature's method of producing rest of the affected part.

II. Muscles and Fasciæ of the Thorax

The muscles belonging exclusively to this region are the

Intercostales externi.	Triangularis sterni.
Intercostales interni.	Levatores costarum.
Infracostales.	Diaphragm.

Intercostal fasciæ.—In each intercostal space thin but firm layers of fascia cover the outer surface of the External intercostal and the inner surface of the Internal intercostal muscle; and a third layer, the *middle intercostal fascia*, more delicate, is interposed between the two planes of muscular fibres. They are best marked in those situations where the muscular fibres are deficient, as between the External intercostal muscles and sternum in front, and between the Internal intercostals and vertebral column, behind.

The **Intercostal muscles** (fig. 518) are two thin planes of muscular and tendinous fibres occupying each of the intercostal spaces. They are named *external* and *internal* from their surface relations—the external being superficial to the internal.

The **External intercostals** (mm. intercostales externi) are eleven in number on either side. They extend from the tubercles of the ribs, behind, to the outer ends of the cartilages of the ribs, in front, where they terminate in a thin membrane, the *anterior intercostal membrane*, which is continued forwards to the sternum. Each arises from the lower border of a rib, and is inserted into the upper border of the rib below. In the two lower spaces they extend to the ends of the cartilages, and in the upper two or three spaces they do not quite reach the ends of the ribs. They are thicker than the Internal intercostals, and their fibres are directed obliquely downwards and outwards on the back of the chest, and downwards, forwards, and inwards on the front.

The **Internal intercostals** (mm. intercostales interni) are also eleven in number on either side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the false ribs, and extend backwards as far as the angles of the ribs, whence they are continued to the vertebral column by a thin aponeurosis, the *posterior intercostal membrane*. Each arises from

the ridge on the inner surface of a rib, as well as from the corresponding costal cartilage, and is inserted into the upper border of the rib below. Their fibres are also directed obliquely, but pass in a direction opposite to those of the External intercostals.

The **Infracostales** (mm. subcostales) consist of muscular and aponeurotic fasciculi, which vary in number and length: they are placed on the inner surfaces of the ribs, where the Internal intercostal muscles cease; each arises from the inner surface of one rib, and is inserted into the inner surface of the first, second, or third rib below. Their fibres run in the same direction as those of the Internal intercostals. They are most frequent between the lower ribs.

The **Triangularis sterni** (m. transversus thoracis) is a thin plane of muscular and tendinous fibres, situated upon the inner wall of the front of the chest (fig. 500). It arises on either side from the lower third of the posterior surface of the sternum, from the posterior surface of the ensiform cartilage, and from the sternal ends of the costal cartilages of the lower three or four true ribs. Its fibres diverge upwards and outwards, to be inserted by digitations into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis; those which succeed are oblique, while the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body.

FIG. 500.—Posterior surface of sternum and costal cartilages, showing Triangularis sterni muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The **Levatores costarum** (fig. 499), twelve in number on either side, are small tendinous and fleshy bundles, which arise from the extremities of the transverse processes of the seventh cervical and upper eleven thoracic vertebræ; they pass obliquely downwards and outwards, like the fibres of the External intercostals, and each is inserted into the upper border of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle. Each of the inferior Levatores divides into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebræ.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

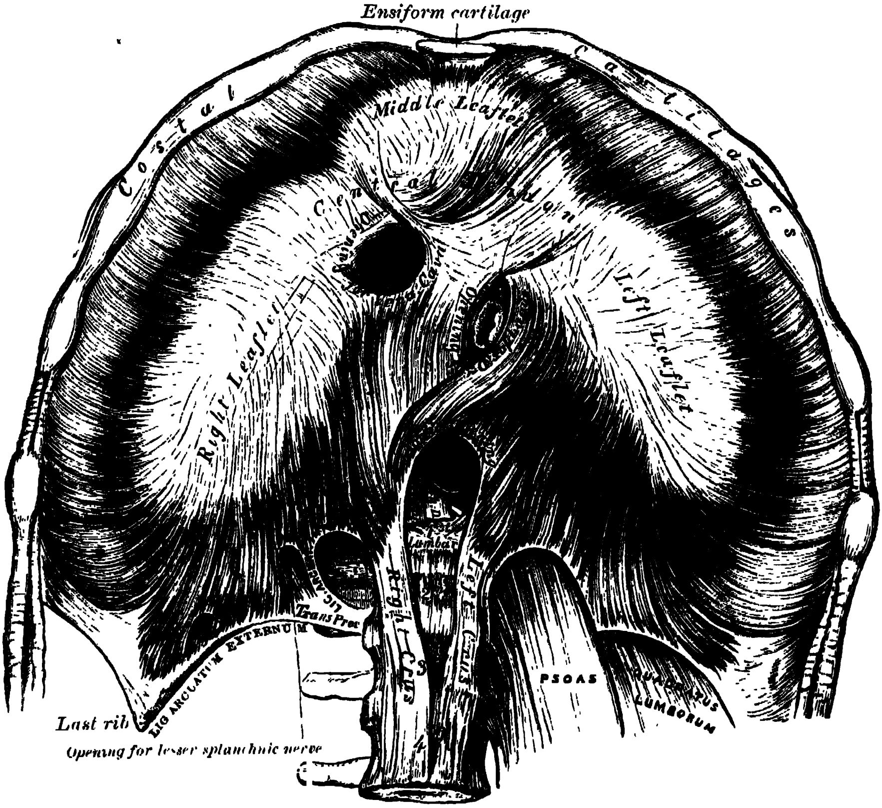
The **Diaphragm** (diaphragma) (fig. 501) is a dome-shaped musculo-fibrous septum which separates the thoracic from the abdominal cavity, its convex

upper surface forming the floor of the former, and its concave under surface the roof of the latter. Its peripheral part consists of muscular fibres which take origin from the circumference of the thoracic outlet and converge to be inserted into a central tendon.

It arises anteriorly by two fleshy slips from the back of the ensiform cartilage; on either side from the inner surfaces of the cartilages and adjacent portions of the lower six ribs interdigitating with the Transversalis abdominis; behind from aponeurotic arches, named the *ligamenta arcuata*, and from the lumbar vertebræ by two pillars or *crura*. The ligamenta arcuata are five in number—one mesial, and two, an internal and an external, on either side.

The *ligamentum arcuatum internum* is a tendinous arch in the fascia covering the upper part of the Psoas magnus; its inner end is continuous with the outer tendinous margin of the corresponding crus, and is attached to the outer

FIG. 501.—The Diaphragm. Under surface.



side of the body of the first or second lumbar vertebra; its outer end is fixed to the front of the transverse process of the first and, sometimes also, to that of the second lumbar vertebra.

The *ligamentum arcuatum externum* is the thickened upper margin of the anterior lamella of the lumbar aponeurosis. It arches across the upper part of the Quadratus lumborum, and is attached by its inner extremity to the front of the transverse process of the first lumbar vertebra, by its outer to the tip and lower margin of the twelfth rib.

The *crura*.—At their origins the crura are tendinous in structure, and blend with the anterior common ligament of the vertebral column. The *right crus*, larger and longer than the left, arises from the anterior surfaces of the bodies and intervertebral discs of the upper three lumbar vertebræ, while the *left crus* arises from the corresponding parts of the upper two only. The internal tendinous margins of the crura pass forwards and inwards, and meet

in the middle line to form an arch across the front of the aorta; this arch, which is often poorly defined, is known as the *ligamentum arcuatum medium*.

From this series of origins the fibres of the Diaphragm converge to be inserted into the central tendon. The fibres arising from the ensiform cartilage are very short, and occasionally aponeurotic; those from the internal and external arcuate ligaments, and more especially those from the ribs and their cartilages, are longer, and describe marked curves as they ascend and converge to their insertion. The fibres of the crura and those from the ligamentum arcuatum medium diverge as they ascend, the outermost being directed upwards and outwards to the central tendon, the innermost decussating in front of the aorta, and then diverging to surround the œsophagus before reaching their insertion. The fibres from the right crus are more numerous than those from the left, and pass in front of them.

The *central tendon* (centrum tendineum) of the Diaphragm is a thin but strong tendinous aponeurosis situated near the centre of the vault formed by the muscle, but somewhat closer to the front than to the back of the thorax, so that the posterior muscular fibres are the longer. It is situated immediately below the pericardium, with which it is partially blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions or leaflets separated from one another by slight indentations. The right leaflet is the largest, the middle, directed towards the ensiform cartilage the next in size, and the left the smallest. In structure the tendon is composed of several planes of fibres, which intersect one another at various angles and unite into straight or curved bundles—an arrangement which affords it additional strength.

Openings in the Diaphragm.—The Diaphragm is pierced by a series of apertures to permit of the passage of structures between the thorax and abdomen. Three large openings—the aortic, the œsophageal, and the vena caval—and a series of smaller ones are described.

The *aortic opening* (hiatus aorticus) is the lowest and most posterior of the three large apertures; it lies at the level of the twelfth thoracic vertebra. Strictly speaking, it is not an aperture in the Diaphragm but an osseo-aponeurotic opening between it and the vertebral column, and therefore behind the Diaphragm; occasionally some tendinous fibres prolonged across the bodies of the vertebræ from the inner parts of the lower ends of the crura pass behind the aorta, and thus convert the opening into a fibrous ring. The aperture is situated slightly to the left of the middle line, and is bounded in front by the ligamentum arcuatum medium and crura, and behind by the body of the first lumbar vertebra. Through it pass the aorta, the vena azygos major and the thoracic duct; occasionally the vena azygos major is transmitted through the right crus.

The *œsophageal opening* (hiatus œsophageus) is situated at the level of the tenth thoracic vertebra; it is elliptical in form, muscular in structure, and bounded by the decussating fibres of the two crura.* The anterior edge is occasionally formed by the margin of the central tendon. The aperture is placed above, in front, and a little to the left of the aortic opening, and transmits the œsophagus, the pneumogastric nerves, and some small œsophageal arteries.

The *vena caval opening* (foramen venæ cavæ) is the highest of the three, and is situated about the level of the disc between the eighth and ninth thoracic vertebræ. It is quadrilateral in form, and is placed at the junction of the right and middle leaflets of the central tendon, so that its margins are tendinous. It transmits the inferior vena cava, the wall of which is adherent to the margins of the opening, and some branches of the right phrenic nerve.

Of the *lesser apertures*, two in the right crus transmit the greater and lesser right splanchnic nerves; three in the left crus give passage to the greater and lesser left splanchnic nerves and the vena azygos minor. The gangliated cords of the sympathetic usually enter the abdominal cavity behind the Diaphragm, under the internal arcuate ligaments. On either side two small intervals exist at which the muscular fibres of the Diaphragm are deficient

* Low (*Journal of Anatomy and Physiology*, vol. xlii.), in twenty five cases which he examined, failed to find a fasciculus from the left crus to the right margin of the œsophageal opening. He regards the œsophageal passage in the Diaphragm as formed by the splitting of the mesial fibres of the right crus.

and are replaced by areolar tissue. One between the fibres of origin from the ensiform cartilage and those from the cartilages of the adjoining ribs transmits the superior epigastric branch of the internal mammary artery and some lymphatics from the abdominal wall and convex surface of the liver. The other, between the fibres springing from the internal and external arcuate ligaments, is less constant; when this interval exists, the upper and back part of the kidney is separated from the pleura by areolar tissue only.

Relations.—The upper surface of the Diaphragm is in relation with three serous membranes, viz. on either side the pleura, which separates it from the base of the corresponding lung, and on the middle leaflet of the central tendon the pericardium, which intervenes between it and the heart. The central portion lies on a slightly lower level than the summits of the lateral portions. The greater part of the under surface is covered by the peritoneum. The right side is accurately moulded over the convex surface of the right lobe of the liver, the right kidney, and right suprarenal capsule, the left over the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney, and left suprarenal capsule.

Nerves.—The Diaphragm is supplied by the phrenic and lower intercostal nerves.

Actions.—The Diaphragm is the principal muscle of inspiration, and presents the form of a dome concave towards the abdomen. The central part of the dome is tendinous, and the pericardium is attached to its upper surface; the circumference is muscular. During inspiration the lowest ribs are fixed, and from these and the crura the muscular fibres contract and draw downwards and forwards the central tendon with the attached pericardium. In this movement the curvature of the Diaphragm is scarcely altered, the dome moving downwards nearly parallel to its original position and pushing before it the abdominal viscera. The descent of the abdominal viscera is permitted by the elasticity of the abdominal wall, but the limit of this is soon reached. The central tendon applied to the abdominal viscera then becomes a fixed point for the action of the Diaphragm, the effect of which is to elevate the lower ribs and through them to push forwards the gladiolus sterni and the upper ribs. The right cupola of the Diaphragm, lying on the liver, has a greater resistance to overcome than the left, which lies over the stomach, but to compensate for this the right crus and the fibres of the right side generally are stronger than those of the left.

In all expulsive acts the Diaphragm is called into action to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and previous to the expulsion of urine or fæces, or of the fœtus from the uterus, a deep inspiration takes place. The height of the Diaphragm is constantly varying during respiration; it also varies with the degree of distension of the stomach and intestines and with the size of the liver. After a forced expiration the right cupola is on a level in front with the fourth costal cartilage, at the side with the fifth, sixth, and seventh ribs, and behind with the eighth rib; the left cupola is a little lower than the right. Halls Dally * states that the absolute range of movement between deep inspiration and deep expiration averages in the male and female 30 mm. on the right side and 28 mm. on the left; in quiet respiration the average movement is 12·5 mm. on the right side and 12 mm. on the left.

Skiagraphy shows that the height of the Diaphragm in the thorax varies considerably with the position of the body. It stands highest when the body is horizontal and the patient on his back, and in this position it performs the largest respiratory excursions with normal breathing. When the body is erect the dome of the Diaphragm falls, and its respiratory movements become smaller. The dome falls still lower when the sitting posture is assumed, and in this position its respiratory excursions are smallest. These facts may, perhaps, explain why it is that patients suffering from severe dyspnœa are most comfortable and least short of breath when they sit up. When the body is horizontal and the patient on his side, the two halves of the Diaphragm do not behave alike. The uppermost half sinks to a level lower even than when the patient sits, and moves little with respiration; the lower half rises higher in the thorax than it does when the patient is supine, and its respiratory excursions are much increased. In unilateral disease of the pleura or lungs analogous interference with the position or movement of the Diaphragm can generally be observed skiagraphically.

* 'Inquiry into the Physiological Mechanism of Respiration.' *Journal of Anatomy and Physiology*, vol. xliii. 1908.

It appears that the position of the Diaphragm in the thorax depends upon three main factors, viz.: (1) the elastic retraction of the lung-tissue, tending to pull it upwards; (2) the pressure exerted on its under surface by the viscera: this naturally tends to be a negative pressure, or downward suction, when the patient sits or stands, and positive, or an upward pressure, when he lies; (3) the intra-abdominal tension due to the abdominal muscles. These are in a state of contraction in the standing position and not in the sitting; hence the Diaphragm, when the patient stands, is pushed up higher than when he sits.

The Intercostal muscles, internal and external, have probably no action in moving the ribs. They contract simultaneously and form strong elastic supports which prevent the intercostal spaces being pushed out or drawn in during respiration. The anterior portions of the Internal intercostals probably have an additional function in keeping the chondro-sternal and interchondral joint surfaces in apposition, the posterior parts of the External intercostals performing a similar function for the costo-vertebral articulations.

The Levatores costarum being inserted near the fulcra of the ribs can have little action on the ribs; they act as rotators and lateral flexors of the vertebral column.

The Triangularis sterni draws down the costal cartilages, and is therefore a muscle of expiration.

Mechanism of Respiration

The respiratory movements must be examined during (*a*) quiet respiration, and (*b*) forced respiration.

Quiet respiration.—The first and second pairs of ribs are fixed by the Scaleni and by the resistance of the cervical structures; the last pair, and through it the eleventh, by the Quadratus lumborum. The other ribs are elevated, so that the first two intercostal spaces are diminished while the others are increased in width. It has already been shown (p. 392) that elevation of the third, fourth, fifth, and sixth ribs leads to an increase in the antero-posterior and transverse diameters of the thorax: the vertical diameter is increased by the descent of the diaphragmatic dome so that the lungs are expanded in all directions except backwards and upwards. Elevation of the eighth, ninth, and tenth ribs is accompanied by an outward and backward movement, leading to an increase in the transverse diameter of the upper part of the abdomen; the elasticity of the anterior abdominal wall allows a slight increase in the antero-posterior diameter of this part, and in this way the decrease in the vertical diameter of the abdomen is compensated and space provided for its displaced viscera. Expiration is effected by the elastic recoil of its walls and by the action of the abdominal muscles, which push back the viscera displaced downwards by the Diaphragm.

Forced respiration.—All the movements of quiet respiration are here carried out, but to a greater extent. In inspiration the shoulders and the vertebral borders of the scapulæ are fixed and the limb muscles, Trapezius, Serratus magnus, Pectorals, and Latissimus dorsi, are called into play. The Scaleni are in stronger action, and the Sterno-mastoids also assist when the head is fixed by drawing up the sternum and by fixing the clavicles. The first rib is therefore no longer stationary, but, with the sternum, is raised; with it all the other ribs except the last are raised to a higher level. In conjunction with the increased descent of the Diaphragm this provides for a considerable augmentation of all the thoracic diameters. The anterior abdominal muscles come into action so that the umbilicus is drawn upwards and backwards, but this allows the Diaphragm to exert a more powerful influence on the lower ribs; the transverse diameter of the upper part of the abdomen is greatly increased and the subcostal angle opened out. The deeper muscles of the back, e.g. the Serrati postici superiores and Erectores spinæ, are also brought into action; the thoracic curve of the vertebral column is partially straightened, and the whole column, above the lower lumbar vertebræ, drawn backwards. This increases the antero-posterior diameters of the thorax and upper part of the abdomen and widens the intercostal spaces. Forced expiration is effected by the recoil of the walls and by the contraction of the antero-lateral muscles of the abdominal wall, and the Serrati postici inferiores and Triangularis sterni.

Halls Dally (*op. cit.*) gives the following figures as representing the average changes which occur during deepest possible respiration. The presternum moves 30 mm. in an

upward and 14 mm. in a forward direction; the width of the subcostal angle, at a level of 30 mm. below the meso-metasternal articulation, is increased by 26 mm.; the umbilicus is retracted and drawn upwards for a distance of 13 mm.

III. Muscles of the Abdomen

The muscles of the abdomen may be divided into two groups: 1, The antero-lateral muscles; 2, The posterior muscles.

1. Antero-lateral Muscles

The muscles of this group are:

Obliquus Externus.	Transversalis.
Obliquus Internus.	Rectus.
Pyramidalis.	

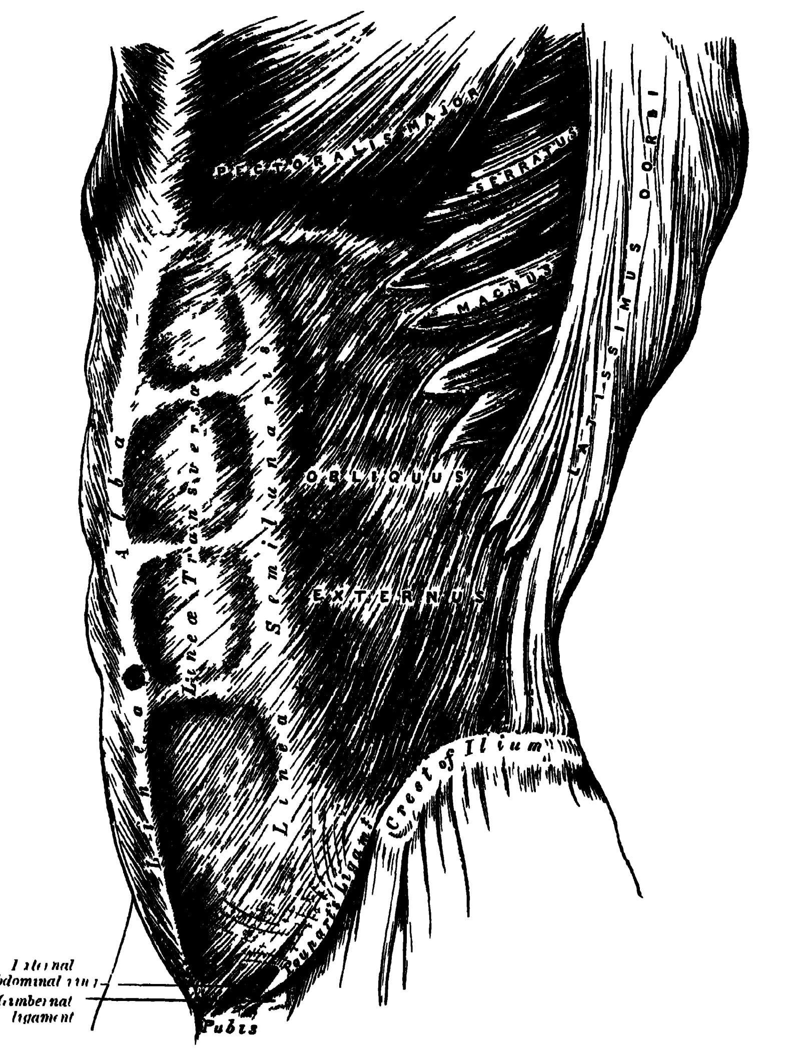
The **superficial fascia** of the abdomen consists, over the greater part of the abdominal wall, of a single layer of fascia which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands. The superficial layer (*fascia of Camper*) is thick, areolar in texture, and contains in its meshes adipose tissue, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the superficial fascia of the thigh. In the male, this fascia is continued over the penis and outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish colour, and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backwards to be continuous with the superficial fascia of the perinæum. In the female, this fascia is continued into the labia majora. The deeper layer (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer, and contains a considerable quantity of yellow elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of the External oblique, but in the middle line it is more intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on to the dorsum of the penis, forming the suspensory ligament; above, it is continuous with the superficial fascia over the rest of the trunk; below and externally, it blends with the fascia lata of the thigh a little below Poupart's ligament; internally and below, it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backwards into continuity with the deep layer of the superficial fascia of the perinæum (*fascia of Colles*). In the female, it is continued into the labia majora and thence to the fascia of Colles.

The **Obliquus externus abdominis** (fig. 502) is situated on the side and fore part of the abdomen, being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall of the abdomen. It arises, by eight fleshy digitations, from the external surfaces and lower borders of the lower eight ribs; these digitations are arranged in an oblique line which runs downwards and backwards, the upper ones being attached close to the cartilages of the corresponding ribs, the lowest to the apex of the cartilage of the last rib, the intermediate ones to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downwards, and are received between corresponding processes of the Serratus magnus; the three lower ones diminish in size from above downwards, receiving between them corresponding processes from the Latissimus dorsi. From these attachments the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downwards, to be inserted into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downwards and forwards, terminate in an aponeurosis, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior spine of the ilium.

The *aponeurosis of the External oblique* is a thin but strong membranous structure, the fibres of which are directed obliquely downwards and inwards.

It is joined with that of the opposite muscle along the median line, and covers the whole of the front of the abdomen; above, it is covered by and gives origin to the lower border of the Pectoralis major; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior spine of the ilium to the spine of the pubis and the linea ilio-pectinea. In the median line, it interlaces with the aponeurosis of the opposite muscle, forming the linea alba, which extends from the ensiform cartilage to the symphysis pubis.

Fig. 502.—The External oblique muscle.



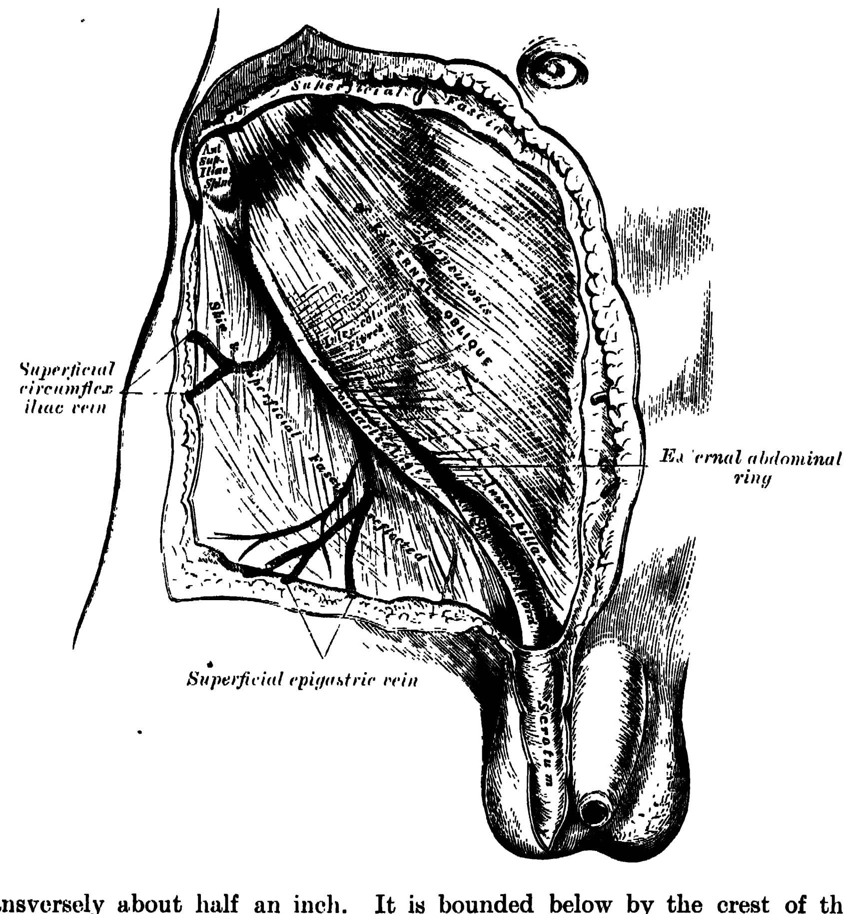
That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the pubis is a thick band, folded inwards, and continuous below with the fascia lata: it is called *Poupart's ligament*. The portion which is reflected from Poupart's ligament at the spine of the pubis along the pectineal line is called *Gimbernat's ligament*. From the point of attachment of the latter to the pectineal line, a few fibres pass upwards and inwards, behind the inner pillar of the external abdominal ring, to the linea alba. They diverge as they ascend, and form a thin triangular fibrous layer, which is called the *triangular fascia*.

In the aponeurosis of the External oblique, immediately above the crest of the pubis, is a triangular opening, the *external abdominal ring*, formed by a separation of the fibres of the aponeurosis in this situation.

The following parts of the aponeurosis of the External oblique muscle require further description, viz. the external abdominal ring, the intercolumnar fibres and fascia, Poupart's ligament, Gimbernat's ligament, and the triangular fascia.

The **external** or **superficial abdominal ring** (annulus inguinalis subcutaneus) is an interval in the aponeurosis of the External oblique, just above and to the outer side of the crest of the pubis. The aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and

FIG. 503.—The external abdominal ring.



transversely about half an inch. It is bounded below by the crest of the pubis; on either side by the margins of the opening in the aponeurosis, which are called the *columns* or *pillars of the ring*; and above, by a series of curved fibres, the *intercolumnar* (fig. 503), which pass across the upper angle of the ring, so as to increase its strength.

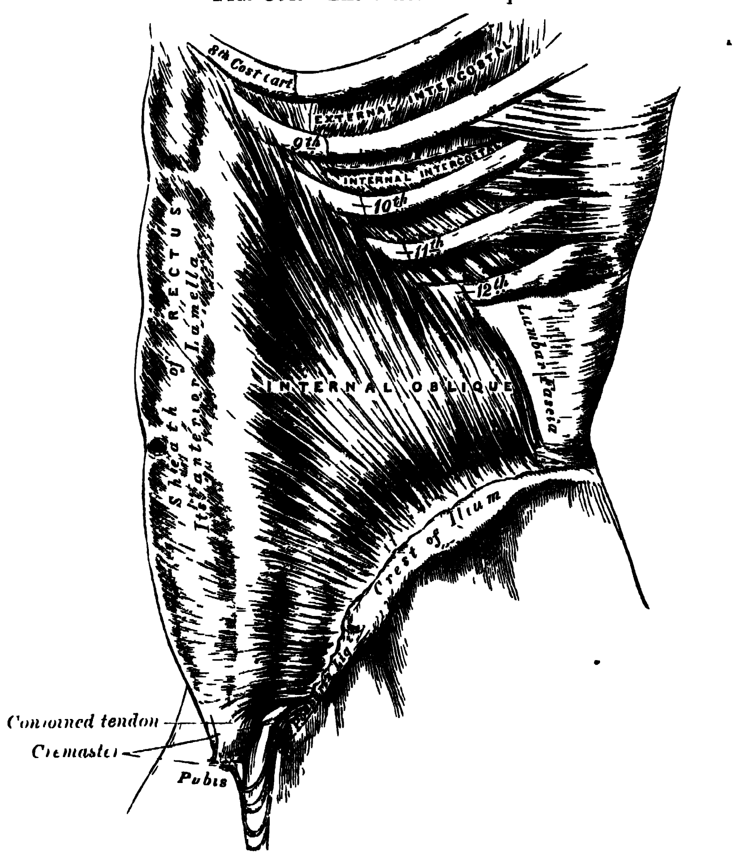
The external or inferior pillar (crus inferius) is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the pubis; it is curved so as to form a kind of groove, upon which the spermatic cord rests. The internal or superior pillar (crus superius) is a broad, thin, flat band, which is attached to the front of the symphysis pubis, interlacing with its fellow of the opposite side, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord and ilio-inguinal nerve in the male, and to the round ligament of the uterus and

the ilio-inguinal nerve in the female : it is much larger in men than in women, on account of the large size of the spermatic cord.

The **intercolumnar fibres** (fibræ intercrurales) are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the External oblique, describing a curve with the convexity downwards. They have received their name from stretching across between the two pillars of the external ring. They are much thicker and stronger at the outer margin of the external ring, where they are connected to Poupart's ligament, than internally, where they are inserted into the linea alba. They are more strongly developed in the male than in the female. The intercolumnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another.

Fig. 504.—The Internal oblique muscle.



These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia, which, as it is attached to the pillars of the ring, covers it in, and is called the *intercolumnar fascia.* This **intercolumnar fascia** is continued down as a tubular prolongation around the spermatic cord and testis, and encloses them in a distinct sheath ; hence it is also called the *external spermatic fascia.* The external abdominal ring is only seen as a distinct aperture after the external spermatic fascia has been removed from its pillars.

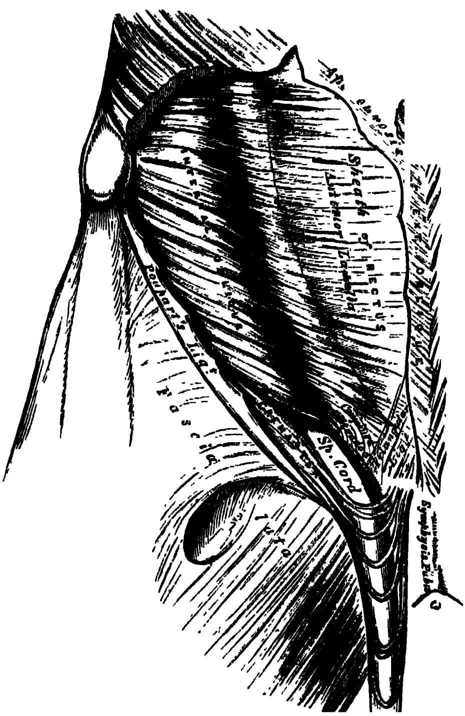
Poupart's ligament (lig. inguinale) is the lower border of the aponeurosis of the External oblique muscle, and extends from the anterior superior spine of the ilium to the spine of the pubis. From this latter point it is reflected backwards and outwards to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is convex

downwards towards the thigh, where it is continuous with the fascia lata. Its outer half is rounded, and oblique in direction. Its inner half gradually widens at its attachment to the pubis, is more horizontal in direction, and lies beneath the spermatic cord.

Nearly the whole of the space included between the crural arch and the innominate bone is filled in by the parts which descend from the abdomen into the thigh.

Gimbernat's ligament (lig. lacunare) is that part of the aponeurosis of the External oblique muscle which is reflected backwards and outwards from the spine of the pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base directed outwards. Its base, or outer margin, is concave, thin, and sharp, and forms the inner boundary of the crural ring. Its apex corresponds to the spine of the pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is attached to Poupart's ligament. Its surfaces are directed upwards and downwards.

Fig. 505.—The Cremaster muscle.



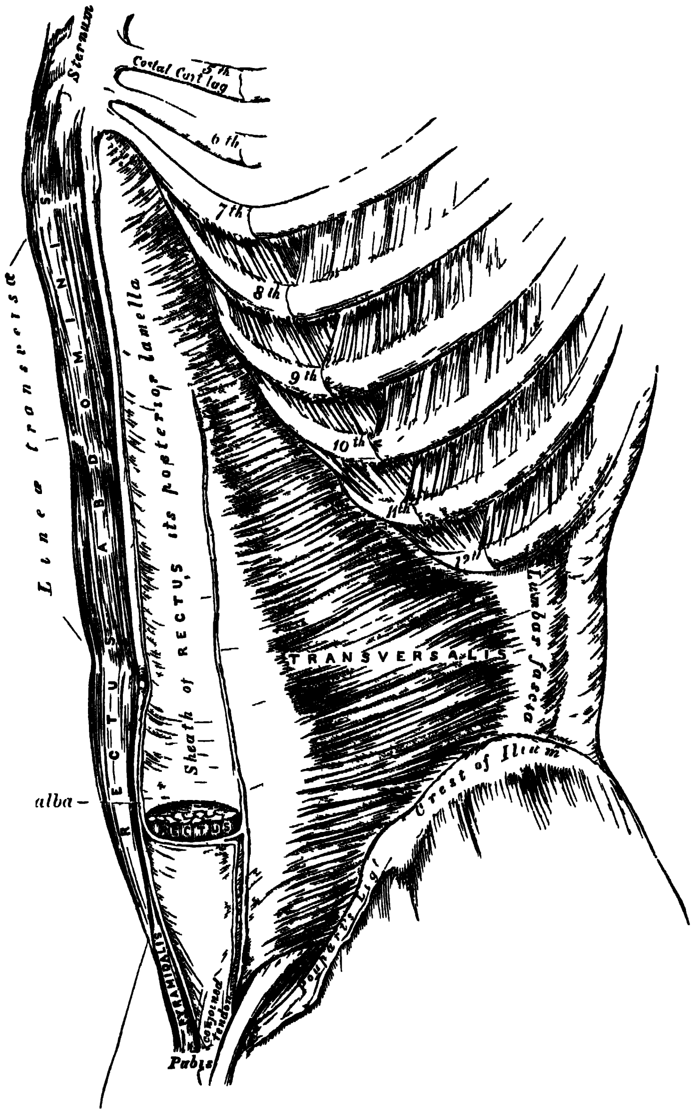
The **triangular fascia** (lig. inguinale reflexum) of the abdomen is a layer of tendinous fibres of a triangular shape, formed by an expansion from Gimbernat's ligament and the outer pillar of the ring. It passes inwards behind the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring, and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

Ligament of Cooper.—This is a strong fibrous band, which was first described by Sir Astley Cooper. It extends outwards from the base of Gimbernat's ligament along the ilio-pectineal line, to which it is attached. It is strengthened by the pectineal aponeurosis, and by a lateral expansion from the lower attachment of the linea alba (adminiculum lineæ albæ).

The **Obliquus internus abdominis** (fig. 504), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form, and situated at the side and fore part of the abdomen. It arises, by fleshy fibres, from the outer half of Poupart's ligament, being attached to the groove on its upper surface, from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia. From this origin the fibres diverge, those from Poupart's ligament, few in number, and paler in colour than the rest, arch downwards and inwards across the spermatic cord in the male and the round ligament in the female, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the pubis and inner part of the ilio-pectineal line behind Gimbernat's ligament, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. Those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be inserted into the linea alba. Those arising from the middle third of the origin from the crest of the ilium pass obliquely upwards and inwards, and terminate

in an aponeurosis; this divides at the outer border of the Rectus muscle into two lamellæ, which are continued forwards, one in front of and the other behind this muscle, to the linea alba: the posterior lamella being also connected to the cartilages of the seventh, eighth, and ninth ribs. The most posterior fibres pass almost vertically upwards, to be inserted into the lower borders of the cartilages of the three lower ribs, being continuous with the Internal intercostal muscles.

Fig. 506.—The Transversalis, Rectus, and Pyramidalis muscles



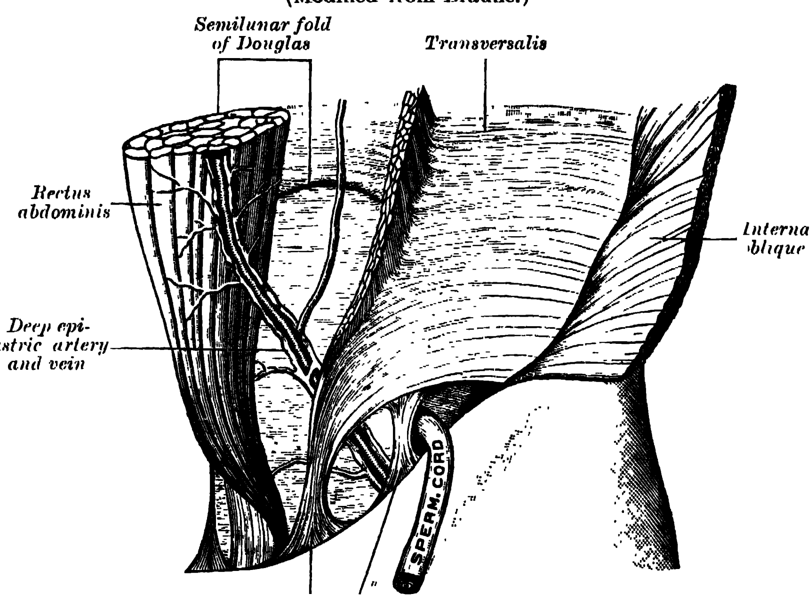
The Cremaster (fig. 505) is a thin muscular layer, composed of a number of fasciculi which arise from the middle of Poupart's ligament where its fibres are continuous with those of the Internal oblique and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as

low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *cremasteric fascia*. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the spine and crest of the pubis and into the front of the sheath of the Rectus.

It will be observed that the origin and insertion of the Cremaster are precisely similar to those of the lower fibres of the Internal oblique. This fact is explained by the manner in which the testis and cord are invested by this muscle. At an early period of fœtal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent towards the scrotum, which takes place before birth, it carries on it some fibres from the lower part of the muscle, and these accompany the testis and cord into the scrotum.

The **Transversalis abdominis** (m. transversus abdominis) (fig. 506), so called from the direction of its fibres, is the most internal of the flat muscles of the abdomen, being placed immediately beneath the Internal oblique. It arises by fleshy fibres from the outer third of Poupart's ligament, from the

FIG. 507.—The ligaments of Henle and Hesselbach, seen from in front. (Modified from Braune.)



anterior three-fourths of the inner lip of the crest of the ilium, from the inner surfaces of the cartilages of the lower six ribs, interdigitating with the Diaphragm, and from the lumbar aponeurosis, which may be regarded as the posterior aponeurosis of the muscle, and which has been seen to divide into three lamellæ (see page 493). The muscle terminates in front in a broad aponeurosis, the lower fibres of which curve downwards and inwards, and are inserted, together with those of the Internal oblique, into the crest of the pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. Throughout the rest of its extent the aponeurosis passes horizontally inwards, and is inserted into the linea alba; its upper three-fourths passing behind the Rectus muscle, blending with the posterior lamella of the Internal oblique; its lower fourth passing in front of the Rectus.

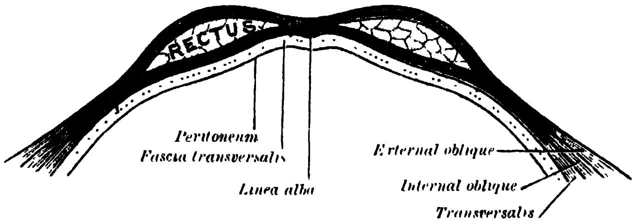
The *conjoined tendon* of the Internal oblique and Transversalis is mainly formed by the lower part of the tendon of the Transversalis, and is inserted into the crest of the pubis and ilio-pectineal line immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. The conjoined tendon is sometimes divided

into an outer and an inner portion—the former being termed the *ligament of Hesselbach*; the latter, the *ligament of Henle* (fig. 507).

The **Rectus abdominis** is a long flat muscle, which extends along the whole length of the front of the abdomen, being separated from its fellow of the opposite side by the linea alba. It is much broader, but thinner, above than below, and arises by two tendons, the external or larger being attached to the crest of the pubis, the internal, smaller portion, interlacing with its fellow of the opposite side, and being connected with the ligaments covering the front of the symphysis pubis. The muscle is inserted by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs. The upper portion, attached principally to the cartilage of the fifth rib, usually has some fibres of insertion into the anterior extremity of the rib itself. Some fibres are occasionally connected with the costo-xiphoid ligaments, and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number, which have received the name of *lineæ transversæ* (inscriptiones tendineæ). One of these is usually situated opposite the umbilicus, one corresponds to the extremity of the ensiform cartilage, and the other is about midway between the ensiform cartilage and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance; they may pass only halfway across it, and are intimately adherent in front to the sheath in which the muscle is enclosed. Sometimes one or two additional lines, generally incomplete, may be seen below the umbilicus.

FIG. 508.—Diagram of sheath of Rectus.



The Rectus is enclosed in a sheath (fig. 508) formed by the aponeuroses of the Oblique and Transversalis muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus, it divides into two lamellæ, one of which passes in front of the Rectus, blending with the aponeurosis of the External oblique, the other, behind it, blending with the aponeurosis of the Transversalis, and these, joining again at its inner border, are inserted into the linea alba. This arrangement of the aponeurosis exists from the costal margin to midway between the umbilicus and symphysis pubis, where the posterior wall of the sheath terminates in a thin curved margin, the *semilunar fold of Douglas* (linea semicircularis), the concavity of which looks downwards towards the pubis: below this level the aponeuroses of all three muscles pass in front of the Rectus without any separation. The extremities of the fold of Douglas descend as pillars to the pubis. The inner pillar is attached to the symphysis pubis; the outer pillar, the ligament of Hesselbach, or outer part of the conjoined tendon, passes downwards as a distinct band on the inner side of the internal abdominal ring, and there its fibres divide into two sets, internal and external: the internal fibres are attached to the ascending ramus of the pubis and the pectineal fascia; the external ones pass to the Psoas fascia, to the deep surface of Poupart's ligament, and to the tendon of the Transversalis on the outer side of the ring. The Rectus muscle, in the situation where its sheath is deficient below, is separated from the peritoneum by the fascia transversalis (fig. 509). Since the tendons of the Internal oblique and Transversalis only reach as high as the costal margin, it follows that above this level the sheath of the Rectus is also deficient behind, the muscle resting directly on

the cartilages of the ribs, and being covered merely by the tendon of the External oblique.

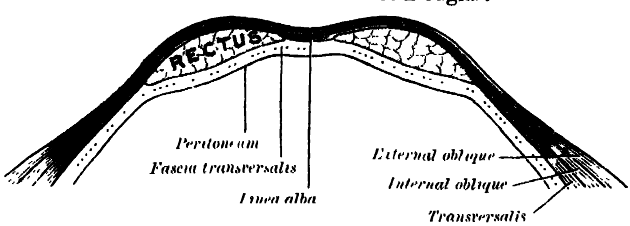
The **Pyramidalis** is a small muscle, triangular in shape, placed at the lower part of the abdomen in front of the Rectus, and contained in the sheath of that muscle. It arises by tendinous fibres from the front of the pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upwards, diminishing in size as it ascends, and terminates by a pointed extremity which is inserted into the linea alba, midway between the umbilicus and the pubis. This muscle may be wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it is double on one side, and the muscles of the two sides are sometimes of unequal size. It may extend higher than the level stated above.

Besides the Rectus and Pyramidalis muscles, the sheath of the Rectus contains the superior and deep epigastric arteries, and the terminations of the lumbar arteries and lower intercostal arteries and nerves.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Transversalis and Internal oblique also receive filaments from the hypogastric branch of the ilio-hypogastric and sometimes from the ilio-inguinal. The Cremaster is supplied by the genital branch of the genito-crural and the Pyramidalis usually by the twelfth thoracic.

The **linea alba** is a tendinous raphe seen along the middle line of the abdomen, extending from the ensiform cartilage to the symphysis pubis, and attached to both. It is placed between the inner borders of the Recti, and is formed by the blending of the aponeuroses of the Obliqui and Trans-

FIG. 509.—Diagram of a transverse section through the anterior abdominal wall, below the semilunar fold of Douglas.



versales muscles. It is narrow below, corresponding to the linear interval existing between the Recti; but broader above, as these muscles diverge from one another in their ascent; it becomes of considerable breadth after great distension of the abdomen from pregnancy or ascites. At its lower end the linea alba has a double attachment—its superficial fibres passing in front of the inner heads of the Recti to the symphysis pubis, while its deeper fibres form a triangular lamella, attached behind the Recti to the posterior lip of the crest of the pubis, and named the *adminiculum lineæ albæ*. It presents numerous apertures for the passage of vessels and nerves; the umbilicus, which in the fœtus exists as an aperture and transmits the umbilical vessels, is obliterated in the adult, the cicatrix being stronger than the neighbouring parts; hence umbilical hernia occurs in the adult *near* the umbilicus, while in the fœtus it occurs *at* the umbilicus.

The **lineæ semilunares** are two curved tendinous lines placed one on either side of the linea alba. Each corresponds with the outer border of the Rectus muscle, extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, reinforced in front by that of the External oblique, and behind by that of the Transversalis.

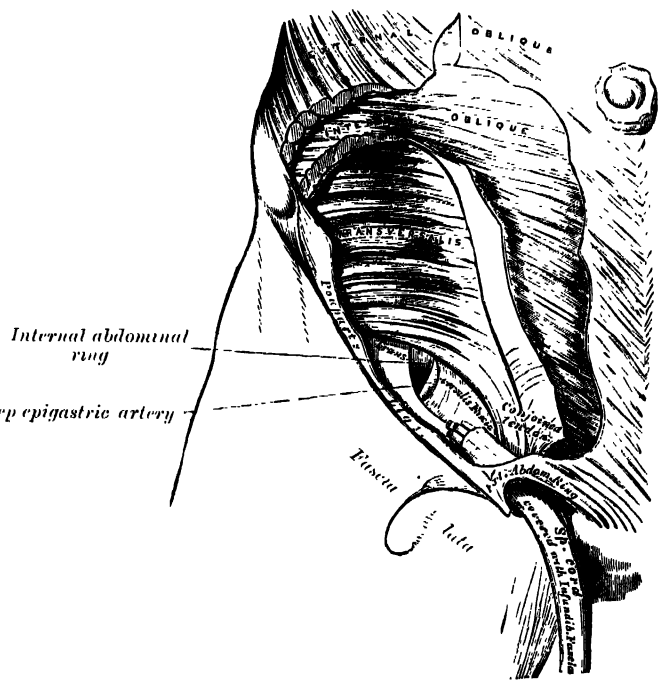
Actions.—When the pelvis and thorax are fixed, the abdominal muscles compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the Diaphragm. By these means assistance is given in expelling the fœtus from the uterus, the fæces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and vertebral column be fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone be fixed, the thorax is bent directly forward, when the muscles of both sides act; when the muscles of only one side contract the trunk is bent towards that side and rotated towards the opposite side.

If the thorax be fixed, the muscles, acting together, draw the pelvis upwards, as in climbing; or, acting singly, they draw the pelvis upwards, and bend the vertebral column to one side or the other. The Recti, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The fascia transversalis is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the extra-peritoneal fat. It forms part of the general layer of fascia lining the abdominal parietes, and is directly continuous with the iliac and pelvic fasciæ. In the inguinal region, the transversalis fascia is thick and dense in structure and joined by

Fig. 510.—The left internal abdominal ring.



fibres from the aponeurosis of the Transversalis muscle, but it becomes thin as it ascends to the Diaphragm, and blends with the fascia covering the under aspect of this muscle. In front, it unites across the middle line with the fascia on the opposite side of the body; and behind, it becomes lost in the fat which covers the posterior surfaces of the kidneys. Below, it has the following attachments: posteriorly, to the whole length of the crest of the ilium, between the attachments of the Transversalis and Iliacus muscles; between the anterior superior spine of the ilium and the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the pubis and ilio-pectineal line, behind the conjoined tendon, with which it is united; it descends in front of the femoral vessels to form the anterior wall of the femoral sheath. Beneath Poupart's ligament it is strengthened by a band of fibrous tissue, which is only loosely connected to Poupart's ligament, and is specialised as the *deep crural arch*. The spermatic cord in the male and the round ligament in the female pass through the

transversalis fascia at a point called the *internal abdominal ring*. This opening is not visible externally since the transversalis fascia is prolonged on these structures as the *infundibuliform fascia*.

The internal or deep abdominal ring (annulus inguinalis abdominalis) is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart's ligament (fig. 510). It is of an oval form, the long axis of the oval being vertical; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded, above and externally, by the arched fibres of the Transversalis; below and internally, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the *infundibuliform fascia*, is continued round the cord and testis, enclosing them in a distinct covering.

Extra-peritoneal connective tissue.—Between the inner surface of the general layer of the fascia which lines the interior of the abdominal and pelvic cavities, and the peritoneum, there is a considerable amount of connective tissue, termed the *extra-peritoneal* or *subperitoneal connective tissue*.

The *parietal* portion lines the cavity in varying quantities in different situations. It is especially abundant on the posterior wall of the abdomen, and particularly around the kidneys, where it contains much fat. On the anterior wall of the abdomen, except in the pubic region, and on the roof of the abdomen, it is scanty, and here the transversalis fascia is more closely connected with the peritoneum. There is a considerable amount of extra-peritoneal connective tissue in the pelvis.

The *visceral* portion follows the course of the branches of the abdominal aorta between the layers of the mesenteries and other folds of peritoneum which connect the various viscera to the abdominal wall, and assist in fixing them. The two portions are directly continuous with each other.

The deep crural arch.—Curving over the external iliac vessels, just at the point where they become femoral, on the abdominal side of Poupart's ligament and loosely connected with it, is a thickened band of fibres called the deep crural arch. It is apparently a thickening of the fascia transversalis, joined externally to the centre of the lower margin of Poupart's ligament, and arching across the front of the crural sheath to be inserted by a broad attachment into the spine of the pubis and ilio-pectineal line, behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting.

Surface Form.—The skin of the abdomen is thin and sensitive. In the male, it is often thickly hair-clad, especially towards the lower part of the middle line. In the female, the hairs are confined to the pubes. After distension from pregnancy or other causes, the skin commonly presents transverse white lines, which are quite smooth, being destitute of papillæ. These are known as *striæ gravidarum*.

The only muscles of the abdomen which have any considerable influence on surface form are the External oblique and Rectus. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked in a muscular subject, interdigitating with those of the Serratus magnus; the lower digitations are not visible, being covered by the thick border of the Latissimus dorsi. Its attachment to the crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the iliac furrow. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscular fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the *linea semilunaris*, which may be exactly determined by putting the muscle into action. It corresponds with a curved line, with its convexity outwards, drawn from the end of the cartilage of the ninth rib to the spine of the pubis; at the level of the umbilicus, it is about three inches from the median line. The surface of the Rectus presents three transverse furrows, the *lineæ transversæ*. The upper two of these, viz. one opposite or a little below the tip of the ensiform cartilage, and the other midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the linea alba, varies in position as regards its height. It is placed from three-quarters of an inch to an inch above the level of the tubercles of the iliac crests, and usually corresponds to the disc between the third and fourth lumbar vertebræ.

2. Posterior Muscles of the Abdomen

Psoas magnus.	Iliacus.
Psoas parvus.	Quadratus lumborum.

The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fasciæ covering them, will be described with the muscles of the lower extremity (see page 564).

The fascia covering the Quadratus lumborum.—This is the most anterior of the three layers of the lumbar aponeurosis. It is a thin layer of fascia covering the anterior surface of the Quadratus lumborum, and attached, internally, to the bases of the transverse processes of the lumbar vertebræ; below, to the ilio-lumbar ligament; above, to the apex and lower border of the last rib.

The upper margin of this fascia, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the ligamentum arcuatum externum (page 502).

The **Quadratus lumborum** (fig. 499, page 495) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the ilio-lumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is inserted into the lower border of the last rib for about half its length, and by four small tendons into the apices of the transverse processes of the upper four lumbar vertebræ. Occasionally a second portion of this muscle is found in front of the preceding. It arises from the upper borders of the transverse processes of the lower three or four lumbar vertebræ, and is inserted into the lower margin of the last rib. The Quadratus lumborum is contained in a sheath formed by the anterior and middle lamellæ of the lumbar aponeurosis, in front of which are the colon, the kidney, the Psoas, and the Diaphragm; between the fascia and the muscle are the last thoracic, ilio-inguinal, and ilio-hypogastric nerves.

Nerve-supply.—The last thoracic and first and second lumbar nerves supply this muscle.

Actions.—The Quadratus lumborum draws down the last rib, and acts as a muscle of inspiration by helping to fix the origin of the Diaphragm. If the thorax and spine are fixed, it may act upon the pelvis, raising it towards its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

IV. Muscles and Fasciæ of the Pelvis

Obturator internus.	Levator ani.
Pyriformis.	Coccygeus.

The muscles within the pelvis may be divided into two groups: (1) the Obturator internus and the Pyriformis, which are muscles of the lower extremity, and will be described with these (page 575); (2) the Levator ani and the Coccygeus, which together form the *pelvic diaphragm* and are associated with the pelvic viscera. The classification of the two groups under a common heading is convenient in connection with the fasciæ investing the muscles. These fasciæ are closely related to one another and to the deep fascia of the perinæum, and in addition have special connections with the fibrous coverings of the pelvic viscera; it is customary therefore to describe them together under the term *pelvic fascia*.

Pelvic fascia.—The fascia of the pelvis may be resolved into: (A) the fascial sheaths of the Obturator internus, Pyriformis, and pelvic diaphragm; (B) the fascia associated with the pelvic viscera.

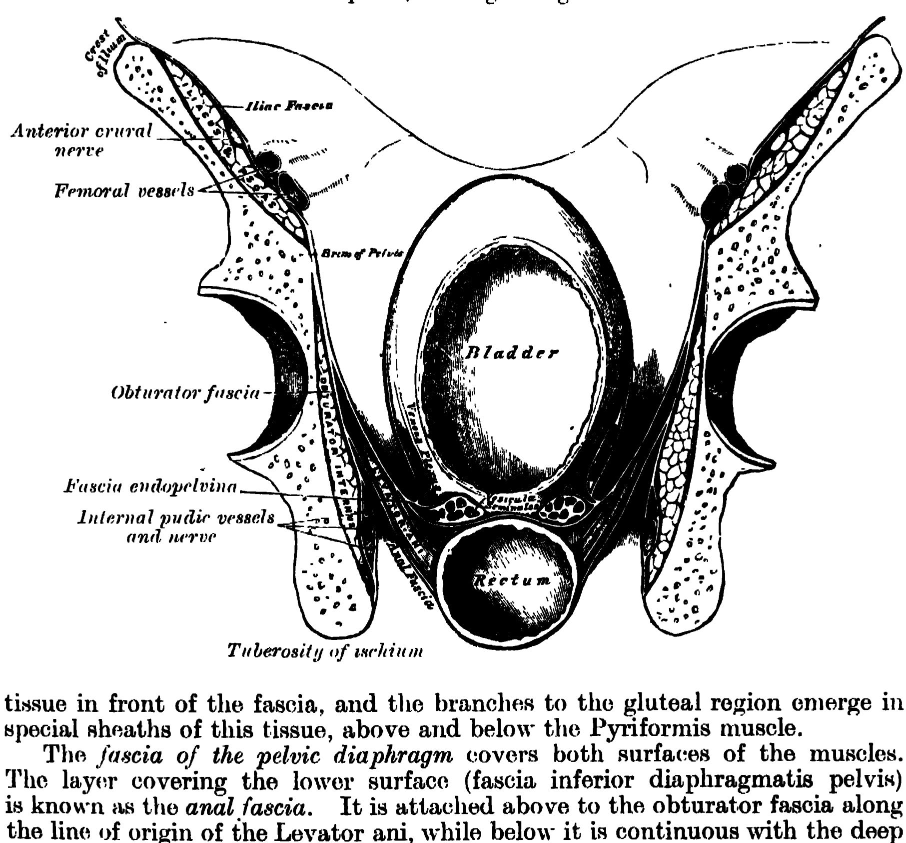
The *fascia of the Obturator internus* covers the pelvic surface of, and is attached round the margin of the origin of, the muscle. Above, it is loosely connected to the back part of the ilio-pectineal line, and here it is continuous with the iliac fascia. In front of this, as it follows the line of origin of the Obturator internus, it gradually separates from the iliac fascia and the continuity between the two is retained only through the periosteum. It arches

beneath the obturator vessels and nerve, completing the obturator canal, and at the front of the pelvis is attached to the back of the body of the pubis. Below, the obturator fascia is attached to the falciform process of the great sacro-sciatic ligament and to the pubic arch where it becomes continuous with the deep layer of the fascial sheath of the Compressor urethræ (deep layer of the triangular ligament). Behind, it is prolonged out on the Obturator internus into the gluteal region.

The pudic vessels and nerve cross the pelvic surface of the Obturator internus and are enclosed in a special canal—*Alcock's canal*—formed by the obturator fascia.

The *fascia of the Pyriformis* is very thin and is attached to the front of the sacrum and the sides of the great sacro-sciatic foramen; it is prolonged out on the muscle into the gluteal region. At its sacral attachment round the margins of the anterior sacral foramina it comes into intimate association with and ensheathes the nerves emerging from these foramina. Hence the sacral nerves are frequently described as lying behind the fascia. The internal iliac vessels and their branches, on the other hand, lie in the subperitoneal

FIG. 511.—Coronal section of pelvis, showing arrangement of fasciæ from behind.



tissue in front of the fascia, and the branches to the gluteal region emerge in special sheaths of this tissue, above and below the Pyriformis muscle.

The *fascia of the pelvic diaphragm* covers both surfaces of the muscles. The layer covering the lower surface (fascia inferior diaphragmatis pelvis) is known as the *anal fascia*. It is attached above to the obturator fascia along the line of origin of the Levator ani, while below it is continuous with the deep layer of the triangular ligament and with the fascia on the Internal sphincter ani. The layer covering the upper surface of the pelvic diaphragm (pars diaphragmatica fasciæ pelvis) follows, above, the line of origin of the Levator ani and is therefore somewhat variable. In front it is attached to the back of the symphysis pubis about three-quarters of an inch above its lower border. It can then be traced outwards across the back of the body of the pubis for a distance of about half an inch, when it reaches the obturator fascia. It is attached to this fascia along a line which pursues a somewhat irregular course to the spine of the ischium. The irregularity of this line is due to the fact that the origin of the Levator ani, which in lower forms is from the pelvic brim, is in man lower down, on the obturator fascia. Tendinous fibres of origin

of the muscle are therefore often found extending up towards, and in some cases reaching, the pelvic brim, and on these the fascia is carried.

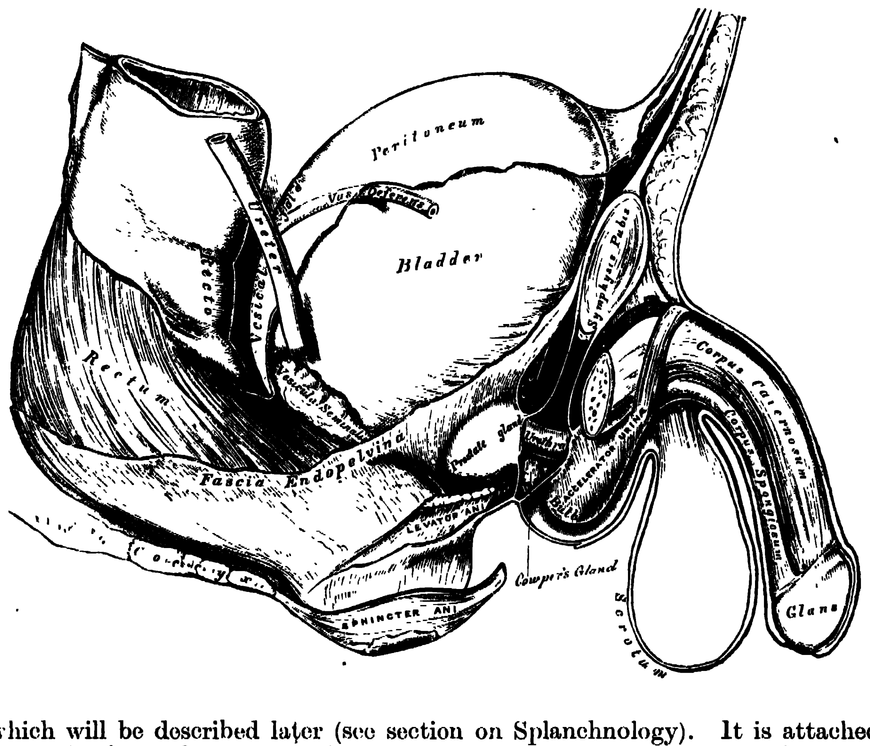
It will be evident that the fascia covering that part of the Obturator internus above the origin of the Levator ani is a composite fascia and includes the following: (*a*) the obturator fascia; (*b*) the fascia of the Levator ani; (*c*) degenerated fibres of origin of the Levator ani. This portion was formerly described as *the* pelvic fascia.

The lower margin of the fascia covering the upper surface of the pelvic diaphragm is attached along the line of insertion of the muscle.

At the level of a line extending from the lower part of the symphysis pubis to the spine of the ischium is a thickened whitish band in this upper layer of the pelvic diaphragmatic fascia. It is termed the *white line* (arcus tendineus fasciæ pelvis), and marks the line of attachment of the special fascia (pars endopelvina fasciæ pelvis) which is associated with the pelvic viscera.

The *fascia endopelvina* is to be regarded as a thickening of the subperitoneal tissue round the various pelvic viscera, to form for them fibrous coverings

FIG. 512.—Side view of pelvic viscera of the male subject, showing the fascia endopelvina.

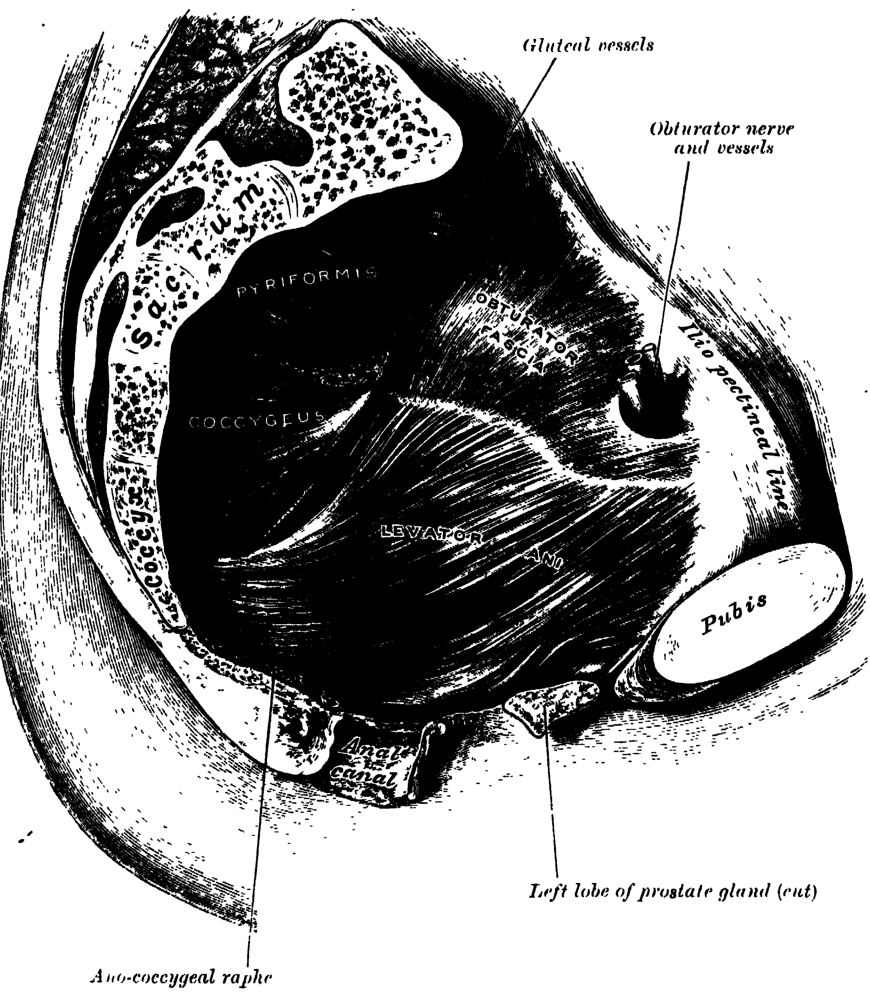


which will be described later (see section on Splanchnology). It is attached to the fascia on the upper surface of the pelvic diaphragm along the white line, and has been subdivided in accordance with the viscera to which it is related. Thus its anterior part, known as the *vesical layer*, forms the anterior and lateral ligaments of the bladder. Its middle part crosses the floor of the pelvis between the rectum and vesiculæ seminales as the *recto-vesical layer*; in the female this is perforated by the vagina. Its posterior portion passes to the side of the rectum; it forms a loose sheath for the rectum, but is firmly attached round the anal canal; this portion is known as the *rectal layer*.

The **Levator ani** (fig. 513) is a broad, thin muscle, situated on the side of the pelvis. It is attached to the inner surface of the side of the true pelvis, and descends to unite with its fellow of the opposite side and form the greater part of the floor of the pelvic cavity. It supports the viscera in this cavity and surrounds the various structures which pass through it. It arises, in front, from the posterior surface of the body of the pubis on the outer side

of the symphysis; behind, from the inner surface of the spine of the ischium; and between these two points, from the obturator fascia. Posteriorly, this fascial origin corresponds, more or less closely, with the white line (page 519), but in front, the muscle arises from the fascia at a varying distance above the white line, in some cases reaching nearly as high as the canal for the obturator vessels and nerve. The fibres pass downwards to the middle line of the floor of the pelvis; the most posterior are inserted into the sides of the last two segments of the coccyx; those placed more anteriorly unite with the muscle of the opposite side, in a median fibrous raphe (*ano-coccygeal raphe*), which extends between the coccyx and the margin of the anus. The

FIG. 513.—Left levator ani from within.



middle fibres are inserted into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres descend upon the side of the prostate gland to unite beneath it with the muscle of the opposite side, joining with the fibres of the External sphincter and Transversus perinæi muscles at the central tendinous point of the perinæum.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate gland, descending by its side, and surrounding it as in a sling, it has been described by Santorini and others as a distinct muscle, under the name of *Levator prostatæ*. In the female the anterior fibres of the Levator ani descend upon the side of the vagina.

Relations.—By its *upper* or *pelvic surface*, with the fascia which separates it from the bladder, prostate, rectum, and peritoneum. By its *lower* or *perineal surface*, it forms the inner boundary of the ischio-rectal fossa. and is covered by a thin layer of fascia, the *ischio-rectal* or *anal fascia*, given off from the obturator fascia. Its *posterior border* is free and separated from the Coccygeus muscle by a cellular interspace. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, pass from the pelvis.

The Levator ani may be divided into ilio-coccygeal and pubo-coccygeal parts.

The *Ilio-coccygeus* arises from the ischial spine and from the posterior part of the pelvic fascia, and is attached to the coccyx and ano-coccygeal raphe: it is usually thin, and may fail entirely, or be largely replaced by fibrous tissue. An accessory slip at its posterior part is sometimes named the *Ilio-sacralis*. The *Pubo-coccygeus* arises from the back of the pubis and from the anterior part of the obturator fascia, and 'is directed backwards almost horizontally along the side of the anal canal towards the coccyx and sacrum, to which it finds attachment. Between the termination of the vertebral column and the anus, the two pubo-coccygei muscles come together and form a thick, fibro-muscular layer lying on the raphe formed by the Ilio-coccygei' (Thompson). The greater part of this muscle is inserted into the coccyx and into the last one or two pieces of the sacrum. This insertion into the vertebral column is, however, not admitted by all observers. The fibres which form a sling for the rectum are named the *Pubo-rectalis* or *Sphincter recti*. They arise from the lower part of the symphysi pubis, and from the upper layer of the triangular ligament. They meet with the corresponding fibres of the opposite side around the lower part of the rectum, and form for it a strong sling.

Nerve-supply.—The Levator ani is supplied by a branch from the fourth sacral nerve and by a branch which is sometimes derived from the perineal, sometimes from the inferior hæmorrhoidal division of the pudic nerve.

The **Coccygeus** (fig. 513) is situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising by its apex from the spine of the ischium and lesser sacro-sciatic ligament, and inserted by its base into the margin of the coccyx and into the side of the lowest piece of the sacrum. It assists the Levator ani and Pyriformis in closing in the back part of the outlet of the pelvis.

Nerve-supply.—The Coccygeus is supplied by a branch from the fourth and fifth sacral nerves.

Actions.—The Levatores ani constrict the lower end of the rectum and vagina. They elevate and invert the lower end of the rectum after it has been protruded and everted during the expulsion of the fæces. They are also muscles of forced expiration. The Coccygei muscles pull forward and support the coccyx, after it has been pressed backwards during defæcation or parturition. The Levatores ani and Coccygei together form a muscular diaphragm which supports the pelvic viscera.

V. Muscles and Fasciæ of the Perinæum

The perinæum corresponds to the outlet of the pelvis. Its deep boundaries are - in front, the pubic arch and the subpubic ligament; behind, the tip of the coccyx; and on either side the rami of the pubis and ischium, and the great sacro-sciatic ligament. The space is somewhat lozenge-shaped and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on either side by the inner side of the thigh. A line drawn transversely across in front of the ischial tuberosities divides the space into two portions. The posterior contains the termination of the anal canal and is known as the *ischio-rectal* or *anal region*; the anterior, which contains the external urogenital organs, is termed the *urogenital region*.

The muscles of the perinæum may therefore be divided into two groups:

1. Those of the ischio-rectal region.
2. Those of the urogenital region: A, In the male; B, In the female.

1. Muscles and Fasciæ of the Ischio-rectal Region

Corrugator cutis ani. External sphincter ani. Internal sphincter ani.

The **superficial fascia** is very thick, areolar in texture, and contains much fat in its meshes. On either side a pad of fatty tissue extends deeply between

the Levator ani and Obturator internus into a space known as the *ischio-rectal fossa.*

The **deep fascia** forms the lining of the ischio-rectal fossa; it comprises the anal fascia, and the portion of obturator fascia below the origin of Levator ani.

Ischio-rectal fossa.—The fossa is somewhat prismatic in shape, with its base directed to the surface of the perinæum, and its apex at the line of meeting of the obturator and anal fasciæ. It is bounded internally by the External sphincter ani, and the anal fascia; externally by the tuberosity of the ischium and the obturator fascia; anteriorly by the fascia of Colles covering the transversus perinæi, and by the deep layer of the triangular ligament; posteriorly by the Gluteus maximus and the great sacro-sciatic ligament. Crossing the space transversely are the inferior hæmorrhoidal vessels and nerves; at the back part are the perineal and perforating cutaneous branches of the pudendal plexus; while from the fore part the superficial perineal vessels and nerves emerge. The internal pudic vessels and nerve lie in Alcock's canal on the external wall. The fossa is filled with fatty tissue across which numerous fibrous bands extend from side to side.

Applied Anatomy.—Abscess in the ischio-rectal fossa commonly occurs; it is most often the result of infection from the bowel, and is especially prone to occur in tuberculous subjects; occasionally it follows perforation by a foreign body which has been swallowed, such as a fish bone. The abscess may bulge at the side of the anus, at the border of Gluteus maximus, or against the rectal wall. There is great pain on defæcation, and, on examining the bowel, fulness on the side of the abscess may be detected. If left to itself the pus will find exit through the skin, or into the rectum, between the two Sphincters; and the condition will degenerate into one of the varieties of fistula, owing to the constant pull of the Sphincter preventing closure of the walls of the cavity. These abscesses should be opened at the earliest possible moment, as they tend to track and burrow widely into the soft fat in the fossa, and also in the subcutaneous tissues. An incision should be made tangential to the anus over the region of the ischio-rectal fossa, and should then be converted into a T, by making another incision outwards at right angles to it, so that the wound may be kept open and may heal up from the bottom. Frequently, however, in spite of care, a fistula ensues which requires division of the External sphincter for its cure.

The **Corrugator cutis ani.**—Around the anus is a thin stratum of involuntary muscular fibre, which radiates from the orifice. Internally, the fibres fade off into the submucous tissue, while externally they blend with the true skin. By its contraction it raises the skin into ridges around the margin of the anus.

The **Sphincter ani externus** (fig. 514) is a thin, flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length, from its anterior to its posterior extremity, being about an inch in breadth, opposite the anus. It consists of two strata, superficial and deep. The *superficial*, constituting the main portion of the muscle, arises from a narrow tendinous band, the *ano-coccygeal raphe*, which stretches from the tip of the coccyx to the posterior margin of the anus; it forms two flattened planes of muscular tissue, which encircle the anus and meet in front to be inserted into the central tendinous point of the perinæum, joining with the Transversus perinæi, the Levator ani, and the Accelerator urinæ. The *deeper portion* forms a complete sphincter to the anal canal. Its fibres surround the canal, closely applied to the Internal sphincter, and in front blend with the other muscles at the central point of the perinæum. In a considerable proportion of cases the fibres decussate in front of the anus, and are continuous with the Transversus perinæi. Posteriorly, they are not attached to the coccyx, the fibres of opposite sides being continuous behind the anal canal. The upper edge of the muscle is ill-defined, since fibres are given off from it to join the Levator ani.

Nerve-supply.—A branch from the fourth sacral and twigs from the inferior hæmorrhoidal branch of the internal pudic supply the muscle.

Actions.—The action of this muscle is peculiar. 1. It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle it keeps the anal canal and orifice closed. 2. It can be put into a condition of greater contraction under the influence of the will, so as more firmly to occlude the anal aperture in expiratory efforts, unconnected with defæcation. 3. Taking its fixed

point at the coccyx, it helps to fix the central point of the perinæum, so that the Accelerator urinæ may act from this fixed point.

The **Sphincter ani internus** is a muscular ring which surrounds the anal canal for about an inch; its inferior border being contiguous with, but quite separate from, the External sphincter. This muscle is about a sixth of an inch in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. Its lower border is about a quarter of an inch from the external orifice. It is paler in colour and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

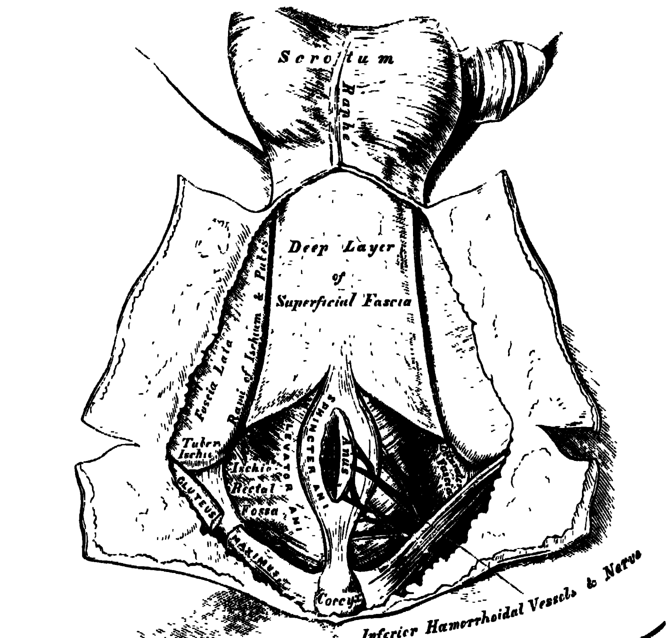
2. A MUSCLES AND FASCIÆ OF THE UROGENITAL REGION IN THE MALE (figs. 514, 515)

Transversus perinæi.	Erector penis.
Accelerator urinæ.	Compressor urethræ.

Superficial fascia.—The superficial fascia of this region consists of two layers, superficial and deep.

The *superficial layer* is thick, loose, areolar in texture, and contains in its meshes much adipose tissue, the amount of which varies in different subjects. In front, it is continuous with the dartos of the scrotum; behind, it is continuous with the subcutaneous areolar tissue surrounding the anus; and,

FIG. 514.—The perinæum.
The integument and superficial layer of superficial fascia reflected.



on either side, with the same fascia on the inner sides of the thighs. In the middle line, it is adherent to the skin of the raphe and to the deep layer of the superficial fascia.

The *deep layer of superficial fascia* (fascia of Colles) (fig. 514) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos of the scrotum, the deep fascia of the penis, the fascia of the spermatic

cord, and Scarpa's fascia upon the anterior wall of the abdomen; on either side it is firmly attached to the margins of the rami of the pubis and ischium, external to the crus penis and as far back as the tuberosity of the ischium; posteriorly, it curves round the Transversus perinæi muscles to join the lower margin of the triangular ligament. In the middle line, it is connected with the superficial fascia and with the median septum of the Accelerator urinæ muscle. This fascia not only covers the muscles in this region, but sends upwards a vertical septum from its deep surface, which separates the back part of the subjacent space into two, the septum being incomplete in front.

The central tendinous point of the perinæum.—This is a fibrous point in the middle line of the perinæum, between the urethra and the rectum; and about half an inch in front of the anus. At this point six muscles converge and are attached: viz. the External sphincter ani, the Accelerator urinæ, the two Transversi perinæi, and the anterior fibres of the Levatores ani; so that by the contraction of these muscles, which extend in different directions, it serves as a fixed point of support.

The **Transversus perinæi** is a narrow muscular slip, which passes more or less transversely across the perineal space in front of the anus. It arises by tendinous fibres from the inner and fore part of the tuberosity of the ischium, and, running inwards, is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, with the External sphincter ani behind, and with the Accelerator urinæ in front. In some cases, the fibres of the deeper layer of the Sphincter ani decussate in front of the anus and are continued into this muscle. Occasionally it gives off fibres, which join with the Accelerator urinæ of the same side.

Nerve-supply.—It is supplied by the perineal branch of the internal pudic.

Actions.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perinæum.

The **Accelerator** or **Ejaculator urinæ** (m. bulbocavernosus) is placed in the middle line of the perinæum, in front of the anus. It consists of two symmetrical parts, united along the median line by a tendinous raphe. It arises from the central tendon of the perinæum and from the median raphe in front. Its fibres diverge like the plumes of a quill-pen; the most posterior form a thin layer, which is lost on the superficial surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis; the anterior fibres, the longest and most distinct, spread out over the side of the corpus cavernosum, to be inserted partly into that body, anterior to the Erector penis, occasionally extending to the pubis, and partly terminating in a tendinous expansion which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and reflecting it outwards from the surface of the corpus spongiosum.

Actions.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed by Krause to assist in the erection of the corpus spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis by compressing the dorsal vein, as they are inserted into, and continuous with, the fascia of the penis.

The **Erector penis** (m. ischiocavernosus) covers the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis; and from the rami of the pubis and ischium on either side of the crus. From these points fleshy fibres succeed, and end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

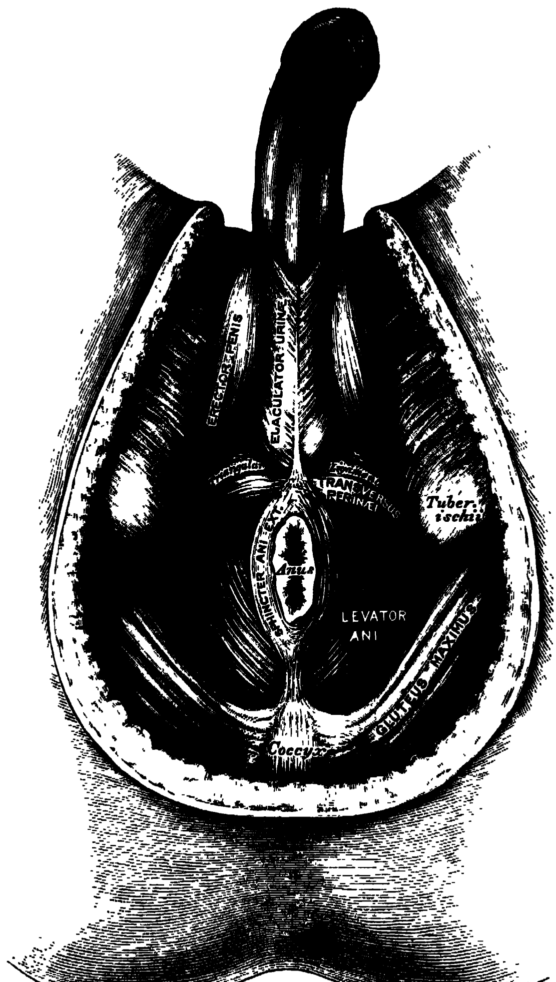
Nerve-supply.—The Erector penis is supplied by the perineal branch of the internal pudic.

Action.—The Erector penis compresses the crus penis, and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urinæ, externally by the Erector penis, and behind by the Transversus perinæi. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forwards in it are the superficial perineal vessels and nerves, and the long pudendal nerve. The transverse perineal artery courses along the posterior boundary of the space on the Transversus perinæi.

The deep fascia of the urogenital region forms an investment for the Compressor urethræ, but within it lie also the deep vessels and nerves of this part, the whole forming a transverse septum which is known as the

FIG. 515.—Muscles of male perinæum.



diaphragma urogenitale. From its shape it is usually termed the *triangular ligament*, and it is stretched almost horizontally across the pubic arch, so as to close in the front part of the outlet of the pelvis. It consists of two dense membranous laminæ, which are united along their posterior borders, but are separated in front by intervening structures. The superficial of these two layers, the *inferior layer of the triangular ligament* (fascia diaphragmatica uro- [redacted]. Its apex is directed forwards, and is separated from the subpubic ligament by an oval opening for the transmission of the dorsal vein of the penis. Its lateral margins are attached on either side to the rami of the pubis and

ischium, above the crus penis. Its base is directed towards the rectum, and connected to the central tendinous point of the perinæum. It is continuous with the deep layer of the superficial fascia behind the Transversus perinæi muscle, and with a thin fascia which covers the under surface of the Levator ani muscle (*anal fascia*).

This layer of the triangular ligament is perforated, about an inch below the symphysis pubis, by the urethra, the aperture for which is circular in form and about a quarter of an inch in diameter; by the arteries to the bulb and the ducts of Cowper's glands close to the urethral orifice; by the arteries to the corpora cavernosa—one on either side close to the pubic arch and about halfway along the attached margin of the ligament; by the dorsal arteries and nerves of the penis near the apex of the ligament. Its base is also perforated by the superficial perineal vessels and nerves, while between its apex and the subpubic ligament the deep dorsal vein of the penis passes upwards into the pelvis.

If the superficial or inferior layer of the triangular ligament be detached on either side, the following structures will be seen between it and the deep layer: the dorsal vein of the penis; the membranous portion of the urethra, and the Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and dorsal nerves of the penis; the arteries and nerves of the bulb, and a plexus of veins.

The *deep or superior layer of the triangular ligament* (fascia diaphragmatica urogenitalis superior) is continuous with the obturator fascia and stretches across the pubic arch. If the obturator fascia be traced inwards after leaving the Obturator internus muscle, it will be found attached by some of its deeper or anterior fibres to the inner margin of the ischio-pubic ramus, while its superficial or posterior fibres pass over this attachment to form the superior layer of the triangular ligament. Behind, this layer of the fascia is continuous with the inferior layer and with the fascia of Colles, and in front it is continuous with the fascial sheath of the prostate gland.

The **Compressor urethræ** (m. constrictor urethræ) surrounds the whole length of the membranous portion of the urethra, and is contained between the two layers of the triangular ligament. It arises by aponeurotic fibres from the junction of the rami of the pubis and ischium, to the extent of half or three-quarters of an inch: each segment of the muscle passes inwards, and divides into two fasciculi, which surround the urethra from the prostate gland behind to the bulbous portion of the urethra in front; and unite, at the upper and lower surfaces of this tube, with the muscle of the opposite side, by means of a tendinous raphe.

Nerve-supply.—The perineal branch of the internal pudic supplies this muscle.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the Acceleratores urinæ, are relaxed, and only come into action at the end of the process to eject the last drops of the fluid.

2. B. Muscles of the Urogenital Region in the Female (fig. 516)

Transversus perinæi.	Erector clitoridis.
Sphincter vaginæ.	Compressor urethræ.

The **Transversus perinæi** in the female is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inwards, is inserted into the central point of the perinæum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Sphincter vaginæ in front.

Nerve-supply.—This muscle is supplied by the perineal branch of the internal pudic.

Action.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perinæum.

The **Sphincter vaginæ** (m. bulbocavernosus) surrounds the orifice of the vagina, and is homologous with the Accelerator urinæ in the male. It covers the outer aspect of the vestibular bulbs, and is attached posteriorly

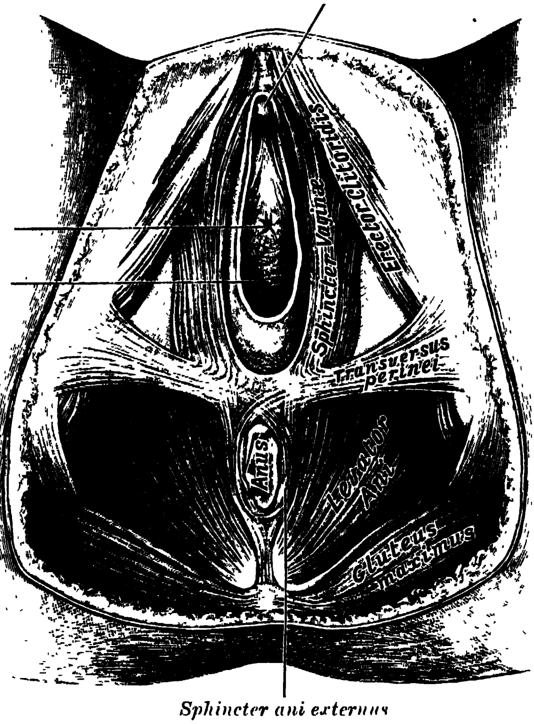
to the central tendinous point of the perinæum, where it blends with the External sphincter ani. Its fibres pass forwards on either side of the vagina, to be inserted into the corpora cavernosa of the clitoris, a fasciculus crossing over the body of the organ so as to compress the dorsal vein.

Nerve-supply.—It is supplied by the perineal branch of the internal pudic.

Actions.—The Sphincter vaginæ diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris, compressing the dorsal vein during the contraction of the muscle.

The **Erector clitoridis** (m. ischiocavernosus) corresponds with the Erector penis in the male, but is smaller. It covers the unattached surface of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on the side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface

FIG. 516.—Muscles of the female perinæum. (Modified from a drawing by Peter Thompson.)



of the tuberosity of the ischium, behind the crus clitoridis; from the surface of the crus; and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, and end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

Nerve-supply.—The perineal branch of the internal pudic supplies this muscle.

Actions.—The Erector clitoridis compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The **triangular ligament** in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the subpubic ligament. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the Transversus perinæi muscle.

Like the triangular ligament in the male, it consists of two layers, between which are to be found the following structures: the dorsal vein of the clitoris,

a portion of the urethra and the Compressor urethræ muscle, the glands of Bartholin and their ducts; the pudic vessels and the dorsal nerves of the clitoris; the arteries and nerves of the bulbi vestibuli, and a plexus of veins.

The **Compressor urethræ** (m. constrictor urethræ) arises on either side from the margin of the descending ramus of the pubis. The fibres, passing inwards, divide into two sets: those of the fore part of the muscle are directed across the subpubic arch in front of the urethra to blend with the muscular fibres of the opposite side; while those of the hinder and larger part pass inwards to blend with the wall of the vagina behind the urethra.

Nerve-supply.—It is supplied by the perineal branch of the internal pudic.

MUSCLES AND FASCIÆ OF THE UPPER EXTREMITY

The muscles of the upper extremity are divisible into groups, corresponding with the different regions of the limb.

I. Thoracic Region

1. *Anterior Thoracic Region.*

Pectoralis major. Pectoralis minor.
Subclavius.

2. *Lateral Thoracic Region.*

Serratus magnus.

II. Shoulder and Arm

3. *Acromial Region.*

Deltoid.

4. *Anterior Scapular Region.*

Subscapularis.

5. *Posterior Scapular Region.*

Supraspinatus. Teres minor.
Infraspinatus. Teres major.

6. *Anterior Humeral Region.*

Coraco-brachialis. Biceps.
Brachialis anticus.

7. *Posterior Humeral Region.*

Triceps. Subanconeus.

III. Forearm

8. *Anterior Radio-ulnar Region.*

Superficial Layer:
Pronator teres.
Flexor carpi radialis.
Palmaris longus.
Flexor carpi ulnaris.
Flexor sublimis digitorum.

Deep Layer:
Flexor profundus digitorum.
Flexor longus pollicis.
Pronator quadratus.

9. *Radial Region.*

Brachio-radialis (Supinator longus).
Extensor carpi radialis longior.
Extensor carpi radialis brevior.

10. *Posterior Radio-ulnar Region.*

Superficial Layer:
Extensor communis digitorum.
Extensor minimi digiti.
Extensor carpi ulnaris.
Anconeus.

Deep Layer:
Supinator brevis.
Extensor ossis metacarpi pollicis.
Extensor brevis pollicis.
Extensor longus pollicis.

I. Muscles and Fasciæ of the Thoracic Region

1. *Anterior Thoracic Region*

Pectoralis major. Pectoralis minor.
Subclavius.

The **superficial fascia** of the anterior thoracic region is a loose cellulo-fibrous layer, enclosing masses of fat in its spaces. It is continuous with the

superficial fascia of the neck and upper extremity above, and of the abdomen below. Opposite the mamma it divides into two layers, one of which passes in front of, the other behind that gland; from both layers numerous septa pass into the gland, supporting its various lobes: from the anterior layer, fibrous processes pass forwards to the integument and nipple. These processes were called by Sir A. Cooper the *ligamenta suspensoria*, from the support they afford to the gland in this situation.

The **deep fascia** of the anterior thoracic region (fascia pectoralis) is a thin lamina, covering the surface of the Pectoralis major, and sending numerous prolongations between its fasciculi: it is attached, in the middle line, to the front of the sternum; above, to the clavicle; externally and below it becomes continuous with the fascia over the shoulder, axilla, and thorax. It is very thin over the upper part of the Pectoralis major muscle, thicker in the interval between it and the Latissimus dorsi, where it closes in the axillary space, and forms the *fascia axillaris*; it divides at the outer margin of the latter muscle into two layers, one of which passes in front, and the other behind it; these proceed as far as the spinous processes of the thoracic vertebræ, to which they are attached. As the fascia leaves the lower edge of the Pectoralis major to pass across the floor of the axilla it sends a layer upwards under cover of the muscle: this lamina splits to envelop the Pectoralis minor, at the upper edge of which it becomes continuous with the costo-coracoid membrane. The hollow of the armpit, seen when the arm is abducted, is produced mainly by the traction of this fascia on the axillary floor, and hence the lamina is sometimes named the *suspensory ligament* of the axilla. At the lower part of the thoracic region the deep fascia is well developed, and is continuous with the fibrous sheaths of the Recti abdominis.

Applied Anatomy.—In cases of suppuration in the axilla, the axillary fascia prevents the extension of the pus in a downward direction, and so it has a tendency to spread upwards, beneath the Pectoral muscles, towards the root of the neck. Early evacuation is therefore necessary. The incision should be made midway between the anterior and posterior axillary folds, so as to avoid the long thoracic and subscapular vessels, and the edge of the knife should be directed away from the axillary vessels.

The **Pectoralis major** (fig. 517) is a broad, thick, triangular muscle, situated at the upper and fore part of the chest and in front of the axilla. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; from the cartilages of all the true ribs, with the exception, frequently, of the first, or seventh, or both, and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge towards their insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outwards and downwards, and are usually separated from the rest by a slight interval: those from the lower part of the sternum, and the cartilages of the lower true ribs, run upwards and outwards; while the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches broad, which is inserted into the outer bicipital ridge of the humerus. This tendon consists of two laminæ, placed one in front of the other, and usually blended together below. The anterior lamina, the thicker, receives the clavicular and the upper fibres of the sternal portion of the muscle; its fibres are inserted in the same order as that in which they arise: that is to say, the outermost fibres of origin from the clavicle are inserted at the uppermost part of the bicipital ridge; the upper fibres of origin from the sternum pass down to the lowermost part of this anterior lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The posterior lamina of the tendon receives the attachment of the lower fibres of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend the higher, turning backwards successively behind the superficial and upper ones, so that the tendon appears to be twisted. The posterior lamina reaches higher on the humerus than the anterior one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion

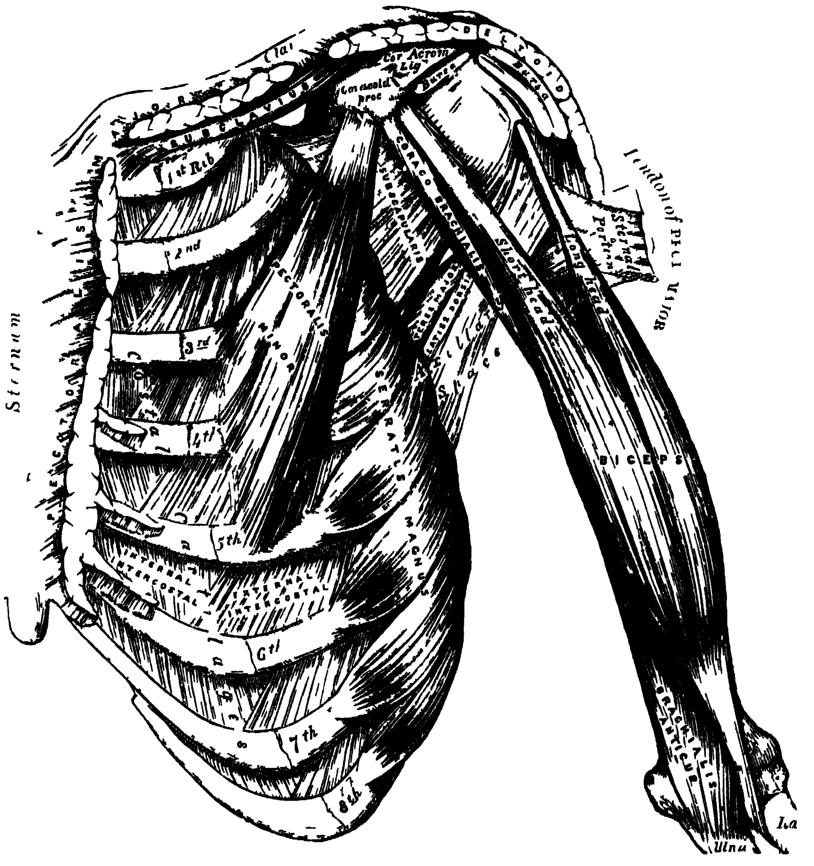
and protects the axillary vessels and nerves. Traced upwards, it splits to enclose the Subclavius muscle, and its two layers are attached to the clavicle, one in front of and the other behind the muscle ; the latter layer fuses with the deep cervical fascia and with the sheath of the axillary vessels. Internally, it blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib internal to the origin of the Subclavius muscle. Externally, it is very thick and dense, and is attached to the coracoid process. The portion extending from the first rib to the coracoid process is often whiter and denser than the rest, and is sometimes called the *costo-coracoid ligament.* Below this, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle ; from the lower border of the Pectoralis minor it is continued downwards to join the axillary fascia, and outwards to join

FIG. 518.—Muscles of the chest and front of the arm, with the boundaries of the axilla.



the fascia over the short head of the Biceps. The costo-coracoid membrane is pierced by the cephalic vein, acromio-thoracic artery and vein, superior thoracic artery, and external anterior thoracic nerve.

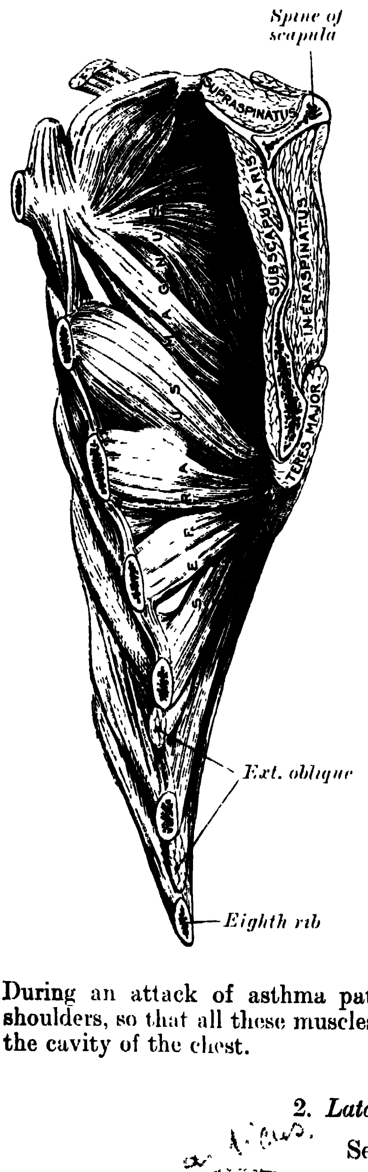
The **Pectoralis minor** (fig. 518) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises by three tendinous digitations, from the upper margins and outer surfaces of the third, fourth, and fifth ribs, near their cartilages, and from the aponeuroses covering the Intercostal muscles; the fibres pass upwards and outwards, and converge to form a flat tendon, which is inserted into the inner border and upper surface of the coracoid process of the scapula.

Relations.—By its *anterior surface* it is in relation with the Pectoralis major, the external anterior thoracic nerve, and the thoracic branches of the acromio-thoracic artery.

By its *posterior surface*, with the ribs, Intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and brachial plexus of nerves. Its *upper border* is separated from the clavicle by a narrow triangular interval which is occupied by the costo-coracoid membrane, behind which are the axillary vessels and nerves. Running parallel to the *lower border* of the muscle is the long thoracic artery, and piercing the muscle is the internal anterior thoracic nerve.

The **Subclavius** is a small triangular muscle, placed in the interval between the clavicle and the first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the rhomboid ligament; the fleshy fibres proceed obliquely upwards and outwards, to be inserted into the groove on the under surface of the clavicle between the rhomboid and conoid ligaments.

FIG. 519.—Serratus magnus. (From a preparation in the Museum of the Royal College of Surgeons of England.)



Relations.—Its *deep surface* is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the costo-coracoid membrane, which, with the clavicle, forms an osseo-fibrous sheath in which the muscle is enclosed.

Nerves.—The Pectoralis major is supplied by the external and internal anterior thoracic nerves; through these nerves the muscle receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the eighth cervical and first thoracic nerves through the internal anterior thoracic nerve. The Subclavius is supplied by a filament derived from the fifth and sixth cervical nerves.

Actions.—If the arm has been raised by the Deltoid, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forwards the arm, bringing it across the front of the chest, and at the same time rotates it inwards. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downwards and inwards to the thorax, and throwing the inferior angle backwards. The Subclavius depresses the shoulder, drawing the clavicle downwards and forwards. When the arms are fixed, all three muscles act upon the ribs, drawing them upwards and expanding the chest, and thus becoming very important agents in forced inspiration. During an attack of asthma patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in dilating the cavity of the chest.

2. *Lateral Thoracic Region*

Serratus magnus

The **Serratus magnus** (m. serratus anterior) (fig. 519) is a thin, irregularly quadrilateral muscle, situated between the ribs and the scapula at the upper and lateral part of the chest. It arises by fleshy digitations from the outer

surfaces and upper borders of the upper eight or nine ribs, and from the aponeuroses covering the intervening Intercostal muscles. Each digitation (except the first) arises from the corresponding rib; the first digitation arises from the first and second ribs, and from the fascia covering the first intercostal space. From this extensive attachment the fibres pass backwards, closely applied to the chest-wall, and reach the vertebral border of the scapula, and are inserted into its ventral aspect in the following manner. The first digitation, arising from the first and second ribs, is inserted into a triangular area on the ventral surface of the superior angle. The next two digitations (i.e. from the second and third ribs) spread out to form a thin, triangular sheet, the base of which is directed backwards and is inserted into nearly the whole length of the ventral surface of the vertebral border. The lower five or six digitations converge to form a fan-shaped mass, the apex of which is inserted, by muscular and by tendinous fibres, into a triangular impression on the ventral surface of the inferior angle. The lower four slips interdigitate at their origins with the upper five slips of the External oblique muscle of the abdomen.

Relations.—This muscle is partly covered, in front, by the Pectoral muscles and by the mammary gland; behind, by the Subscapularis. The axillary vessels and nerves lie upon its upper part, while its deep surface rests upon the ribs and Intercostal muscles.

Nerves.—The Serratus magnus is supplied by the posterior thoracic nerve, which is derived from the fifth, sixth, and seventh cervical nerves.

Actions.—The Serratus magnus, as a whole, carries the scapula forwards, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forwards the lower angle and assist the Trapezius in rotating the bone at the sterno-clavicular joint, and thus assist this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoid in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus rotates. After the Deltoid has raised the arm to a right angle with the trunk, the Serratus magnus and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus magnus may assist in raising and everting the ribs; but it is not the important inspiratory muscle it was formerly believed to be.

Applied Anatomy.—When the muscle is paralysed, the vertebral border, and especially the lower angle of the scapula, leave the ribs and stand out prominently on the surface, giving a peculiar 'winged' appearance to the back (page 294). The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

II. Muscles and Fasciæ of the Shoulder and Arm

The **superficial fascia** of the upper extremity is a thin fibro-cellular layer, containing the superficial veins and lymphatics and the cutaneous nerves. It is most distinct in front of the elbow, where it contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Subcutaneous bursæ are found in this fascia over the acromion, the olecranon, and the knuckles.

The **deep fascia** of the upper extremity comprises the fascia of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

3. *Acromial Region*

Deltoid.

The **deep fascia** covering the Deltoid invests the muscle, and sends numerous prolongations between its fasciculi. In front it is continuous with the fascia covering the Pectoralis major; behind, where it is thick and strong, with that covering the Infraspinatus; above, it is attached to the clavicle,

the acromion, and the spine of the scapula; below, it is continuous with the deep fascia of the arm.

The **Deltoid** (m. deltoideus) (fig. 517) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Δ inverted. It covers the shoulder-joint in front, behind, and on the outer side. It arises from the anterior border and upper surface of the outer third of the clavicle; from the outer margin and upper surface of the acromion process, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its inner end. From this extensive origin the fibres converge towards their insertion, the middle passing vertically, the anterior obliquely backwards and outwards, the posterior obliquely forwards and outwards; they unite to form a thick tendon, which is inserted into a rough triangular prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of oblique fibres; these arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downwards parallel to one another in the substance of the muscle. The oblique fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upwards from the insertion of the muscle and alternate with the descending septa. The portions of the muscle which arise from the clavicle and spine of the scapula are not arranged in this manner, but pass from their origin above to be inserted into the margins of the inferior tendon.

Relations.—The Deltoid is in relation by its *superficial surface* with the integument, the superficial and deep fascia, Platysma, and supra-acromial nerves. Its *deep surface* is separated from the capsule of the shoulder-joint by a large synovial bursa, and covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coraco-brachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the upper part of the shaft of the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and humeral branch of the acromio-thoracic artery: lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoid is supplied by the fifth and sixth cervical through the circumflex nerve.

Actions.—The Deltoid raises the arm directly from the side, so as to bring it at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forwards; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backwards.

Applied Anatomy.—The Deltoid is very liable to atrophy, and in this condition dislocation of the shoulder-joint is simulated as there is flattening of the shoulder and apparent prominence of the acromion process; the distance also between the acromion process and the head of the bone is increased, and the tips of the fingers can be inserted between them. Atrophy of the Deltoid may be due to disuse, such as follows chronic arthritis or permanent injury of the shoulder-joint. It also frequently results from degenerations occurring in the spinal cord, or injury to the circumflex nerve ('crutch-palsy'). The Deltoid and Spinati often escape in myopathic atrophies affecting the other muscles of the upper arm or shoulder in young persons.

4. *Anterior Scapular Region*

Subscapularis.

The **fascia subscapularis** is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle.

The **Subscapularis** (fig. 518) is a large triangular muscle which fills up the subscapular fossa, and arises from its internal two-thirds and from the lower

two-thirds of the groove on the axillary border of the bone. Some fibres arise from tendinous laminæ which intersect the muscle and are attached to ridges on the bone; others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps. The fibres pass outwards, and, gradually converging, terminate in a tendon which is inserted into the lesser tuberosity of the humerus and the front of the capsular ligament of the shoulder-joint. The tendon of the muscle is separated from the neck of the scapula and anterior part of the capsular ligament of the shoulder-joint by a large bursa, which communicates with the cavity of the joint by an aperture in the capsular ligament.

FIG. 520.—Muscles on the dorsum of the scapula and the Triceps.

Relations.—The *anterior surface* of this muscle forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus magnus, Coraco-brachialis, and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is in relation with the scapula and the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres major and Latissimus dorsi.

Nerves.—The Subscapularis is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inwards; when the arm is raised, it draws the humerus forwards and downwards. It is a powerful defence to the front of the shoulder joint, preventing displacement of the head of the bone.

5. *Posterior Scapular Region* (fig. 520)

Supraspinatus.	Teres minor.
Infraspinatus.	Teres major.

The **fascia supraspinata** completes the osseo-fibrous case in which the Supraspinatus muscle is contained; it affords attachment, by its deep

surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament.

The **Supraspinatus** occupies the whole of the supraspinous fossa, arising from its internal two-thirds, and from the strong fascia which covers its surface. The muscular fibres converge to a tendon, which passes across the upper part of the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is inserted into the highest of the three impressions on the great tuberosity of the humerus.

The **fascia infraspinata** is a dense fibrous membrane, covering in the Infraspinatus muscle and fixed to the circumference of the infraspinous fossa; it affords attachment, by its inner surface, to some fibres of that muscle. It is intimately attached to the deltoid fascia along the overlapping border of the Deltoid muscle.

The **Infraspinatus** is a thick triangular muscle, which occupies the chief part of the infraspinous fossa, arising by fleshy fibres from its internal two-thirds; and by tendinous fibres from the ridges on its surface: it also arises from a strong fascia which covers it externally, and separates it from the Teretes major et minor. The fibres converge to a tendon, which glides over the external border of the spine of the scapula, and, passing across the posterior part of the capsular ligament of the shoulder-joint, is inserted into the middle impression on the great tuberosity of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a synovial bursa, which may communicate with the joint cavity.

The **Teres minor** is a narrow, elongated muscle, which arises from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminæ, one of which separates it from the Infraspinatus, the other from the Teres major. Its fibres run obliquely upwards and outwards; the upper ones terminate in a tendon which is inserted into the lowest of the three impressions on the great tuberosity of the humerus; the lower fibres are inserted directly into the humerus immediately below this impression. The tendon of this muscle passes across, and is united with, the posterior part of the capsular ligament of the shoulder-joint.

The **Teres major** is a thick but somewhat flattened muscle, and arises from the oval area on the dorsal surface of the inferior angle of the scapula, and from the fibrous septa interposed between it and the Teres minor and Infraspinatus; the fibres are directed upwards and outwards, and terminate in a flat tendon, about two inches in length, which is inserted into the inner bicipital ridge of the humerus. The tendon, at its insertion into the humerus, lies behind that of the Latissimus dorsi, from which it is separated by a synovial bursa, the two tendons being, however, united along their lower borders for a short distance.

Nerves.—The Supra- and Infra-spinatus muscles are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the Teres minor, by the fifth cervical, through the circumflex; and the Teres major, by the fifth and sixth cervical, through the lower subscapular.

Actions.—The Supraspinatus assists the Deltoid in raising the arm from the side, and fixes the head of the humerus in the glenoid cavity. The Infraspinatus and Teres minor rotate the head of the humerus outwards: they also assist in carrying the arm backwards. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the Supraspinatus supporting it above, and preventing displacement of the head of the humerus upwards, while the Infraspinatus and Teres minor protect it behind, and prevent dislocation backwards. The Teres major assists the Latissimus dorsi in drawing the previously raised humerus downwards and backwards, and in rotating it inwards; when the arm is fixed it may assist the Pectorals and Latissimus dorsi in drawing the trunk forwards.

6. *Anterior Humeral Region* (fig. 518)

Coraco-brachialis. Biceps. Brachialis anticus.

The deep fascia of the arm (fascia brachii) is continuous with that covering the Deltoid and the Pectoralis major, by means of which it is attached, above,

to the clavicle, acromion, and spine of the scapula; it forms a thin, loose, membranous sheath investing the muscles of the arm, and sends inwards septa between them; it is composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being thin over the Biceps, but thicker where it covers the Triceps, and over the condyles of the humerus: it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi on the inner side, and from the Deltoid externally. On either side it gives off a strong intermuscular septum, which is attached to the corresponding supra-condylar ridge and condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The *external intermuscular septum* extends from the lower part of the anterior bicipital ridge, along the external supracondylar ridge, to the outer epicondyle; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis anticus, Brachio-radialis and Extensor carpi radialis longior in front, and is perforated by the musculo-spiral nerve and superior profunda artery. The *internal intermuscular septum*, thicker than the preceding, extends from the lower part of the posterior lip of the bicipital groove below the Teres major, along the internal supracondylar ridge to the inner epicondyle; it is blended with the tendon of the Coraco-brachialis, and affords attachment to the Triceps behind and the Brachialis anticus in front. It is perforated by the ulnar nerve, the inferior profunda artery, and the posterior branch of the anastomotic artery. At the elbow, the deep fascia is attached to all the prominent points round the joint, viz. the epicondyles of the humerus and the olecranon process of the ulna, and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the internal intermuscular septum, is an oval opening in the deep fascia, which transmits the basilic vein and some lymphatic vessels.

The **Coraco-brachialis**, the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum, between the two muscles; the fibres pass downwards, backwards, and a little outwards, to be inserted by means of a flat tendon into an impression at the middle of the inner surface and internal border of the shaft of the humerus between the origins of the Triceps and Brachialis anticus. It is perforated by the musculo-cutaneous nerve. The inner border of the muscle forms a guide to the position of the terminal portion of the axillary and upper part of the brachial arteries.

Relations.—The Coraco-brachialis is in relation by its *anterior surface* with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it; by its *posterior surface*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the humerus, and the anterior circumflex vessels; by its *inner border*, with the third part of the axillary and the upper part of the brachial artery and the median and musculo-cutaneous nerves; by its *outer border*, with the short head of the Biceps and Brachialis anticus.

The **Biceps** (m. biceps brachii) is a long fusiform muscle, occupying the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The short head (caput breve) arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coraco-brachialis. The long head (caput longum) arises from the supraglenoid tubercle at the upper margin of the glenoid cavity, and is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by the transverse humeral ligament and by a fibrous prolongation from the tendon of the Pectoralis major. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can readily be separated until within about three inches of the elbow-joint. Here they end in a flattened tendon, which is inserted into the rough posterior portion of the tuberosity of the radius, a synovial bursa being interposed between the tendon and the front part of

the tuberosity. As the tendon of the muscle approaches the radius it is twisted upon itself, so that its anterior surface becomes external and is applied to the tuberosity of the radius at its insertion. Opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the *bicipital fascia* (*semilunar fascia*), which passes obliquely downwards and inwards across the brachial artery, and is continuous with the deep fascia covering the origins of the Flexor muscles of the forearm (fig. 517).

A third head to the Biceps is occasionally found, arising at the upper and inner part of the Brachialis anticus with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. In some instances the third head consists of two slips, which pass down, one in front of, the other behind the artery, concealing the vessel in the lower half of the arm.

Relations.—Its *anterior surface* is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciæ and the integument. Its *posterior surface* rests above on the shoulder-joint and upper part of the humerus; below, it lies on the Brachialis anticus, with the musculo-cutaneous nerve intervening between the two, and on the Supinator brevis. Its *inner border* is in relation with the Coraco-brachialis, and overlaps the brachial vessels and median nerve; its *outer border*, with the Deltoid and Brachio-radialis.

The **Brachialis anticus** (m. brachialis) is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backwards, and is broader in the middle than at either extremity. It arises from the lower half of the front of the humerus; and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below to within an inch of the margin of the articular surface. It also arises from the intermuscular septa, but more extensively from the inner than the outer; it is separated from the outer below by the Brachio-radialis and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is inserted into the tubercle of the ulna and the rough depression on the anterior surface of the coronoid process, being received into an interval between two fleshy slips of the Flexor profundus digitorum.

Relations.—The Brachialis anticus is in relation by its *anterior surface* with the Biceps, the brachial vessels, musculo-cutaneous and median nerves; by its *posterior surface*, with the humerus and front of the elbow-joint; by its *inner border*, with the Triceps, ulnar nerve, and Pronator teres, from which it is separated by the intermuscular septum; by its *outer border*, with the musculo-spiral nerve, radial recurrent artery, the Brachio-radialis, and Extensor carpi radialis longior.

Nerves.—The muscles of this group are supplied by the musculo-cutaneous nerve. The Brachialis anticus usually receives an additional filament from the musculo-spiral. The Coraco-brachialis receives its supply primarily from the seventh cervical, the Biceps and Brachialis anticus from the fifth and sixth cervical nerves.

Actions.—The Coraco-brachialis draws the humerus forwards and inwards, and at the same time assists in retaining the head of the bone in contact with the glenoid cavity. The Biceps is a flexor of the elbow and, to a less extent, of the shoulder: it is also a powerful supinator, and serves to render tense the deep fascia of the forearm by means of the bicipital fascia given off from its tendon. The Brachialis anticus is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps and Brachialis anticus flex the arm upon the forearm, as is seen in efforts of climbing.

Applied Anatomy.—The long tendon of the Biceps is sometimes dislocated from the bicipital groove. When this takes place, the arm becomes fixed in a position of abduction, but the head of the humerus can be felt in its proper position. It can generally be replaced by flexing the forearm on the arm and rotating the limb. Rupture of the long tendon of the Biceps may also take place.

7. *Posterior Humeral Region*

Triceps. Subanconeus.

The **Triceps** (m. triceps brachii) (fig. 520) is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and divided above into three parts, hence its name. These

three portions have been named (1) the middle, scapular, or long head; (2) the external, or long humeral head; and (3) the internal, or short humeral head. The external and internal heads are separated by the musculo-spiral groove containing the musculo-spiral nerve and superior profunda vessels.

The *middle* or *scapular head* (caput longum) arises by a flattened tendon from a rough triangular depression on the scapula, immediately below the glenoid cavity, being blended at its upper part with the capsular ligament; the muscular fibres pass downwards between the two other portions of the muscle, and join with them in the tendon of insertion.

The *external head* (caput laterale) arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculo-spiral groove and from the external border of the humerus and the external intermuscular septum; the fibres from this origin converge towards the tendon of insertion.

The *internal head* (caput mediale) arises from the posterior surface of the shaft of the humerus, below the musculo-spiral groove: it is narrow and pointed above, and extends from the insertion of the Teres major to within an inch of the trochlear surface: it also arises from the internal border of the humerus and from the back of the whole length of the internal and lower part of the external intermuscular septa. Some of the fibres are directed downwards to the olecranon, while others converge to the tendon of insertion.

The *tendon* of the Triceps commences about the middle of the back part of the muscle: it consists of two aponeurotic laminæ, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent; the other is more deeply seated in the substance of the muscle. After receiving the attachment of the muscular fibres, they join together above the elbow, and are inserted, for the most part, into the posterior portion of the upper surface of the olecranon process; a band of fibres is, however, continued downwards, on the outer side, over the Anconeus, to blend with the deep fascia of the forearm.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (fig. 520). The triangular space contains the dorsalis scapulæ vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps externally. The quadrangular space transmits the posterior circumflex vessels and the circumflex nerve; it is bounded by the Teres minor above, the Teres major below, the scapular head of the Triceps internally, and the humerus externally.

The **Subanconeus** is the name given to a few fibres from the under surface of the lower part of the Triceps muscle, which are inserted into the posterior ligament and synovial membrane of the elbow-joint. By some authors it is regarded as the homotype of the Subcrureus in the lower limb, but it is not a separate muscle.

Nerves.—The Triceps is supplied by the seventh and eighth cervical nerves through the musculo-spiral nerve.

Actions.—The Triceps is the great extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the Biceps and Brachialis anticus. When the arm is extended, the long head of the muscle may assist the Teres major and Latissimus dorsi in drawing the humerus backwards and in adducting it to the thorax. The long head protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downwards and backwards. The Subanconeus draws up the synovial membrane of the elbow-joint during extension of the forearm.

Applied Anatomy.—The existence of the strong insertion from the Triceps into the fascia of the forearm is of importance in excision of the elbow; it should always be carefully preserved from injury by the operator. By means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity—that is to say, by allowing the forearm to drop from its own weight.

III. Muscles and Fasciæ of the Forearm

The **deep fascia** of the forearm (fascia antibrachii), continuous above with that enclosing the arm, is a dense, highly glistening membranous investment,

which forms a general sheath enclosing the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and gives off from its deep surface numerous intermuscular septa, which enclose each muscle separately. In front it is continuous with the anterior annular ligament of the wrist, and forms a sheath for the tendon of the Palmaris longus muscle which passes over the annular ligament to be inserted into the palmar fascia. Behind, near the wrist-joint, it becomes much thickened by the addition of many transverse fibres, and forms the posterior annular ligament. It consists of circular and oblique fibres, connected together by numerous vertical fibres. It is much thicker on the posterior than on the anterior surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Biceps in front, and from the Triceps behind. Its deep surface gives origin to muscular fibres, especially at the upper part of the inner and outer sides of the forearm, and forms the boundaries of a series of cone-shaped cavities, in which the muscles are contained. Besides the vertical septa separating the individual muscles, transverse septa are given off both on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layers of muscles. Numerous apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins. Near the wrist, it is perforated on its anterior surface by the ulnar artery and nerve.

The muscles of the forearm may be subdivided into groups corresponding to the regions they occupy. One group occupies the inner and anterior aspect of the forearm, and comprises the Flexor and Pronator muscles. Another group occupies its outer side; and a third its posterior aspect. The two latter groups include all the Extensor and Supinator muscles.

8. *Anterior Radio-ulnar Region*

The muscles in this region are divided for convenience of description into two groups or layers, superficial and deep.

Superficial Layer (fig. 521)

Pronator teres.	Palmaris longus.
Flexor carpi radialis.	Flexor carpi ulnaris.
Flexor sublimis digitorum.	

These muscles take origin from the internal epicondyle of the humerus by a common tendon; they receive additional fibres from the deep fascia of the forearm near the elbow, and from the septa which pass inwards from this fascia between the individual muscles.

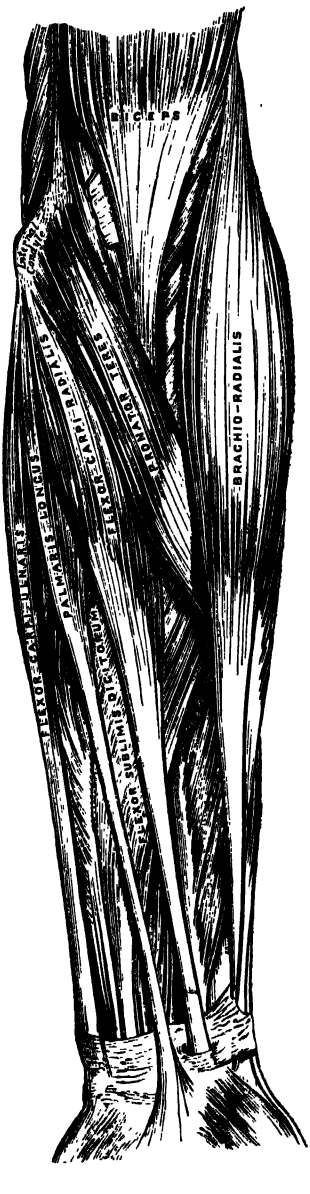
The **Pronator teres** has two heads of origin. One (caput humerale), the larger and more superficial, arises from the humerus, immediately above the internal epicondyle, and from the tendon common to the origin of the other muscles; also from the fascia of the forearm, and intermuscular septum between it and the Flexor carpi radialis. The deep head (caput ulnare) is a thin fasciculus, which arises from the inner side of the coronoid process of the ulna, and joins the preceding at an acute angle. The median nerve enters the forearm between the two heads of the muscle, and is separated from the ulnar artery by the deep head. The muscle passes obliquely across the forearm, and terminates in a flat tendon, which turns over the outer margin of the radius, and is inserted into a rough impression at the middle of the outer surface of the shaft of that bone. The outer border of the muscle forms the inner boundary of a triangular space (*antecubital fossa*) situated in front of the elbow-joint and containing the brachial artery, median nerve, and tendon of the Biceps.

Applied Anatomy.—This muscle, when suddenly brought into very active use, as in the game of lawn tennis, is apt to be strained, producing slight swelling, tenderness, and pain on putting the muscle into action. This is known as 'lawn-tennis arm.'

The **Flexor carpi radialis** lies on the inner side of the preceding muscle. It arises from the internal epicondyle by the common tendon; from the fascia

of the forearm; and from the intermuscular septa between it and the Pronator teres externally, the Palmaris longus internally, and the Flexor sublimis digitorum beneath. Slender and aponeurotic in structure at its commencement, it increases in size, and terminates in a tendon, which forms rather more than the lower half of its length. This tendon passes through a canal in the outer part of the annular ligament, runs through a groove in the trapezium (which is converted into a canal by a fibrous sheath, and lined by a synovial membrane), and is inserted into the base of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger. The radial artery, in the lower part of the forearm, lies between the tendon of this muscle and the Brachio-radialis, and may easily be tied in this situation.

Fig. 521.—Front of the left forearm. Superficial muscles.



The **Palmaris longus** is a slender, fusiform muscle, lying on the inner side of the preceding. It arises from the inner epicondyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender, flattened tendon, which passes over the upper part of the annular ligament, to end in the central part of the palmar fascia and lower part of the annular ligament, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent, and is subject to very considerable variations: it may be tendinous above and muscular below; or it may be muscular in the centre with a tendon above and below; or it may present two muscular bundles with a central tendon; or finally it may consist solely of a tendinous band. Just above the wrist, the median nerve lies close to the tendon, on its outer and posterior aspects.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It arises by two heads, connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head (caput humerale) arises from the inner epicondyle of the humerus by the common tendon; the other (caput ulnare) from the inner margin of the olecranon and from the upper two-thirds of the posterior border of the ulna by an aponeurosis, common to it and the Extensor carpi ulnaris and Flexor profundus digitorum; and from the intermuscular septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon, which occupies the anterior part of the lower half of the muscle, and is inserted into the pisiform bone, and is prolonged from this to the unciform and fifth metacarpal bones by the piso-unciform and piso-metacarpal ligaments; it is also attached by a few fibres to the annular ligament. The ulnar vessels and nerve lie on the outer side of the tendon of this muscle, in the lower two-thirds of the forearm; the tendon forming a guide in tying the artery in this situation.

The **Flexor sublimis digitorum** (m. flexor digitorum sublimis) is placed beneath the Flexor carpi ulnaris; it is the largest of the muscles of the superficial layer, and arises by three heads. One head (caput humerale) arises from the internal epicondyle of the humerus by the common tendon,

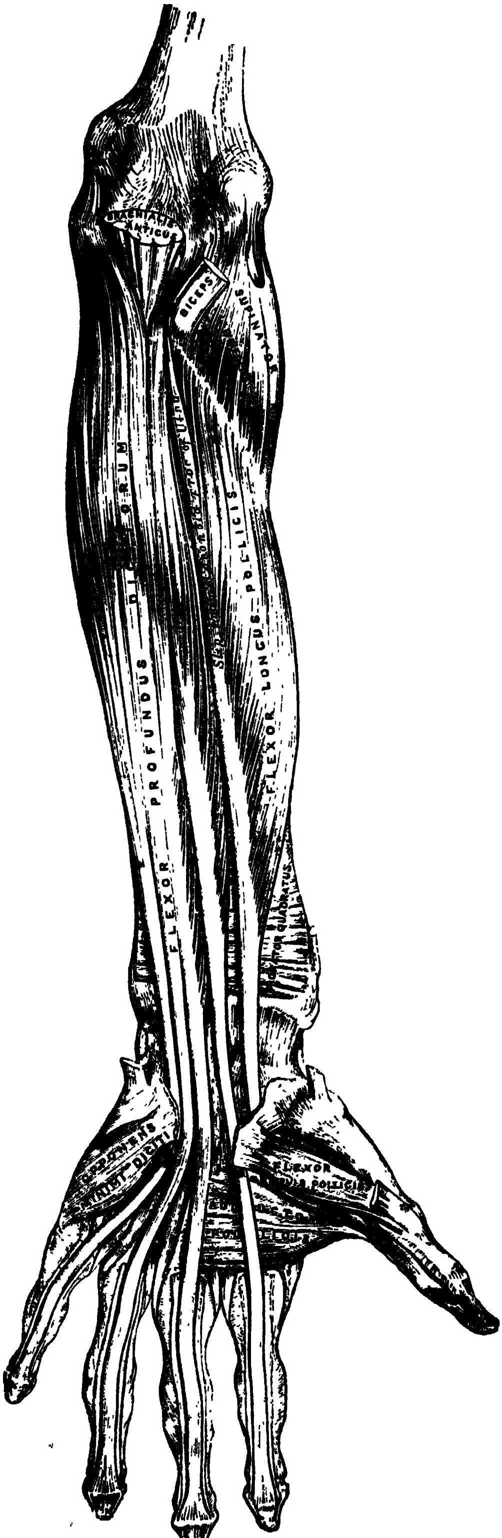


Fig. 522.—Front of the left forearm. Deep muscles.

from the internal lateral ligament of the elbow-joint, and from the intermuscular septa between it and the preceding muscles. The second head (caput ulnare) arises from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator teres (see fig. 358, page 302). The third head (caput radiale) arises from the oblique line of the radius, extending from the bicipital tuberosity to the insertion of the Pronator teres. The fibres pass vertically downwards, forming a broad and thick muscle, which speedily separates into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane gives off a muscular slip to join the part of the superficial plane which is associated with the tendon of the ring finger, and then divides into two parts, which end in tendons for the index and little fingers. As the four tendons thus formed pass beneath the annular ligament into the palm of the hand, they are arranged in pairs, the superficial pair corresponding to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another as they run onwards, and form posterior relations to the superficial palmar arch and digital branches of the median and ulnar nerves. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep Flexor tendon. Finally they subdivide a second time, to be inserted into the sides of the second phalanges about their middle. After leaving the palm, these tendons, accompanied by the deep Flexor tendons, lie in osseo-aponeurotic canals (fig. 522). The canals are completed by strong fibrous sheaths, which arch across the tendons, and are attached on each side to the margins of the phalanges.

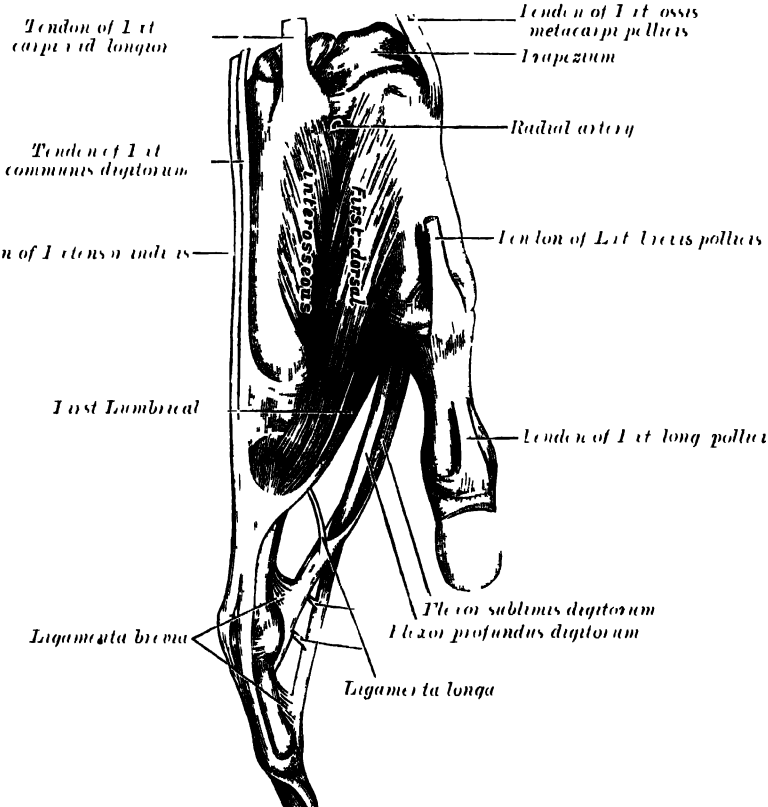
Opposite the middle of the proximal and second phalanges the sheaths are very strong, and the fibres pass transversely; but opposite the joints they are much thinner, and the fibres are directed obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendons.

Deep Layer (fig. 522)

Flexor profundus digitorum. Flexor longus pollicis.
Pronator quadratus.

The **Flexor profundus digitorum** (m. flexor digitorum profundus) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It arises from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and extending below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an aponeurosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of

FIG. 523.—Vincula accessoria and tendons of forefinger.



the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons: these run under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges, the tendons pass through the openings in the tendons of the Flexor sublimis digitorum, and are finally inserted into the bases of the last phalanges. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the three inner fingers are connected together by cellular tissue and tendinous slips, as far as the palm of the hand. The tendons of

this muscle and those of the Flexor sublimis digitorum, while contained in the osseo-aponeurotic canals of the fingers, are invested in synovial sheaths, and are connected to each other, and to the phalanges, by slender, tendinous filaments, called *vincula accessoria* (fig. 523). There are two sets of these: (*a*) the *ligamenta brevia*, which are two in number in each finger, and consist of triangular bands of fibres connecting the tendon of the Flexor sublimis digitorum to the front of the first interphalangeal joint and head of the first phalanx, ~~and the tendon of the~~ Flexor profundus digitorum to the front of the second interphalangeal joint and head of the second phalanx; (*b*) the *ligamenta longa*, which connect the under surfaces of the tendons of the Flexor profundus digitorum to those of the subjacent Flexor sublimis after the tendons of the former have passed through the latter. The ligamenta brevia of the deep Flexor tendons consist largely of yellow elastic tissue, and may assist in drawing down the tendons after flexion of the finger.

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles of the hand.

The **Flexor longus pollicis** (m. flexor pollicis longus) is situated on the radial side of the forearm, lying in the same plane as the preceding. It arises from the grooved anterior surface of the shaft of the radius, extending from immediately below the tuberosity and oblique line, to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane, and generally by a fleshy slip from the inner border of the coronoid process, or from the internal condyle of the humerus. The fibres proceed downwards, and terminate in a flattened tendon, which passes beneath the annular ligament, is then lodged in the interspace between the outer head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and, entering an osseo-aponeurotic canal similar to those for the other Flexor tendons, is inserted into the base of the last phalanx of the thumb. The anterior interosseous nerve and vessels pass downwards on the front of the interosseous membrane between the Flexor longus pollicis and Flexor profundus digitorum.

The **Pronator quadratus** is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It arises from the pronator ridge on the lower part of the anterior surface of the shaft of the ulna; from the inner part of the anterior surface of the lower fourth of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass outwards and slightly downwards, to be inserted into the lower fourth of the outer border and the anterior surface of the shaft of the radius. The deeper fibres of the muscle are inserted into the triangular area above the sigmoid cavity of the radius—an attachment comparable with the origin of the Supinator brevis from the triangular area below the lesser sigmoid cavity of the ulna.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. The Pronator teres, the Flexor carpi radialis, and the Palmaris longus derive their supply primarily from the sixth cervical; the Flexor sublimis digitorum from the seventh and eighth cervical and first thoracic, and the Flexor carpi ulnaris from the eighth cervical and first thoracic nerves. Of the deep layer, the Flexor profundus digitorum is supplied by the eighth cervical and first thoracic through the ulnar, and anterior interosseous branch of the median. The remaining two muscles, Flexor longus pollicis and Pronator quadratus, are also supplied by the eighth cervical and first thoracic through the anterior interosseous branch of the median.

Actions.—These muscles act upon the forearm, the wrist, and hand. The Pronator teres helps to rotate the radius upon the ulna, rendering the hand prone; when the radius is fixed, it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the flexors of the wrist; when acting alone, it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, in bending the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist; when acting alone, it flexes the wrist, inclining it to the ulnar side; and by continuing to contract, it bends the elbow. The Palmaris longus is a tensor of the palmar fascia. It also assists

in flexing the wrist and elbow. The Flexor sublimis digitorum flexes first the middle, and then the proximal phalanges. It assists in flexing the wrist and elbow. The Flexor profundus digitorum is one of the flexors of the phalanges. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one; but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The Flexor longus pollicis is a flexor of the phalanges of the thumb; when the thumb is fixed, it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

9. *Radial Region* (figs. 520, 522)

Brachio-radialis (*Supinator longus*). Extensor carpi radialis longior. Extensor carpi radialis brevior.

The **Brachio-radialis** (*Supinator longus*) is the most superficial muscle on the radial side of the forearm: it is fleshy for the upper two-thirds of its extent, tendinous below. It arises from the upper two-thirds of the external supracondylar ridge of the humerus, and from the external intermuscular septum, being limited above by the musculo-spiral groove. Interposed between it and the Brachialis anticus are the musculo-spiral nerve and the anastomosis between the anterior branch of the superior profunda artery and the radial recurrent. The fibres terminate above the middle of the fore-arm in a flat tendon, which is inserted into the outer side of the base of the styloid process of the radius. The tendon is crossed near its insertion by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; on its ulnar side is the radial artery.

The **Extensor carpi radialis longior** (m. extensor carpi radialis longus) is placed partly beneath the preceding muscle. It arises from the lower third of the external supracondylar ridge of the humerus, from the external intermuscular septum, and by a few fibres from the common tendon of origin of the Extensor muscles of the forearm. The fibres terminate at the upper third of the forearm in a flat tendon, which runs along the outer border of the radius, beneath the Extensor tendons of the thumb; it then passes beneath the posterior annular ligament of the wrist, where it lies in a groove on the back of the radius common to it and the Extensor carpi radialis brevior, immediately behind the styloid process. It is inserted into the posterior surface of the base of the metacarpal bone of the index finger, on its radial side.

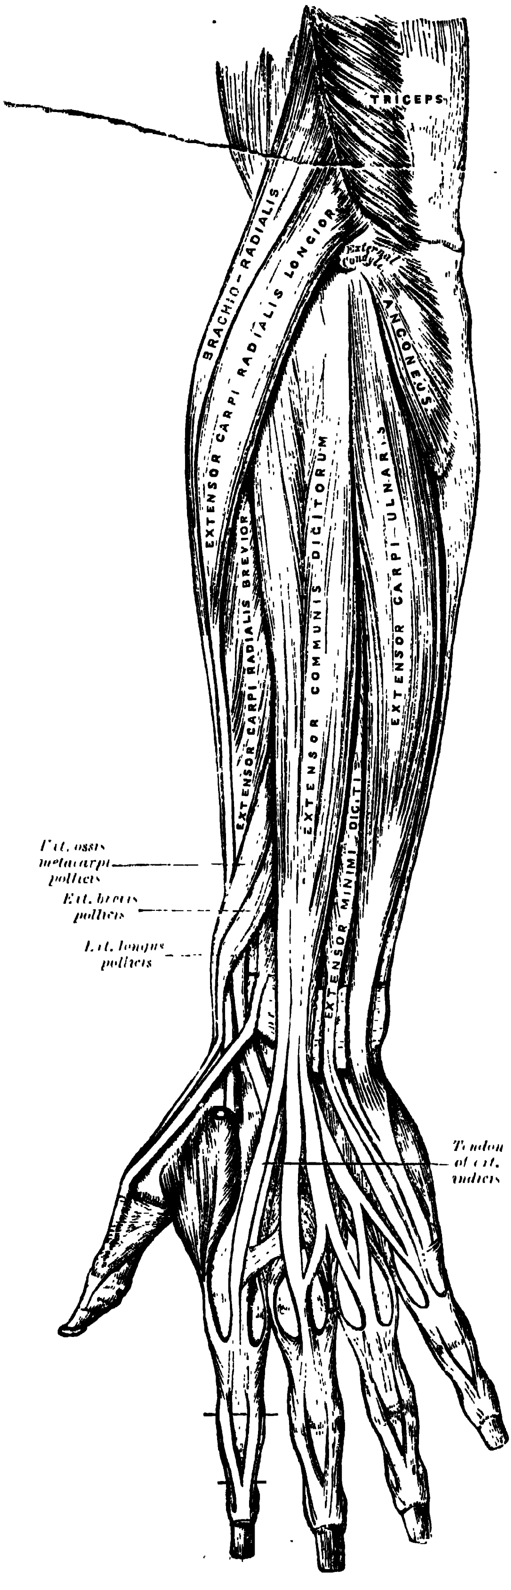
The **Extensor carpi radialis brevior** (m. extensor carpi radialis brevis) is shorter, as its name implies, and thicker than the preceding muscle, beneath which it is placed. It arises from the external epicondyle of the humerus, by a tendon common to it and the three following muscles; from the external lateral ligament of the elbow-joint; from a strong aponeurosis which covers its surface; and from the intermuscular septa between it and the adjacent muscles. The fibres terminate about the middle of the forearm in a flat tendon, which is closely connected with that of the preceding muscle, and accompanies it to the wrist; it passes beneath the Extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is inserted into the posterior surface of the base of the meta-carpal bone of the middle finger, on its radial side. Under the posterior annular ligament of the wrist the tendon lies on the back of the radius in a shallow groove, to the ulnar side of the groove which lodges the tendon of the Extensor carpi radialis longior, and separated from it by a faint ridge.

The tendons of the two preceding muscles pass through the same com-partment of the annular ligament, and are lubricated by a single synovial membrane.

10. *Posterior Radio-Ulnar Region* (fig. 524)

The muscles in this region are divided for purposes of description into two groups or layers, superficial and deep.

FIG. 524.—Posterior surface of the forearm. Superficial muscles.



Superficial Layer

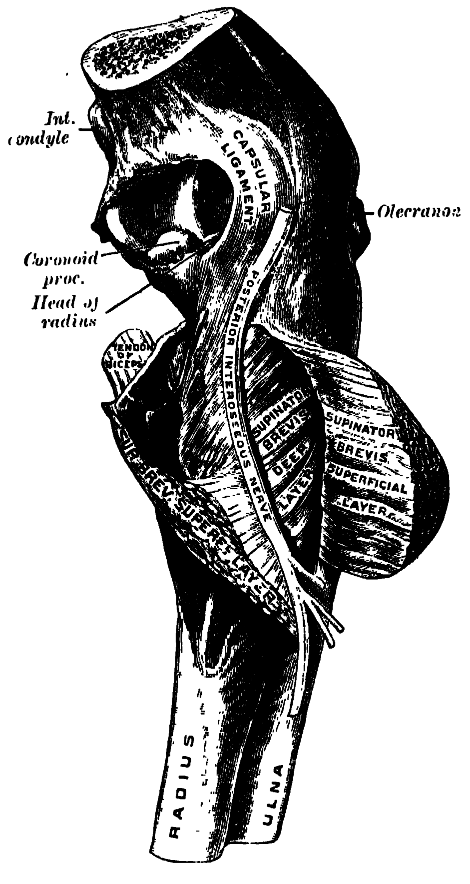
Extensor communis digitorum.
Extensor minimi digiti.
Extensor carpi ulnaris.
Anconeus.

The **Extensor communis digitorum** (m. extensor digitorum communis) is situated at the back part of the forearm. It arises from the external epicondyle of the humerus, by the common tendon; from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It divides below into four tendons, which pass, together with that of the Extensor indicis, through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, and, after passing across the back of the hand, are inserted into the second and third phalanges of the fingers in the following manner. Opposite the metacarpo-phalangeal articulation each tendon is bound by fasciculi to the lateral ligaments and serves as the posterior ligament; after having passed the joint, it spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx and is reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first interphalangeal joint this aponeurosis divides into three slips, a middle and two lateral: the former is inserted into the base of the second phalanx; and the two lateral, which are continued onwards along the sides of the second phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the last phalanx. As the tendons cross the interphalangeal joints, they furnish them with posterior ligaments. The tendon to the index finger is accompanied by the Extensor indicis, which lies on its inner side. On the back of the hand, the three inner tendons — those to the middle, ring, and little fingers—are connected by two obliquely placed bands, one from the third tendon passing downwards and outwards to the second tendon, and the other passing from the

same tendon downwards and inwards to the fourth. Occasionally the first tendon is connected to the second by a thin transverse band.

The **Extensor minimi digiti** (m. extensor digiti quinti proprius) is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It arises from the common Extensor tendon by a thin tendinous slip; and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate compartment in the annular ligament behind the inferior radio-ulnar joint, then divides into two as it crosses the hand, and is finally inserted into the expansion of the Extensor tendon on the dorsum of the first phalanx of the little finger.

FIG. 525.—Supinator brevis. (From a preparation in the Museum of the Royal College of Surgeons of England.)



The **Extensor carpi ulnaris** is the most superficial muscle on the ulnar side of the forearm. It arises from the external epicondyle of the humerus, by the common tendon; by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon, which runs through a groove behind the styloid process of the ulna, passing through a separate compartment in the annular ligament, and is inserted into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

The **Anconeus** is a small triangular muscle, placed on the back of the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It arises by a separate tendon from the back part of the external epicondyle of the humerus, and is inserted into the side of the olecranon, and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inwards.

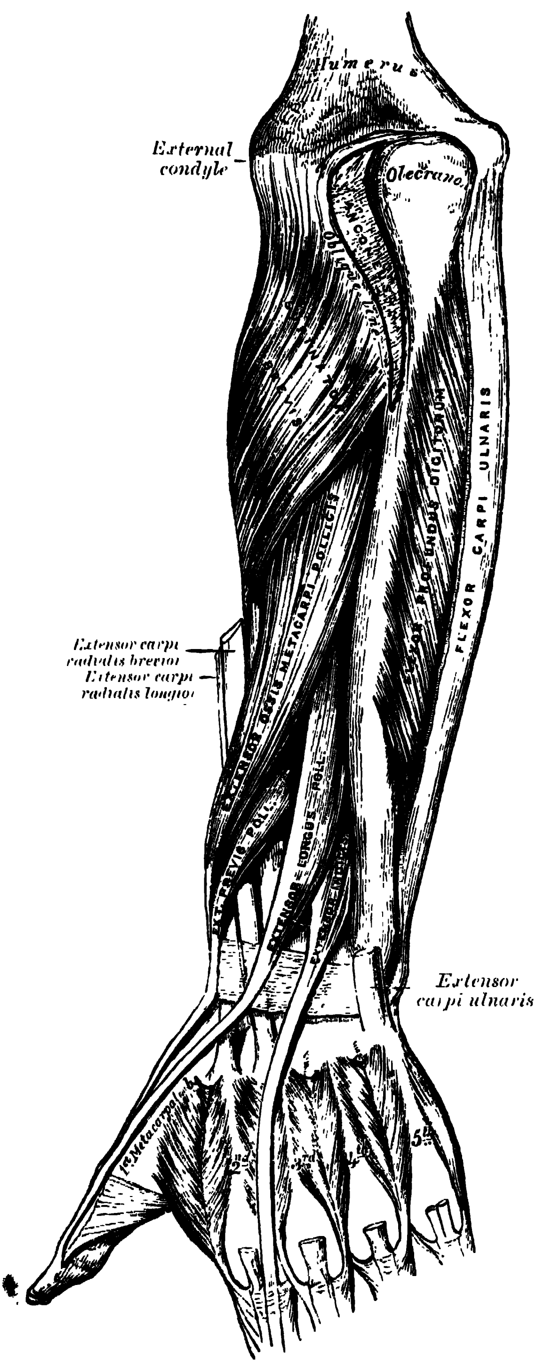
Deep Layer (figs. 525, 526)

Supinator brevis.	Extensor brevis pollicis.
Extensor ossis metacarpi pollicis.	Extensor longus pollicis.
Extensor indicis.	

The **Supinator brevis** (m. supinator) (fig. 525) is a broad muscle, of a hollow cylindrical form, curved round the upper third of the radius. It consists of two distinct planes of muscular fibres, between which the posterior interosseous nerve lies. The two planes arise in common, the superficial one by tendinous, and the deeper by muscular fibres: from the external epicondyle of the humerus; from the external lateral ligament of the elbow-joint, and the orbicular ligament; from the ridge on the ulna, which runs obliquely downwards from the posterior extremity of the lesser sigmoid cavity;

from the triangular depression below that cavity; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are inserted into the outer edge of the bicipital tuberosity and the oblique line of the radius, as low down as the insertion of the Pronator teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its inner surface: the greater part of this portion of the muscle is inserted into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone.

Fig. 526.—Posterior surface of the forearm. Deep muscles.



The **Extensor ossis metacarpi pollicis** (m. abductor pollicis longus) is the most external and the largest of the deep Extensor muscles; it lies immediately below the Supinator brevis, with which it is sometimes united. It arises from the outer part of the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the shaft of the radius. Passing obliquely downwards and outwards, it terminates in a tendon, which runs through a groove on the outer side of the lower end of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is inserted into the outer side of the base of the metacarpal bone of the thumb. It occasionally gives off two slips near its insertion: one to the trapezium, and the other to blend with the origin of the Abductor pollicis.

The **Extensor brevis pollicis,** the smallest muscle of this group, lies on the inner side of the preceding. It arises from the posterior surface of the shaft of the radius below the Extensor ossis metacarpi pollicis, and from the interosseous membrane. Its direction is similar to that of the Extensor ossis metacarpi pollicis, its tendon passing through the same groove on the outer side of the lower end of the radius, to be inserted into the base of the first phalanx of the thumb. It is closely connected

with the Extensor ossis metacarpi pollicis, of which it is usually regarded as a segment.

The **Extensor longus pollicis** is much larger than the preceding muscle, the origin of which it partly covers. It arises from the outer part of the middle third of the posterior surface of the shaft of the ulna below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon, which passes through a separate compartment in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and brevior, being separated from the other Extensor tendons of the thumb by a triangular interval, in which the radial artery is found; and is finally inserted into the base of the last phalanx of the thumb. The radial artery is crossed by the tendons of all three Extensors of the thumb as they pass from the radius to the digit.

The **Extensor indicis** (m. extensor indicis proprius) is a narrow, elongated muscle, placed on the inner side of, and parallel with, the preceding. It arises from the posterior surface of the shaft of the ulna below the origin of the Extensor longus pollicis, and from the interosseous membrane. Its tendon passes under the annular ligament in the same compartment as that which transmits the Extensor communis digitorum, and opposite the lower end of the corresponding metacarpal bone, joins the ulnar side of the tendon of the Extensor communis which belongs to the index finger.

Nerves.—The Brachio-radialis is supplied by the fifth and sixth, the Extensores carpi radialis longior et brevior by the sixth and seventh, and the Anconeus by the seventh and eighth cervical nerves, all through the musculo-spiral nerve; the remaining muscles are innervated through the posterior interosseous nerve, the Supinator brevis being supplied by the sixth cervical, and all the other muscles by the seventh cervical.

Actions.—The muscles of the radial and posterior aspects of the forearm, which comprise all the Extensor and Supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the Pronator and Flexor muscles. The Anconeus assists the Triceps in extending the forearm. The Brachio-radialis is a flexor of the elbow-joint, but only acts as such when the movement of flexion has been initiated by the Biceps and Brachialis anticus. The Supinator brevis is a supinator: that is to say, when the radius has been carried across the ulna in pronation, and the back of the hand is directed forwards, this muscle carries the radius back again to the outer side of the ulna, and the palm of the hand is again directed forwards. The Extensor carpi radialis longior extends the wrist and abducts the hand. It may also assist in bending the elbow-joint; at all events it serves to fix or steady this articulation. The Extensor carpi radialis brevior assists the Extensor carpi radialis longior in extending the wrist, and may also act slightly as an abductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it towards the ulnar side: by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the middle and terminal phalanges being acted upon mainly by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends the little finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed while the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outwards and backwards from the palm of the hand, and hence it has been called the *Abductor pollicis longus*. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor longus pollicis extends the terminal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the index finger, and by its continued action assists in extending the wrist.

Applied Anatomy.—The tendons of the Extensor muscles of the thumb are liable to become strained, and their sheaths inflamed, after excessive exercise, producing a sausage-shaped swelling along the course of the tendons and giving a peculiar grating sensation

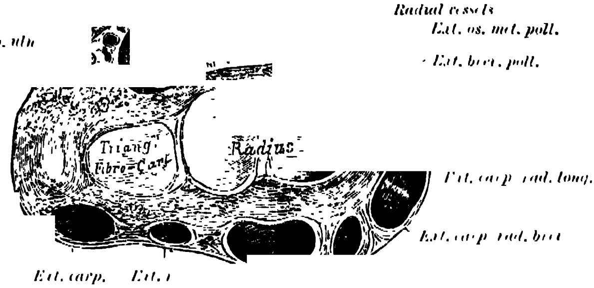
to the finger when the muscles act. The condition is known as *tenosynovitis*, and the coarse grating is quite distinctive.

Paralysis of the Extensor muscles of the wrists and fingers is common in acute or chronic lead-poisoning, and is known as 'wrist-drop.' The Brachio-radialis usually escapes in these cases, unless the muscles of the upper arm are paralysed also. Usually the different Extensor muscles are affected to different extents; thus the thumb, or index, or little finger, may ~~be but slightly~~ implicated, and may recover rapidly while the Extensors of the other fingers or the wrist remain powerless. Some paresis is often shown by the Flexors of the fingers also, these muscles being thrown into a state of tremor whenever extension of the fingers is attempted. Atrophy often follows paralysis in lead poisoning.

IV. Muscles and Fasciæ of the Hand

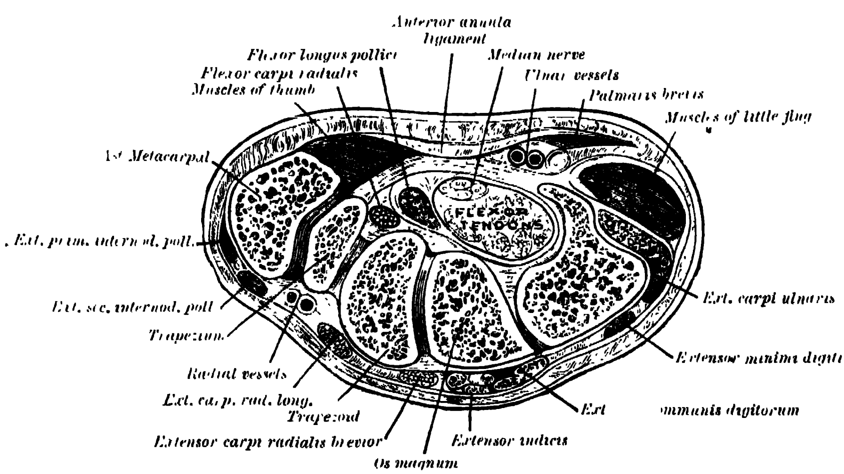
The muscles of the hand are subdivided into three groups: 1, Those of the thumb, which occupy the radial side and produce the *thenar* eminence;

Fig. 527.—Transverse section through the wrist, showing the annular ligaments and the canals for the passage of the tendons.



2, those of the little finger, which occupy the ulnar side and give rise to the *hypothenar* eminence; 3, those in the middle of the palm and within the interosseous spaces.

Fig. 528.—Transverse section through the carpus, showing the relative positions of the tendons, vessels, and nerves. (Henle.)

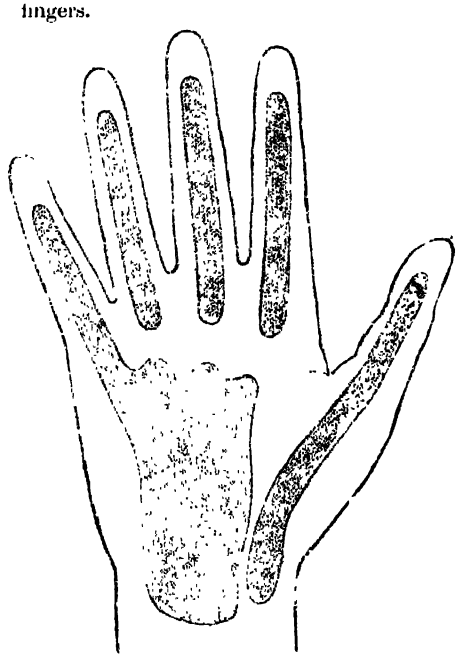


The **anterior annular ligament** (lig. carpi volare) (figs. 527, 528) is a strong, fibrous band, which arches over the carpus, converting the deep groove on the front of the carpal bones into a tunnel, through which the Flexor

tendons of the digits pass. It is attached, internally, to the pisiform and the hook of the unciform; externally, to the tuberosity of the scaphoid, and to the inner part of the anterior surface and the ridge of the trapezium. It is continuous, above, with the deep fascia of the forearm, and may be regarded as a thickened portion of this; and below, with the palmar fascia. It is crossed by the ulnar vessels and nerve, and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligament to the bone. It has inserted into its anterior surface a part of the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from it, below, the small muscles of the thumb and little finger. Beneath it pass the tendons of the Flexores sublimis et profundus digitorum, the tendon of the Flexor longus pollicis, and the median nerve.

The **synovial membranes of the flexor tendons at the wrist.**—There are two synovial membranes which enclose all the tendons as they pass beneath this ligament, one for the Flexores sublimis et profundus digitorum, the other for the Flexor longus pollicis (fig. 529). They extend up into the forearm for about an inch above the annular ligament, and occasionally communicate with each other under the ligament. The sheath which surrounds the Flexor tendons of the fingers extends downwards about halfway along the metacarpal bones, where it terminates in blind diverticula around the tendons to the index, middle, and ring fingers. In the case of the little finger, it is prolonged on its tendons, and usually communicates with the synovial sheath of that digit. The sheath which envelops the tendon of the Flexor longus pollicis is continued along the thumb as far as the insertion of the tendon.

Fig. 529.—Diagram showing the arrangement of the synovial sheaths of the palm and fingers.

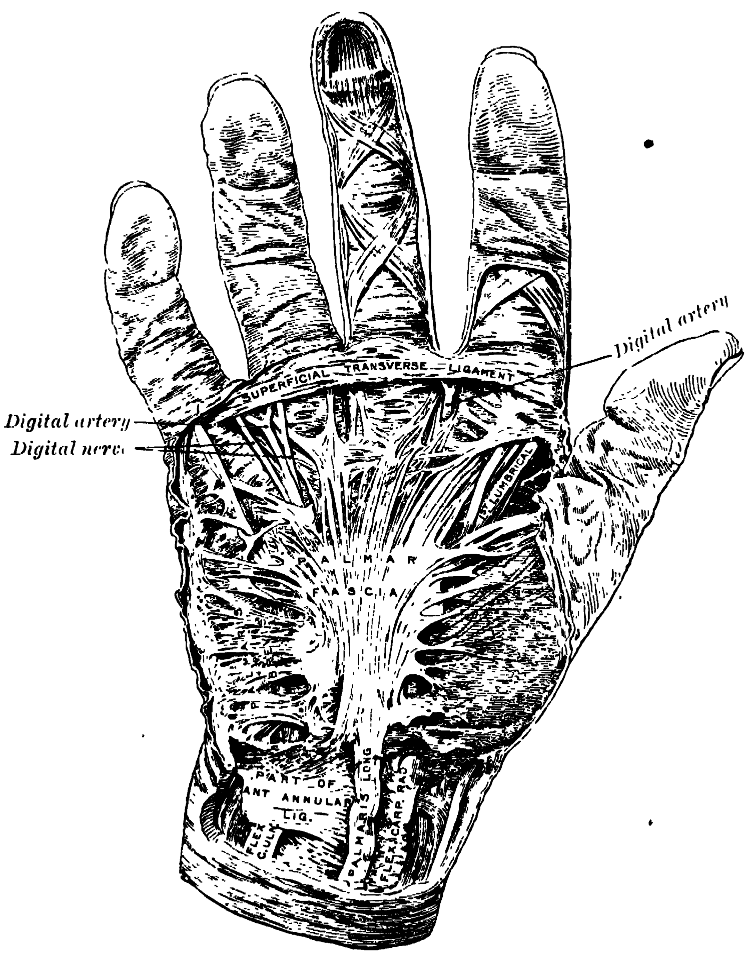


The **posterior annular ligament** (lig. carpi dorsale) (figs. 527, 528) is a strong, fibrous band, extending obliquely downwards and inwards across the back of the wrist, and consisting of part of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It binds down the Extensor tendons in their passage to the fingers, being attached, internally, to the styloid process of the ulna and to the cuneiform and pisiform; externally, to the outer margin of the radius; and, in its passage across the wrist, to the elevated ridges on the posterior surface of the radius. Between it and the bones are formed six compartments for the passage of tendons, each of which is lined by a separate synovial membrane. One is found in each of the following positions: 1, on the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis; 2, behind the styloid process, for the tendons of the Extensores carpi radialis longior et brevior; 3, about the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis; 4, to the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis; 5, opposite the interval between the radius and ulna, for the Extensor minimi digiti; 6, grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris. The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament, down upon the tendons for a variable distance on the back of the hand.

The **deep palmar fascia** (aponeurosis palmaris) (fig. 530) forms a common sheath which invests the muscles of the hand. It consists of a central and two lateral portions.

The *central portion* occupies the middle of the palm, is triangular in shape, of great strength and thickness, and binds down the tendons and protects the vessels and nerves in this situation. It is narrow above, where it is attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. Below, it is broad and expanded, and divides into four slips, one for each finger. Each slip gives off superficial fibres, which are inserted into the skin of the palm and finger, those to the

FIG. 530.—Palmar fascia.
(From a preparation in the Museum of the Royal College of Surgeons of England.)



palm joining the skin at the furrow corresponding to the metacarpo-phalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the fibrous sheaths which confine the Flexor tendons. From the sides of these processes offsets are sent backwards, to be attached to the transverse metacarpal ligament. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the Flexor tendons pass. Between the two processes into which each slip divides is attached the *digital sheath.* The intervals left between the four fibrous slips transmit the digital vessels and nerves, and the tendons of the Lumbricales. At the points of division of the

palmar fascia into the slips above mentioned, numerous strong, transverse fibres (fasciculi transversi) bind the separate processes together. The palmar fascia is intimately adherent to the integument by dense fibro-areolar tissue forming the superficial palmar fascia, and gives origin by its inner margin to the Palmaris brevis. It covers the superficial palmar arch, the tendons of the Flexor muscles, and the branches of the median and ulnar nerves; and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis, and separates the lateral from the middle palmar group of muscles.

The *lateral portions* of the palmar fascia are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger; they are continuous with the central portion of the palmar fascia and with the fascia on the dorsum of the hand.

The **superficial transverse ligament** of the fingers is a thin band of transverse fibres (fasciculi transversi); it stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onwards to their destination.

Applied Anatomy.—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity, known as 'Dupuytren's contraction.' The ring and little fingers are most frequently implicated, but the others may also be involved. The proximal phalanx is drawn down and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

Owing to their constant exposure to injury and septic influences, the fingers are very liable to become the seat of serious inflammatory mischief. To this inflammation the term *paronychia* or *whitlow* is given, and this affection may assume various degrees of severity. In the mildest cases the disease is confined to the superficial layer of the skin, and suppuration takes place beneath it. This is known as *subcuticular paronychia*, and is a comparatively simple condition, for an incision through the epidermis will at once relieve it. The only complication is that the pus may burrow under the nail, causing increased pain. A more severe condition is the *paronychia cellulosa*, in which the pulp of the end of the finger is involved. This is attended with intense throbbing pain, owing to the fact that the inflamed area is covered by thick and often horny epithelium, when the disease occurs in the labouring classes, as it so frequently does. In these cases, unless a timely incision is made, the inflammation is liable to involve the periosteum covering the phalanx, as there is least resistance in this direction, and *subperiosteal paronychia* is set up, which is followed by necrosis of a part or the whole of the ungual phalanx. In other cases, the inflammation may involve the theca of the Flexor tendons, and a *thecal paronychia* may be set up. The inflammation then rapidly spreads up the sheath; but the extent will depend upon the particular digit involved. From the description of the Flexor sheaths given above, it will be evident that inflammation of the sheath of the thumb and little finger may prove a far more formidable affection than that of the other three digits, because the sheaths of these two digits communicate with the large synovial sheaths which surround the Flexor tendons (page 551), and the inflammation may extend into the palm of the hand and beneath the annular ligament into the forearm.

In order to relieve these conditions, free and early incisions are necessary, and must be made with discrimination, in order to avoid wounding important structures. In the pulp of the finger—i.e. over the distal phalanx—the incision should be made in the middle line and down to the bone. In the rest of the finger, the incision should be made in the middle line over the phalanges, and not over the interphalangeal joints. In the palm of the hand, incisions may be made either on the distal or proximal side of the superficial palmar arch. On the distal sides the incisions should be made over the metacarpal bones, preferably those of the index and middle finger. On the proximal side, the safest line of incision is along the radial side of the hypothenar eminence, between the ulnar artery and nerve internally, and the median nerve externally. When suppuration has extended under the annular ligament, and incisions are required in the forearm, the positions in which they should be made are over the tendons of the Flexor sublimis digitorum, between the median nerve and the ulnar artery, and over the tendon of the Flexor longus pollicis, between the radial artery and the tendon of the Flexor carpi radialis.

Chronic inflammation of the common flexor sheath is occasionally met with, constituting a disease known as 'compound palmar ganglion': it presents an hourglass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction, corresponding to the annular ligament, between the two. The fluid can be forced from the one swelling to the other under the ligament, and when this is done, a creaking sensation is sometimes perceived, from the presence of 'melon-seed' bodies in the interior of the ganglion.

11. *Radial Region* (figs. 531, 532)

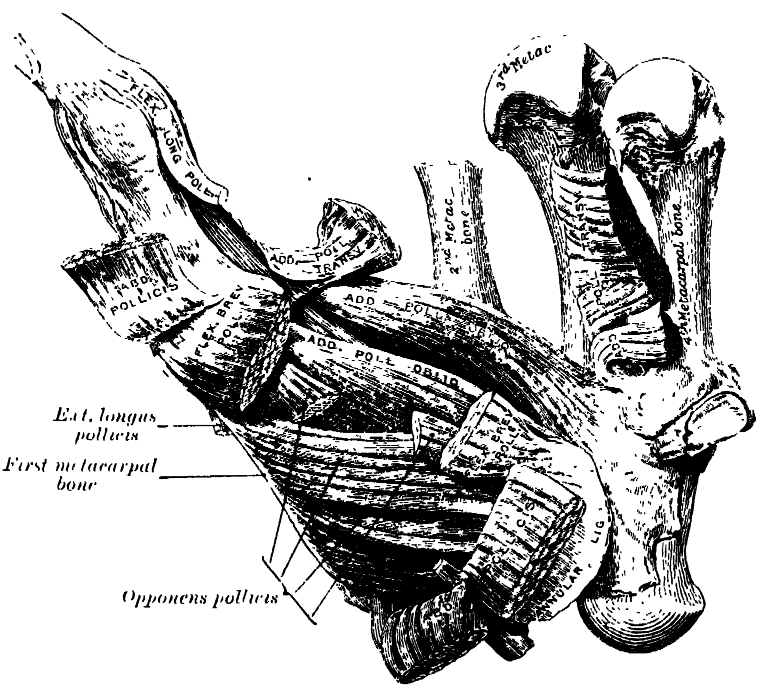
Abductor pollicis.	Flexor brevis pollicis.
Opponens pollicis.	Adductor obliquus pollicis.

Adductor transversus pollicis.

The **Abductor pollicis** (m. abductor pollicis brevis) is a thin, flat muscle, placed immediately beneath the integument. It arises from the annular ligament, the tuberosity of the scaphoid, and the ridge of the trapezium, frequently by two distinct slips. Running outwards and downwards, it is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb and the capsule of the metacarpo-phalangeal articulation.

The **Opponens pollicis** is a small, triangular muscle, placed beneath the preceding. It arises from the palmar surface of the ridge on the trapezium and from the annular ligament, passes downwards and outwards, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

Fig. 531.—Muscles of the thumb.
(From a preparation in the Museum of the Royal College of Surgeons of England.)

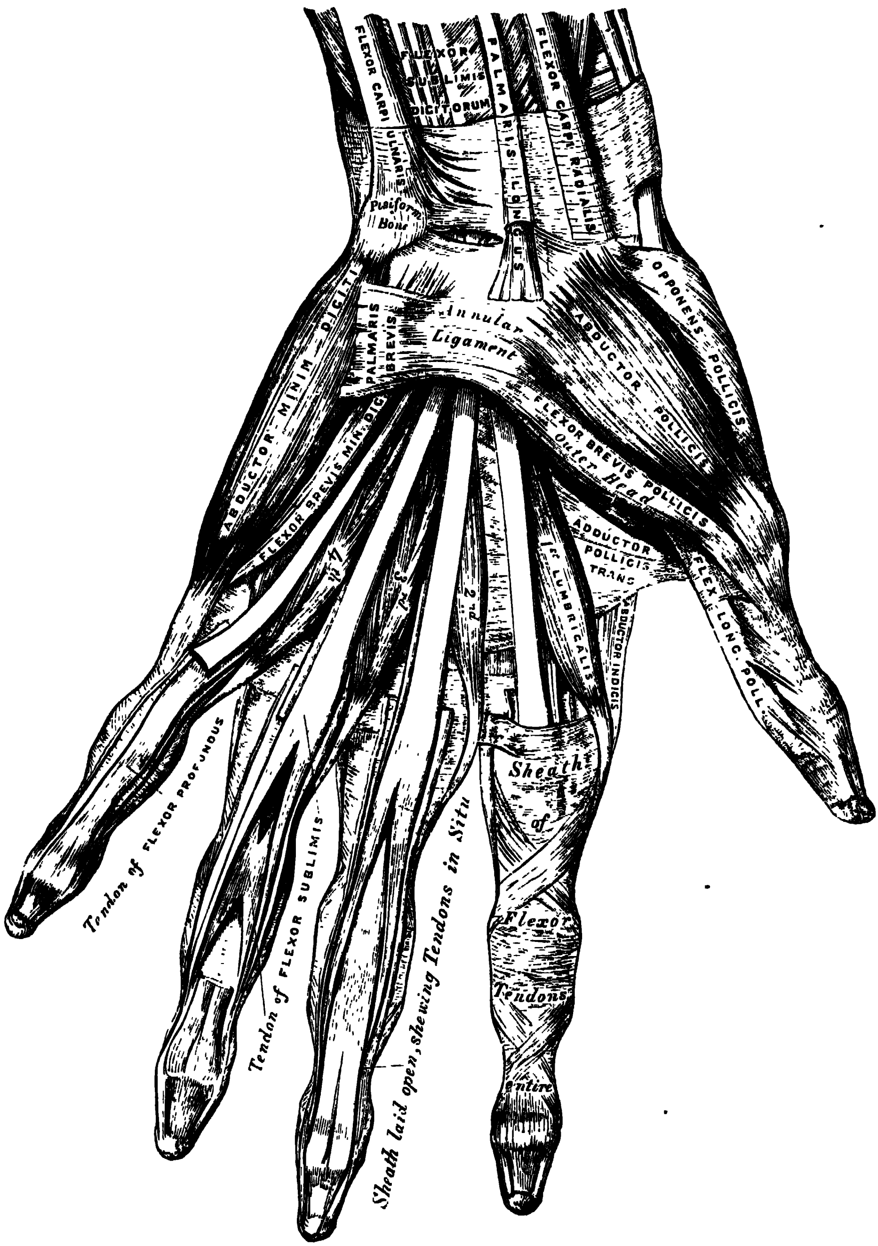


The **Flexor brevis pollicis** consists of two portions, outer and inner. The *outer and more superficial portion* arises from the outer two-thirds of the lower border of the annular ligament and the lower part of the ridge on the trapezium: it passes along the outer side of the tendon of the Flexor longus pollicis, and, becoming tendinous, has a sesamoid bone developed in its tendon, and is inserted into the outer side of the base of the first phalanx of the thumb. The *inner and deeper portion* of the muscle is very small, and arises from the ulnar side of the first metacarpal bone between the Adductor obliquus pollicis and the outer head of the First dorsal interosseous, and is inserted into the inner side of the base of the first phalanx with the Adductor obliquus pollicis.

The **Adductor obliquus pollicis** arises by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior carpal ligaments, and the sheath of the tendon of the Flexor carpi radialis.

From this origin the greater number of fibres pass obliquely downwards and converge to a tendon, which, uniting with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is inserted into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however,

Fig. 532.—Muscles of the left hand. Palmar surface.



passes more obliquely outwards beneath the tendon of the long Flexor to join the superficial portion of the short Flexor and the Abductor pollicis.

The **Adductor transversus pollicis** (fig. 531) is the most deeply seated of this group of muscles. It is of a triangular form, arising by its broad base from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface; the fibres, proceeding outwards, converge, to be inserted,

with the inner part of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb.

Nerves.—The Abductor, Opponens, and outer head of the Flexor brevis pollicis are supplied by the sixth cervical nerve through the median nerve; the inner head of the Flexor brevis, and the Adductors, by the eighth cervical through the ulnar nerve.

Actions.—The Abductor pollicis draws the thumb forwards in a plane at right angles to that of the palm of the hand. The Adductores pollicis are the opponents of this muscle, and approximate the thumb to the palm. The Opponens pollicis flexes the metacarpal bone: that is, draws it inwards over the palm and the Flexor brevis pollicis flexes and adducts the proximal phalanx.

12. *Ulnar Region* (fig. 532)

Palmaris brevis.	Flexor brevis minimi digiti.
Abductor minimi digiti.	Opponens minimi digiti.

The **Palmaris brevis** is a thin, quadrilateral muscle, placed beneath the integument of the ulnar side of the hand. It arises by tendinous fasciculi from the annular ligament and palmar fascia; the fleshy fibres pass inwards, to be inserted into the skin on the inner border of the palm of the hand.

The **Abductor minimi digiti** (m. abductor digiti quinti) is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and terminates in a flat tendon, which divides into two slips; one is inserted into the ulnar side of the base of the first phalanx of the little finger; the other into the ulnar border of the aponeurosis of the Extensor minimi digiti.

The **Flexor brevis minimi digiti** (m. flexor digiti quinti brevis) lies on the same plane as the preceding muscle, on its radial side. It arises from the convex surface of the hook of the unciform bone, and the anterior surface of the annular ligament, and is inserted into the inner side of the base of the first phalanx of the little finger. It is separated from the Abductor at its origin, by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.

The **Opponens minimi digiti** (m. opponens digiti quinti) (fig. 522) is of a triangular form, and placed immediately beneath the preceding muscles. It arises from the convexity of the hook of the unciform bone, and contiguous portion of the annular ligament; its fibres pass downwards and inwards, to be inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

Nerves.—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The Abductor and Flexor brevis minimi digiti abduct the little finger from the ring finger and assist in flexing the proximal phalanx. The Opponens minimi digiti draws forwards the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the inner side of the palm of the hand.

13. *Middle Palmar Region*

Lumbricales.	Interossei.

The **Lumbricales** (fig. 532) are four small fleshy fasciculi, accessories to the Flexor profundus digitorum. They arise from the tendons of this muscle: the first and second, from the radial side and palmar surface of the tendons of the index and middle fingers respectively; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and opposite the metacarpo-phalangeal articulation is inserted into the tendinous expansion of the Extensor communis digitorum covering the dorsal aspect of the finger.

The **Interossei** (figs. 533, 534) are so named from occupying the intervals between the metacarpal bones, and are divided into two sets, a dorsal and a palmar.

The **Dorsal interossei** (interossei dorsales) are four in number, larger than the Palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, each arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeuroses of the common Extensor tendons. Between the double origin of each of these muscles is a narrow triangular interval, through the first of which the radial artery passes; through each of the other three a perforating branch from the deep palmar arch is transmitted.

The *First dorsal interosseous muscle*, or *Abductor indicis*, is larger than the others. It is flat, triangular in form, and arises by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of the hand. The outer head arises from the upper half of the ulnar border of the first metacarpal bone; the inner head, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The *Second* and *Third dorsal interossei* are

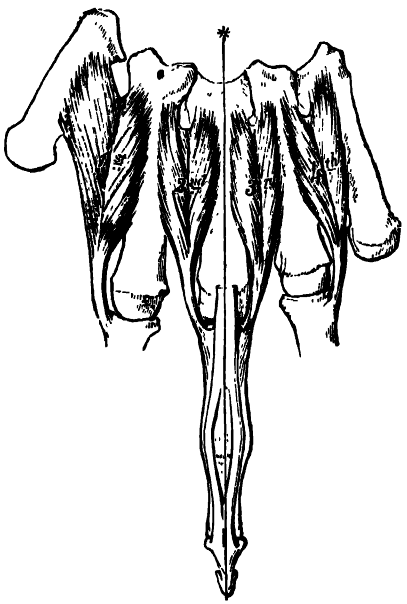


FIG. 533.—The Dorsal interossei of left hand.

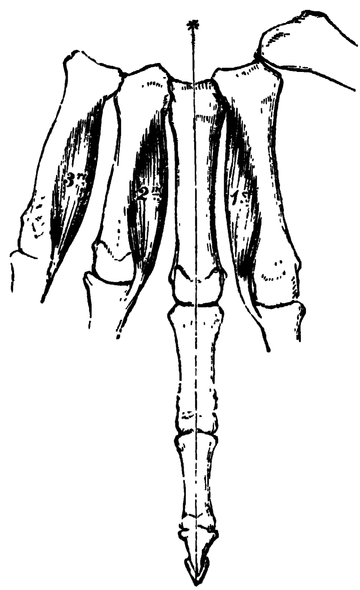

FIG. 534.—The Palmar interossei of left hand.

inserted into the middle finger, the former into its radial, the latter into its ulnar side. The *Fourth* is inserted into the ulnar side of the ring finger.

The **Palmar interossei** (interossei volares), three in number, are smaller than the Dorsal, and placed upon the palmar surfaces of the metacarpal bones, rather than between them. Each arises from the entire length of the metacarpal bone of one finger, and is inserted into the side of the base of the first phalanx and aponeurotic expansion of the common Extensor tendon of the same finger.

The *First* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The *Second* arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The *Third* arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with two Interossei, with the exception of the little finger, in which the Abductor muscle takes the place of one of the pair.

Nerves.—The two outer Lumbricales are supplied by the sixth cervical nerve, through the third and fourth digital branches of the median nerve: the two inner

Lumbricales and all the Interossei are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. The third Lumbrical frequently receives a twig from the median.

Actions.—The Palmar interosseous muscles adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the Dorsal interossei abduct the fingers from that line. In addition to this the Interossei, in conjunction with the Lumbricales, flex the first phalanges at the metacarpo-phalangeal joints, and extend the second and third phalanges in consequence of their insertions into the expansions of the Extensor tendons. The Extensor communis digitorum is believed to act almost entirely on the first phalanges.

Surface Form.—The *Pectoralis major* largely influences surface form and conceals a considerable part of the thoracic wall in front. Its sternal origin presents a border, which bounds and determines the width of the sternal furrow. Its clavicular origin is somewhat depressed and flattened, and between the two portions of the muscle there is often an oblique depression. The outer margin of the muscle is generally well marked above, and forms the inner boundary of a triangular depression, the infraclavicular fossa, which separates the Pectoralis major from the Deltoid. It gradually becomes less marked as it approaches the tendon of insertion, and is more closely blended with the Deltoid muscle. The lower border of the Pectoralis major forms the rounded anterior axillary fold, and corresponds with the direction of the fifth rib. When the arm is raised, the lowest slip of origin of the *Pectoralis minor* produces a local fulness just below the border of the anterior fold of the axilla, and serves to break the sharp outline of the lower border of the Pectoralis major muscle. The origin of the *Serratus magnus* causes a very characteristic surface marking. When the arm is raised from the side, the lower five or six serrations are plainly discernible, forming a zigzag line, caused by the digitations, which diminish in size from above downwards, and have their apices arranged on a curve. When the arm is lying by the side, the first serration to appear at the lower margin of the Pectoralis major is the one attached to the fifth rib.

The *Deltoid*, with the prominence of the upper extremity of the humerus, produces the rounded contour of the shoulder. It is rounder and fuller in front than behind, where it presents a somewhat flattened form. Above, its anterior border presents a rounded, slightly curved eminence, which forms the outer boundary of the infraclavicular fossa; below, it is closely united with the Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. The insertion of the Deltoid is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the *Teres major*; it assists the Latissimus dorsi in forming the thick, rounded, posterior fold of the axilla. When the arm is raised, the *Coraco-brachialis* reveals itself as a long, narrow elevation, which emerges from under cover of the anterior fold of the axilla and runs internal to the shaft of the humerus. The front and inner part of the arm presents the prominence of the Biceps, bounded on either side by an intermuscular depression. This muscle determines the contour of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper tendons are concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form. On either side of the Biceps, at the lower part of the arm, the *Brachialis anticus* is discernible. On the outer side it forms a narrow eminence, which extends some distance up the arm; on the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the *Triceps* may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the tendon of the muscle on the lower part of the back of the arm. The tendon of insertion of the muscle extends about halfway up the back of the arm, and forms an elongated flattened plane when the muscle is in action. Under similar conditions the surface forms produced by the inner and outer heads of the muscle are well seen.

On the anterior aspect of the elbow are two muscular elevations, one on either side, separated above, and converging below so as to form the inner and outer boundaries of a triangular space, the anticubital fossa. Of these, the inner elevation, consisting of the Pronator teres and the Flexors, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle, and gradually tapering off below. The *Pronator teres*, the outermost muscle of the group, forms the inner boundary of the anticubital fossa. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the *Flexor carpi radialis*, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and may be traced downwards to its tendon, which can be felt lying on the front of the wrist, nearer its radial than its ulnar border, and to the inner side of the radial artery. The *Palmaris longus* presents no surface marking

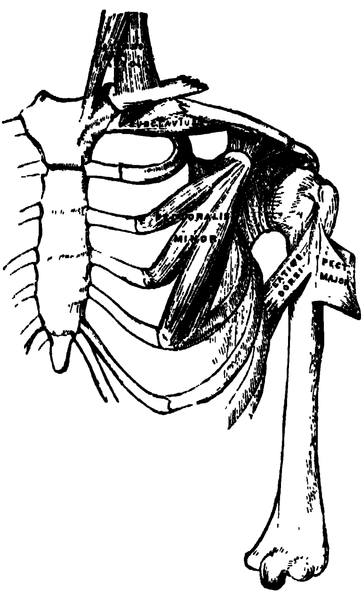
above, but below, its tendon is the most prominent of the tendons on the front of the wrist, standing out, when the muscle is in action, as a sharp tense cord beneath the skin. The *Flexor sublimis digitorum* does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the Palmaris longus and the Flexor carpi ulnaris. The *Flexor carpi ulnaris* occupies a small part of the posterior surface of the forearm, and is separated from the Extensor and Supinator group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The external group of muscles, consisting of the Brachio-radialis, the Extensors and Supinator brevis, occupies the outer, and a considerable portion of the posterior, surface of this region. It forms a fusiform mass, which is altogether on a higher level than that produced by the Pronator teres and Flexors. Its apex is between the Triceps and Brachialis anticus muscles some distance above the elbow-joint; it acquires its greatest breadth opposite the external condyle, below which it shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these eminences consists of the Brachio-radialis and the Extensores carpi radialis longior et brevior, and descends from the external condylar ridge in the direction of the styloid process of the radius. The inner consists of the Extensor communis digitorum, the Extensor minimi digiti, and the Extensor carpi ulnaris; it commences above as a tapering mass at the external condyle of the humerus; above it is separated from the Anconeus by a well-marked furrow, and below, from the Pronator teres and Flexor mass by the ulnar furrow. The only two muscles of this region which require special mention, as independently influencing surface form, are the Brachio-radialis and the Anconeus. The inner border of the *Brachio-radialis* forms the outer boundary of the anticubital fossa. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced to the styloid process of the radius. The *Anconeus* presents a distinct and characteristic surface form in the shape of a triangular, slightly elevated area, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common Extensor group by an oblique depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the interval, caused by the divergence from each other of the two masses into which the Extensor and Supinator group is divided at the lower part of the forearm, an oblique elongated eminence is seen, caused by the emergence of two of the Extensors of the thumb from their deep origin at the back of the forearm. This eminence, full above, flattened and partially subdivided below, runs downwards and outwards over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, and passing onwards to the posterior aspect of the thumb. The tendons of most of the Extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are those of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint, from the styloid process of the radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevior can be perceived as a vertical ridge emerging from under the ulnar border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digiti can be felt; the last being separated from those of the Extensor communis by a slight furrow.

The muscles of the hand are principally concerned, as far as regards surface form, in producing the thenar and hypothenar eminences, and cannot be individually distinguished on the surface. The thenar eminence is larger and rounder than the hypothenar, which presents a long, narrow eminence along the ulnar side of the hand. When the *Palmaris brevis* is in action it produces a wrinkling of the skin over the hypothenar eminence, and a dimple on the ulnar border of the hand. On the back of the hand the *Dorsal interossei* produce elongated swellings between the metacarpal bones. When the thumb is closely adducted to the hand, the First dorsal interosseous (Abductor indicis) forms a prominent fusiform bulging; the other Interossei are not so marked.

The skin over the inner side and front of the forearm is thin, smooth, and sensitive; it contains few hairs and many sweat-glands. Over the outer side and back of the arm and forearm it is thicker, denser, and less sensitive; it contains more hairs and fewer sweat-glands. Over the olecranon the cuticle is thick and rough; the skin is loosely connected to the underlying tissues, and transversely wrinkled when the forearm is extended. At the front of the wrist, the skin presents three transverse furrows, which correspond from above downwards to the position of the styloid process of the ulna, the wrist-joint, and the mid-carpal joint respectively. The skin of the palm of the hand differs

considerably from that of the forearm. At the wrist it suddenly becomes hard and dense and covered with a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density, the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and contains no sebaceous follicles. It is tied down by fibrous bands along the lines of flexion of the digits, producing certain furrows of a permanent character. One of these starting from about the tubercle of the scaphoid, curves round the thenar eminence, and ends on the radial border of the hand, a little above the metacarpo-phalangeal joint of the index finger. It corresponds to the outer border of the central portion of the palmar fascia, and is produced by the movement of the thumb at the carpo-metacarpal joint. A second line begins at the end of the first, and extends obliquely across the palm, upwards and inwards, to the ulnar margin about the middle of the fifth metacarpal bone. A third commences at the ulnar border of the hand, about an inch below the termination of the second, and extends outwards across the palm over the heads of the third, fourth, and fifth metacarpal bones. The last two lines are caused by flexion of the fingers at the metacarpo-phalangeal joints. Over the fingers the skin again becomes thinner, especially at the flexures of the joints; and over the terminal phalanges it is thrown into numerous ridges, in consequence of the arrangement of the papillæ in it. These ridges form, in different individuals, distinctive and permanent patterns, which may be used for purposes of identification. The superficial fascia in the palm is made up of dense fibro-fatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two.

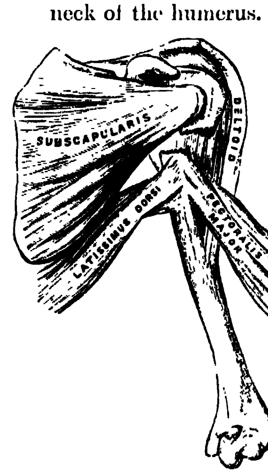
Fig. 535.—Fracture of the middle of the clavicle.



Applied Anatomy.—In considering the actions of the various muscles upon fractures of the upper extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the *middle of the clavicle* (fig. 535) is usually attended with considerable displacement of the outer fragment, which is drawn downwards and inwards, and at the same time rotated, so that its outer end is carried forwards and its inner end backwards. The displacement is produced as follows: the outer fragment is drawn *downwards* by the weight of the arm, the Trapezius not being able to support the weight of the limb. It is drawn *inwards* by the Subclavius and Pectoralis minor, possibly assisted by the Pectoralis major and Latissimus dorsi; and is rotated on an axis drawn through its own centre by the Serratus magnus, which causes the scapula to rotate on the wall of the chest, and carries the acromion and outer end of the outer fragment of the clavicle forwards, and so carries the inner end of the outer portion backwards. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outwards, and, together with the scapula, raised upwards to a level with the inner fragment, and retained in that position.

IG. 536.—Fracture of the surgical neck of the humerus.



In fracture of the *acromial end of the clavicle*, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the *sternal end*, internal to the costo-clavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the *acromion process* outside the ligaments usually arises from violence applied to the upper and outer part of the shoulder. There is great displacement; the

outer fragment being drawn downwards by the weight of the arm, and rotated forwards and inwards, so that it forms a right angle with the rest of the bone.

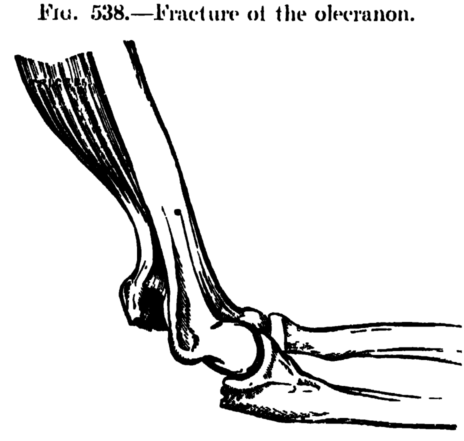
Fracture of the *surgical neck of the humerus* (fig. 536) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment remains in its place under the coraco-acromial ligament; the lower fragment is drawn inwards by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outwards from the side by the Deltoid, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm outwards and downwards. To counteract the opposing muscles, and to keep the fragments in position, a cone-shaped pad should be placed in the axilla, and the arm bandaged to the side by a broad roller passed round the chest in such a manner that the elbow is carried slightly forwards, so as to throw the upper end of the lower fragment backwards and outwards towards the head of the bone. The whole is then covered with a carefully moulded guttapercha or poroplastic shoulder-cap.

Fig. 537.—Fracture of the humerus above the condyles.

In fracture of the *shaft of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity, the upper fragment being drawn inwards by the first-mentioned muscles, and the lower fragment upwards and outwards by the Deltoid. Shortening of the limb results, with a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture take place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

In fracture of the *shaft of the humerus* immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occur in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forwards; but in oblique fracture, the combined actions of the Biceps and Brachialis anticus muscles in front and the Triceps behind draw upwards the lower fragment, causing it to glide over the upper fragment, either backwards or forwards, according to the direction of the fracture. Simple extension reduces the deformity, and the application of a shoulder-cap and splints to the arm will retain the fragments in apposition. Care should be taken not to raise the elbow; but the forearm and hand may be supported in a sling.

Fig. 538.—Fracture of the olecranon.



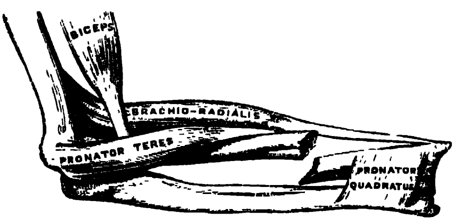
Fracture of the *humerus* (fig. 537) immediately above the condyles deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backwards. If the direction of the fracture is oblique, from above, downwards and forwards, the lower fragment is drawn upwards by the Brachialis anticus and Biceps in front, and the Triceps behind; and at the same time is drawn backwards behind the upper fragment by the Triceps. This injury may be diagnosed from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact that the deformity is remedied by extension, but is reproduced on the discontinuance of it. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. In some cases where the injury has been produced by falls on the elbow, the lower fragment is drawn upwards and forwards, causing a considerable

prominence in front; and the upper fragment projects backwards beneath the tendon of the Triceps.

In fracture of the *olecranon process* (fig. 538) the detached fragment is displaced upwards, by the action of the Triceps muscle, from half an inch to two inches; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in wiring the fragments together; but if for some reason this operation is not desirable, the fragments should be approximated by strapping or a figure-of-8 bandage, and the arm put up in an extended position in order to relax the Triceps. Massage and passive movements must be employed early, for fear of ankylosis. Union, when wiring is not resorted to, is usually fibrous.

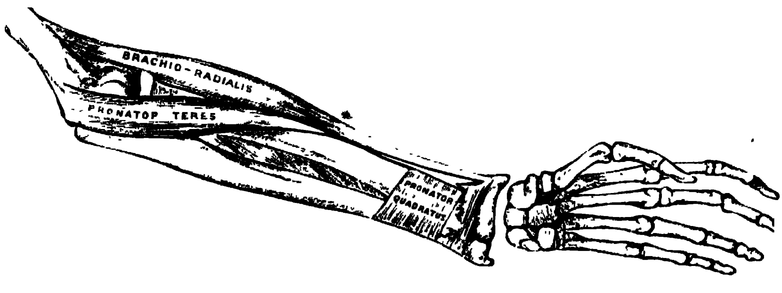
In fracture of the *radius* below the insertion of the Biceps, but above the insertion of the Pronator teres, the upper fragment is strongly supinated by the Biceps and Supinator brevis, and at the same time drawn forwards and flexed by the Biceps; the lower fragment is pronated and drawn inwards towards the ulna by the Pronators. Thus there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator teres (fig. 539), the upper fragment is drawn upwards by the Biceps, and inwards by the Pronator teres, into a position midway between pronation and supination, and a degree of fulness in the upper half of the forearm is thus produced. The lower fragment is drawn downwards and inwards towards the ulna by the Pronator quadratus, and thrown into a state of pronation by the same muscle; at the same time, the Brachio-radialis, by elevating the styloid process, into which it is inserted, will serve to depress the upper end of the lower fragment still more towards the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow. Well-padded splints should be applied on both sides of the forearm from the elbow to the wrist: the hand being allowed to fall will, by its own weight, counteract the action of the Pronator quadratus and Brachio-radialis, and elevate the lower fragment to the level of the upper one.

FIG. 539.—Fracture of the shaft of the radius.



In fracture of the *shaft of the ulna* the upper fragment retains its usual position, but the lower fragment is drawn outwards towards the radius by the Pronator quadratus,

FIG. 540.—Fracture of the lower end of the radius.



producing a well-marked depression at the seat of fracture, and some fulness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the *shafts of the radius and ulna together*, the lower fragments are drawn upwards, sometimes forwards, sometimes backwards, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on the dorsal or palmar surface of the forearm. At the same time the lower fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation. The upper fragment of the radius is drawn upwards and inwards by the Biceps and Pronator teres to a higher level than the ulna; the upper portion of the

ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the *lower end of the radius* (fig. 540) the displacement produced is very considerable, and bears some resemblance to dislocation of the carpus backwards, from which it should be carefully distinguished. The lower fragment is displaced backwards and upwards, but this displacement is due to the force of the blow driving the portion of the bone into this position, and not to any muscular influence. The upper fragment projects forwards, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of the forearm, immediately above the carpus, from the Flexor tendons being thrust forwards. This fracture may be distinguished from dislocation by the relative positions of the styloid processes of the radius and ulna, the former of which is displaced upwards in fracture, and by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected. The age of the patient will assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in that position by well-padded *pistol-shaped* splints.

MUSCLES AND FASCIÆ OF THE LOWER EXTREMITY

The muscles of the lower extremity are subdivided into groups, corresponding with the different regions of the limb.

I. Iliac Region

Psoas magnus.
Psoas parvus.
Iliacus.

II. Thigh

1. *Anterior Femoral Region.*

Tensor fasciæ femoris.
Sartorius.
Quadriceps extensor { Rectus femoris. Vastus externus. Vastus internus. Crureus.
Subcrureus.

2. *Internal Femoral Region.*

Gracilis.
Pectineus.
Adductor longus.
Adductor brevis.
Adductor magnus.

3. *Gluteal Region.*

Gluteus maximus.
Gluteus medius.
Gluteus minimus.
Pyriformis.
Obturator internus.
Gemellus superior.
Gemellus inferior.
Quadratus femoris.
Obturator externus.

4. *Posterior Femoral Region.*

Hamstring muscles { Biceps. Semitendinosus. Semimembranosus.

III. Leg

5. *Anterior Tibio-fibular Region.*

Tibialis anticus.
Extensor proprius hallucis.
Extensor longus digitorum.
Peroneus tertius.

6. *Posterior Tibio-fibular Region*

Superficial Layer.

Gastrocnemius.
Soleus.
Plantaris.

Deep Layer.

Popliteus.
Flexor longus hallucis.
Flexor longus digitorum.
Tibialis posticus.

7. *Fibular Region.*

Peroneus longus.
Peroneus brevis.

IV. Foot

8. *Dorsal Region.*

Extensor brevis digitorum.

9. *Plantar Region.*

First Layer.

Abductor hallucis.
Flexor brevis digitorum.
Abductor minimi digiti.

Second Layer.

Flexor accessorius.
Lumbricales.

Adductor obliquus hallucis.
Adductor transversus hallucis.
Flexor brevis minimi digiti.

Third Layer.

Flexor brevis hallucis.

Fourth Layer.

Interossei.

I. Muscles and Fasciæ of the Iliac Region (fig. 542)

Psoas magnus. Psoas parvus. Iliacus.

The **fascia covering the Psoas and Iliacus** is the layer which lines the back part of the abdominal cavity. It is thin above, and becomes gradually thicker below as it approaches Poupart's ligament.

The *portion covering the Psoas* is thickened above to form the ligamentum arcuatum internum, which stretches from the transverse process of the first lumbar vertebra to the body of the second; internally, it is attached by a series of arched processes to the intervertebral discs, and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum; the intervals left, opposite the constricted portions of the bodies, transmit the lumbar arteries and veins and filaments of the sympathetic cord. Externally, above the crest of the ilium, this portion of the fascia is continuous with the anterior lamella of the lumbar fascia covering the front of the Quadratus lumborum (see page 493), but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The *portion investing the Iliacus* (fascia iliaca) is connected, externally, to the whole length of the inner border of the crest of the ilium; and internally, to the brim of the true pelvis, where it is continuous with the periosteum. At the ilio-pectineal eminence it receives the tendon of insertion of the Psoas parvus, when that muscle exists. External to the femoral vessels, this fascia is intimately connected to the posterior margin of Poupart's ligament, and is continuous with the fascia transversalis. Immediately to the outer side of the femoral vessels the fascia iliaca is prolonged backwards and inwards from Poupart's ligament as a band, the *ilio-pectineal ligament*, which is attached to the ilio-pectineal eminence. This ligament divides the space between Poupart's ligament and the innominate bone into two parts, the inner of which transmits the femoral vessels, the outer the Ilio-psoas and the anterior crural nerve (fig. 444). Internal to the vessels the iliac fascia is attached to the ilio-pectineal line behind the conjoined tendon, where it is again continuous with the fascia transversalis; where the external iliac vessels pass into the thigh, the fascia descends behind them forming the posterior wall of the femoral sheath. The portion of the iliac fascia which passes behind the femoral vessels is also attached to the ilio-pectineal line beyond the limits of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the fascia lata of the thigh. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus are behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The **Psoas magnus** (m. psoas major) (fig. 542) is a long fusiform muscle placed on the side of the lumbar region of the vertebral column and brim of the pelvis. It arises (1) from the anterior surfaces of the bases and lower borders of the transverse processes of all the lumbar vertebræ; (2) from the sides of the bodies and the corresponding intervertebral discs of the last thoracic and all the lumbar vertebræ by five slips, each of which is attached to the adjacent upper and lower margins of two vertebræ, and to the intervertebral disc; (3) from a series of tendinous arches which extend across the constricted parts of the bodies of all the lumbar vertebræ between the previous slips; the lumbar arteries and veins and filaments of the sympathetic cord pass beneath these tendinous arches. The muscle proceeds downwards across the brim of the pelvis, and, diminishing gradually in size, passes beneath Poupart's ligament, and terminates in a tendon, which, after receiving nearly the whole of the fibres of the Iliacus, is inserted into the lesser trochanter of the femur.

Relations.—In the abdomen the Psoas magnus is in relation by its *anterior surface* with the ligamentum arcuatum internum, the fascia covering the muscle, the extra-peritoneal fat and peritoneum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, and genito-crural nerve. In front of the right Psoas is the inferior vena cava and the terminal portion of the ileum, and in front of the left the ilio-pelvic colon. By its *posterior surface* it is in relation with the transverse processes of the lumbar vertebræ, and the Quadratus lumborum from which it is separated by the anterior lamella of the lumbar fascia. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *inner side*, the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the gangliated cord of the sympathetic, and the lumbar glands; with the vena cava inferior on the right, and the aorta on the left side, and along the brim of the pelvis with the external iliac artery.

In the thigh it is in relation, in front, with the fascia lata; behind, with the capsular ligament of the hip, from which it is separated by a synovial bursa which frequently communicates with the cavity of the joint through an opening of variable size; by its *inner border*, with the Pectineus and internal circumflex artery, and also with the femoral artery, which slightly overlaps it; by its *outer border*, with the anterior crural nerve and Iliacus.

The **Psoas parvus** (m. psoas minor) is a long slender muscle, placed in front of the Psoas magnus. It arises from the sides of the bodies of the last thoracic and first lumbar vertebræ and from the intervertebral disc between them. It forms a small muscular bundle, which ends in a long flat tendon, inserted into the ilio-pectineal line and eminence, and, by its outer border, into the fascia iliaca. This muscle is often absent, and sometimes double.

The **Iliacus** is a flat, triangular muscle, which fills up the whole of the iliac fossa. It arises from the upper two-thirds of this fossa, and from the inner margin of the crest of the ilium; behind, from the anterior sacro-iliac and the ilio-lumbar ligaments, and base of the sacrum; in front, it reaches as far as the anterior superior and anterior inferior spinous processes of the ilium, and the notch between them. The fibres converge to be inserted into the outer side of the tendon of the Psoas, some of them being prolonged on to the shaft of the femur for about an inch below and in front of the lesser trochanter.*

Relations.—Within the abdomen the Iliacus is in relation by its *anterior surface* with the iliac fascia, which separates the muscle from the extra-peritoneal fat and peritoneum, and with the external cutaneous nerve; on the right side, with the cæcum; on the left side, with the iliac colon; by its *posterior surface*, with the iliac fossa; by its *inner border*, with the Psoas magnus, and anterior crural nerve

In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus, Sartorius, and profunda femoris artery; behind, with the capsule of the hip-joint, a synovial bursa common to it and the Psoas magnus being interposed.

Nerves.—The Psoas magnus is supplied by branches of the second and third lumbar nerves; the Psoas parvus by a branch of the first lumbar nerve; and the Iliacus by branches of the second and third lumbar nerves through the anterior crural.

Actions.—The Psoas, acting from above, flexes the thigh upon the pelvis, being assisted by the Iliacus; acting from below, with the femur fixed, the Psoas bends the lumbar portion of the vertebral column forwards and to its own side, and then, in conjunction with the Iliacus, tilts the pelvis forwards. When the muscles of both sides are acting from below, they serve to maintain the erect posture, by supporting the vertebral column and pelvis upon the femora, or in continued action bend the trunk and pelvis forwards, as in raising the trunk from the recumbent posture.

The Psoas parvus is a tensor of the iliac fascia.

Applied Anatomy.—There is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseo-fibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

* The Psoas and Iliacus are sometimes regarded as a single muscle, the *Ilio-psoas*, having two heads of origin and a single insertion.

Abscess within the sheath of the Psoas muscle (*psoas abscess*) is generally due to tuberculous caries of the bodies of the lower thoracic or the lumbar vertebræ. When the disease is in the thoracic region, the matter tracks down the posterior mediastinum, in front of the bodies of the vertebræ, and, passing beneath the ligamentum arcuatum internum, enters the sheath of the Psoas muscle, down which it travels as far as the pelvic brim; it then gets beneath the iliac portion of the fascia, and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament into the thigh, to the outer side of the femoral vessels. It thus follows that a psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, the matter finds its way directly into the substance of the Psoas. The muscular fibres are destroyed, and the nerves contained in the abscess are isolated and exposed in its interior; the iliac vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All psoas abscesses do not, however, pursue this course: the matter may leave the sheath of the muscle above the crest of the ilium, and tracking backwards may point in the loin (*lumbar abscess*); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great sacro-sciatic notch, discharge itself on the back of the thigh.

II. Muscles and Fasciæ of the Thigh

1. *Anterior Femoral Region* (figs. 541, 542)

Tensor fasciæ femoris.
Sartorius.

Quadriceps extensor: Rectus femoris. Vastus externus. Vastus internus. Crureus.

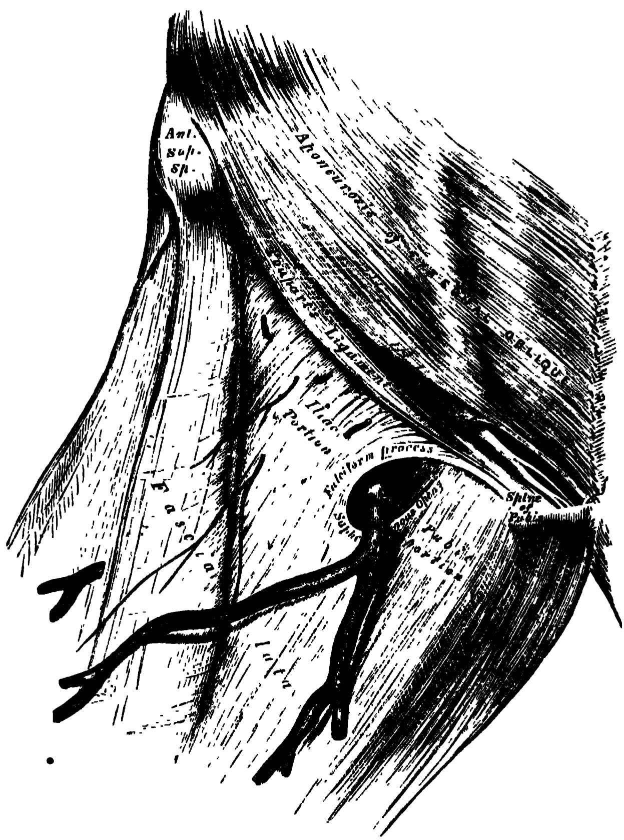
Subcrureus.

The **superficial fascia** forms a continuous layer over the whole of the thigh; it consists of areolar tissue, containing in its meshes much fat, and is capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening in the fascia lata, being closely united to its circumference, and is connected to the sheath of the femoral vessels. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood and lymphatic vessels, hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. A large subcutaneous bursa is found in the superficial fascia over the patella.

The **deep fascia** of the thigh is named, from its great extent, the *fascia lata*; it constitutes a uniform investment for the whole of this region of the limb, but varies in thickness in different parts. Thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and where the Tensor fasciæ femoris is inserted between its layers: it is very thin behind and at the upper and inner part, where it covers the Adductor muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the Biceps externally, from the Sartorius internally, and from the Quadriceps extensor cruris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; externally, to the crest of the ilium; in front, to Poupart's ligament, and to the body of the pubis; and internally, to the descending ramus of the pubis, to the ramus and tuberosity of the ischium, and to the lower border of the great sacro-sciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius to the

upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle; at the lower border of the muscle the two layers reunite. Externally, the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata attached to the front part of the crest of the ilium, and corresponding to the origin of the Tensor fasciæ femoris, passes down the outer side of the thigh as two layers, one superficial to and the other beneath this muscle; these at the lower end of the muscle become blended together into a thick and strong band, having first received the insertion of the muscle. This band is continued downwards, under the name of the *ilio-tibial band*, to be inserted into the external tuberosity of the tibia. The part of the ilio-tibial band which lies beneath the Tensor fasciæ femoris is prolonged upwards to the capsule of the hip, with the outer

FIG. 541.—The saphenous opening.



part of which it becomes continuous. Below, the fascia lata is attached to all the prominent points around the knee-joint, viz. the condyles of the femur, tuberosities of the tibia, and head of the fibula. On either side of the patella it is strengthened by transverse fibres given off from the lower part of the Vastus muscles, which are attached to and support this bone. Of these the outer are the stronger, and are continuous with the ilio-tibial band. From the inner surface of the fascia lata are given off two strong intermuscular septa, which are attached to the whole length of the linea aspera and its prolongations above and below: the external and stronger one, which extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps behind, and gives partial origin to these muscles; the inner one, the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these

there are numerous smaller septa, separating the individual muscles, and enclosing each in a distinct sheath.

The **saphenous opening** (fig. 541).—At the upper and inner part of the thigh, a little below the inner end of Poupart's ligament, is a large oval-shaped aperture in the fascia lata; it transmits the internal saphenous vein, and other smaller vessels, and is termed the *saphenous opening*. The cribriform fascia, which is pierced by the structures passing through the opening, closes the aperture and must be removed to expose it. The fascia lata in this part of the thigh is described as consisting of an iliac and a pubic portion.

The *iliac portion* of the fascia lata is the part on the outer side of the saphenous opening. It is attached, externally, to the crest and anterior superior spine of the ilium and to the whole length of Poupart's ligament, and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the pubis it is reflected downwards and outwards, forming an arched margin, the *falciform process*, or boundary of the saphenous opening; this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels: to its edge is attached the cribriform fascia. The upward and inward prolongation of the falciform process is named the *superior cornu*; its downward and inward prolongation, the *inferior cornu*. The latter is well defined, and is continuous behind the saphenous vein with the pubic portion of the fascia lata.

The *pubic portion* is situated on the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upwards, it covers the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the fascia iliaca, and is attached to the ilio-pectineal line. From this description it may be observed that the iliac portion of the fascia lata lies in front of the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous passes to join the femoral vein.

The **Tensor fasciæ femoris** (m. tensor fasciæ latæ) arises from the anterior part of the outer lip of the crest of the ilium; from the outer surface of the anterior superior spine, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius; and from the inner surface of the fascia lata. It is inserted between the two layers of the ilio-tibial band of the fascia lata about the junction of the middle and upper thirds of the thigh.

The **Sartorius,** the longest muscle in the body, is flat, narrow, and ribbon-like; it arises by tendinous fibres from the anterior superior spine of the ilium and the upper half of the notch below it. It passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur to end in a tendon. This curves obliquely forwards and expands into a broad aponeurosis, which is inserted, in front of the Gracilis and Semitendinosus, into the upper part of the inner surface of the shaft of the tibia, nearly as far forwards as the crest. The upper part of the aponeurosis is curved backwards over the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset, derived from its upper margin, blends with the capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the outer side of a triangular space, *Scarpa's triangle*, the inner side of which is formed by the inner border of the Adductor longus, and the base, turned upwards, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh, the femoral artery is contained in Hunter's canal, on the roof of which lies the Sartorius.

The **Quadriceps extensor** (m. quadriceps femoris) includes the four remaining muscles on the front of the thigh. It is the great extensor muscle of the leg, forming a large fleshy mass, which covers the front and sides of the femur, being united below into a tendon, attached to the patella,

and above, subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, and connected above with the ilium, is called the *Rectus femoris*, from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The portion on the outer side of the femur is termed the *Vastus externus*; that covering the inner side, the *Vastus internus*; and that in front, the *Crureus*. Vastus [illegible]

The **Rectus femoris** is situated in the middle of the anterior region of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: one, the anterior or straight, from the anterior inferior spine of the ilium; the other, the posterior or reflected tendon, from a groove above the brim of the acetabulum. The two unite at an acute angle, and spread into an aponeurosis which is prolonged downwards on the anterior surface of the muscle, and from this the muscular fibres arise. The muscle terminates in a broad and thick aponeurosis, which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the patella in common with the Vasti and Crureus.

The **Vastus externus** (m. vastus lateralis) is the largest part of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the upper part of the anterior intertrochanteric line, to the anterior and inferior border of the root of the great trochanter, to the outer lip of the gluteal ridge, and to the upper half of the outer lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part: this becomes contracted and thickened into a flat tendon inserted into the outer border of the patella, blending with the Quadriceps extensor tendon, and giving an expansion to the capsule of the knee-joint.

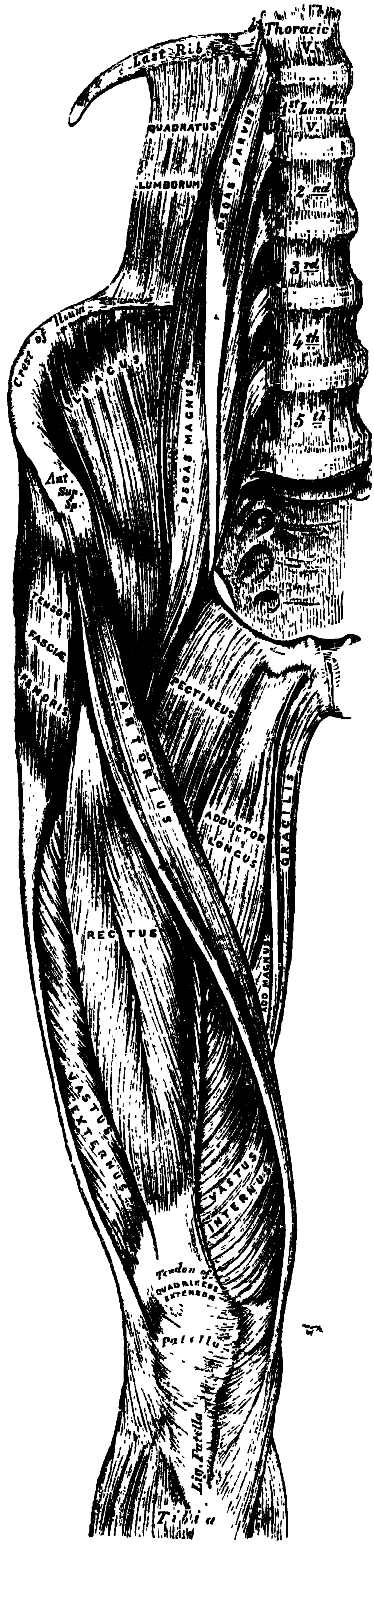
The **Vastus internus** and **Crureus** appear to be inseparably united, but when the Rectus femoris has been reflected a narrow interval will be observed extending upwards from the inner border of the patella between the two muscles. Here they can be separated, and the separation may be continued upwards as far as the lower part of the anterior intertrochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus internus** (m. vastus medialis) arises from the lower half of the anterior intertrochanteric line, the spiral line, the inner lip of the linea aspera, the upper part of the internal supracondylar line, the tendons of the Adductor longus and Adductor magnus and the internal intermuscular septum. Its fibres are directed downwards and forwards, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is inserted into the inner border of the patella and the Quadriceps extensor tendon, an expansion being sent to the capsule of the knee-joint.

The **Crureus** (m. vastus intermedius) arises from the front and outer aspect of the shaft of the femur in its upper two-thirds and from the lower part of the external intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the Quadriceps extensor tendon.

The *tendons* of the different portions of the Quadriceps extensor unite at the lower part of the thigh, so as to form a single strong tendon, which is inserted into the upper part of the patella, some few fibres passing over it to blend with the ligamentum patellæ. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps; and the ligamentum patellæ, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle, the lateral patellar ligaments (see page 430) being fascial expansions from its borders. A synovial bursa, which usually communicates with the cavity of the knee-joint, is situated between the femur and the portion of the Quadriceps extensor tendon above the patella; another is interposed between the tendon and the upper part of the front of the tibia; and a third,

FIG. 542.—Muscles of the iliac and anterior femoral regions.



the *pre-patellar bursa*, is placed over the patella itself. The last often becomes enlarged, constituting 'housemaid's knee.'

The Subcrureus (m. articularis genu) is a small muscle, usually distinct from the Crureus, but occasionally blended with it, which arises from the anterior surface of the lower part of the shaft of the femur, and is inserted into the upper part of the synovial membrane of the knee-joint. It sometimes consists of several separate muscular bundles.

Nerves.—The Tensor fasciæ femoris is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through branches of the anterior crural.

Actions.—The Tensor fasciæ femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct the thigh and to rotate it inwards. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur; and by means of the ilio-tibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next abducts and rotates the thigh outwards. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, as in the squatting position, and hence received its name of Sartorius, or tailor's muscle. When the knee is bent, the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inwards. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh be fixed it will flex the pelvis. The Vastus internus draws the patella inwards as well as upwards.

Applied Anatomy. — A few fibres of the Rectus muscle are occasionally ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as 'cricket thigh.' The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor

may be torn away from its insertion into the patella; or the tendon of the patella may be ruptured about an inch above the bone. This accident is caused in the same manner as fracture of the patella by muscular action, viz. by a violent muscular effort to prevent falling while the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

2. *Internal Femoral Region*

Gracilis. Adductor longus.
Pectineus. Adductor brevis.
Adductor magnus.

The **Gracilis** (figs. 542, 544) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It arises by a thin aponeurosis from the anterior margins of the lower half of the symphysis pubis and the upper half of the pubic arch. The fibres run vertically downwards, and terminate in a rounded tendon, which passes behind the internal condyle of the femur, and, curving round the inner tuberosity of the tibia, becomes flattened, and is inserted into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. At its insertion the tendon is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint, it is separated from it by a synovial bursa common to it and the Semitendinosus.

The **Pectineus** (fig. 542) is a flat, quadrangular muscle, situated at the anterior part of the upper and inner aspect of the thigh. It arises from the ilio-pectineal line, and to a slight extent from the surface of bone in front of it, between the pectineal eminence and spine of the pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downwards, backwards, and outwards, to be inserted into a rough line leading from the small trochanter to the linea aspera.

Relations.—It is in relation by its *anterior surface* with the pubic portion of the fascia lata, which separates it from the femoral vessels and internal saphenous vein; by its *posterior surface*, with the capsular ligament of the hip-joint and the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed; by its *outer border*, with the Psoas, a cellular interval separating them, through which pass the internal circumflex vessels; by its *inner border*, with the margin of the Adductor longus.

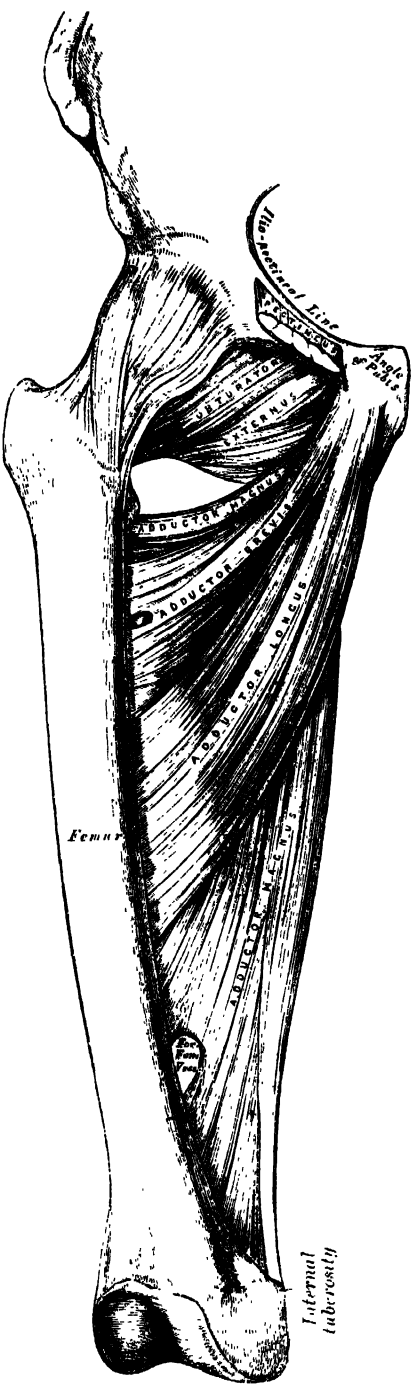
The **Adductor longus** (fig. 543), the most superficial of the three Adductors, is a flat, triangular muscle, lying in the same plane as the Pectineus. It arises by a flat, narrow tendon, from the front of the pubis, at the angle of junction of the crest with the symphysis; and soon expands into a broad fleshy belly. This passes downwards, backwards, and outwards, and is inserted, by an aponeurosis, into the linea aspera, between the Vastus internus and the Adductor magnus, with both of which it is usually blended.

Relations.—It is in relation by its *anterior surface* with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; by its *posterior surface*, with the Adductores brevis et magnus, the anterior division of the obturator nerve, and near its insertion with the profunda artery and vein; by its *outer border*, with the Pectineus; by its *inner border*, with the Gracilis.

The **Adductor brevis** (fig. 543) is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the body and descending ramus of the pubis, between the Gracilis and Obturator externus. Its fibres, passing backwards, outwards, and downwards, are inserted, by an aponeurosis, into the line leading from the small trochanter to the linea aspera and into the upper part of the linea aspera, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—It is in relation by its *anterior surface* with the Pectineus, Adductor longus, profunda femoris artery, and anterior division of the obturator nerve; by its *posterior surface*, with the Adductor magnus, and posterior division of the obturator nerve; by its *outer border*, with the internal circumflex artery, the Obturator externus, and conjoined tendon of the Psoas and Iliacus; by its *inner border*, with the Gracilis and Adductor magnus. It is pierced near its insertion by the second or first and second perforating branches of the profunda femoris artery.

Fig. 543.—Deep muscles of the internal femoral region.



The **Adductor magnus** (fig. 543) is a large triangular muscle, forming a septum between the muscles on the inner and those on the back of the thigh. It arises from a small part of the descending ramus of the pubis, from the ramus of the ischium, and from the outer margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the pubis are very short, horizontal in direction, and are inserted into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus; those from the ramus of the ischium are directed downwards and outwards with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The internal portion of the muscle, composed principally of the fibres arising from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is inserted into the adductor tubercle on the inner condyle of the femur, and is connected by a fibrous expansion to the line leading upwards from the tubercle to the linea aspera. At the insertion of the muscle, a series of osseo-aponeurotic openings, formed by tendinous arches attached to the bone, is seen. The upper four openings are small, and give passage to the perforating branches of the profunda femoris artery. The lowest is of large size, and transmits the femoral vessels from Hunter's canal to the popliteal space.

Relations.—It is in relation by its *anterior surface* with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve; by its *posterior surface*, with the great sciatic nerve, the Gluteus maximus, Biceps, Semitendinosus, and Semimembranosus. Its *superior* or *shortest border* lies parallel with the Quadratus femoris, the internal circumflex artery passing between them. Its

internal or *longest border* is in relation with the Gracilis, Sartorius, and fascia lata. By its *external* or *attached border*, it is inserted into the femur, behind the Adductor brevis and Adductor longus which separate it from the Vastus internus, and in front of the Gluteus maximus and short head of the Biceps which separate it from the Vastus externus.

Nerves.—The three Adductor muscles and the Gracilis are supplied by the third and fourth lumbar nerves through the obturator nerve; the Adductor magnus receiving an additional branch from the sacral plexus through the great sciatic. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the anterior crural, and from the third lumbar by the accessory obturator when it exists. Occasionally it receives a branch from the obturator nerve.*

Actions.—The Pectineus and three Adductors adduct the thigh powerfully; they are especially used in horse exercise, the sides of the saddle being grasped between the knees by the contraction of these muscles. In consequence of the obliquity of their insertions into the linea aspera, they rotate the thigh outwards, assisting the external Rotators, and when the limb has been abducted, they draw it inwards, carrying the thigh across that of the opposite side. The Pectineus and Adductores brevis et longus assist the Psoas and Iliacus in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forwards the lower limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inwards: it is also an adductor of the thigh. If the lower extremities be fixed, these muscles, taking their fixed points below, may act upon the pelvis, serving to maintain the body in an erect posture; or, if their action be continued, flex the pelvis forwards upon the femur.

Applied Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon may be ruptured by suddenly gripping the saddle. Occasionally, especially in cavalry soldiers, the tendon may become ossified, constituting the 'rider's bone.'

3. *Gluteal Region* (fig. 544)

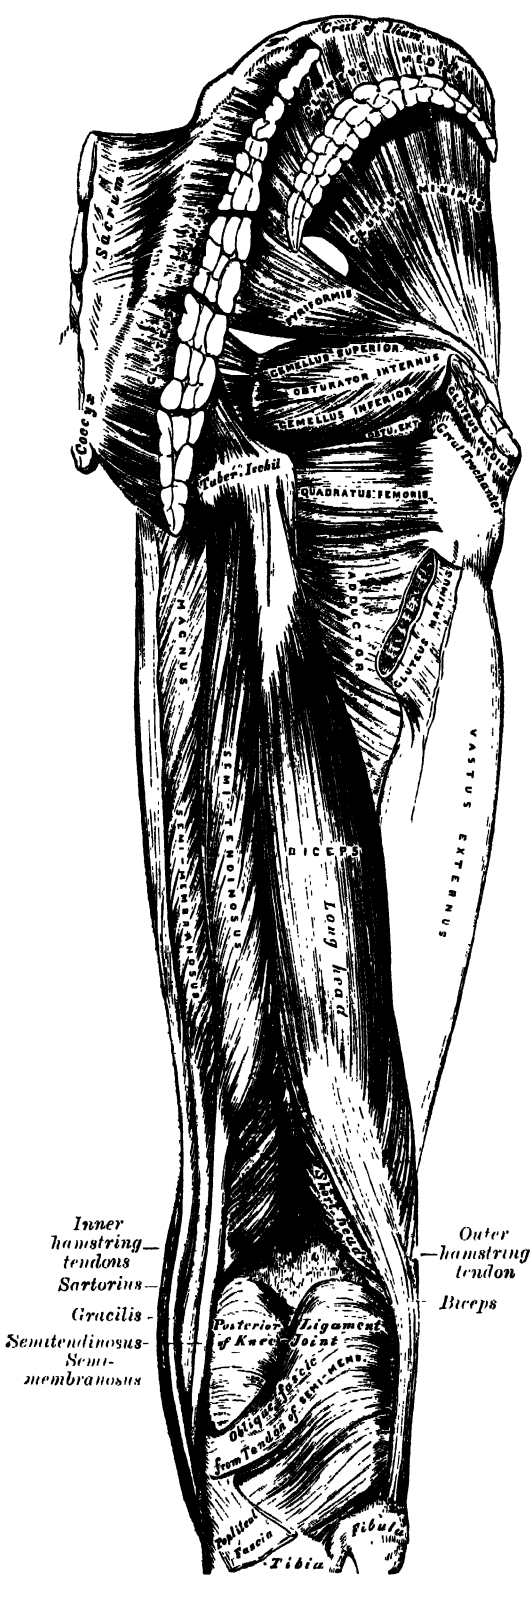
Gluteus maximus.	Obturator internus.
Gluteus medius.	Gemellus superior.
Gluteus minimus.	Gemellus inferior.
Pyriformis.	Quadratus femoris.

Obturator externus.

The **Gluteus maximus**, the most superficial muscle in the gluteal region, is a very broad and thick fleshy mass, of a quadrilateral shape, and forms the prominence of the nates. Its large size is one of the most characteristic points in the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscular fasciculi lying parallel with one another, and collected together into large bundles separated by deep cellular intervals. It arises from the superior curved line of the ilium, and the rough portion of bone, including the crest, immediately above and behind it; from the posterior surface of the lower part of the sacrum and the side of the coccyx; from the aponeurosis of the Erector spinæ, the great sacro-sciatic ligament, and the fascia (gluteal aponeurosis) covering the Gluteus medius. The fibres are directed obliquely downwards and outwards; those forming the upper and larger portion of the muscle, together with the superficial fibres of the lower portion, terminate in a thick tendinous lamina, which passes across the great trochanter, and is inserted into the fascia lata covering the outer side of the thigh; the deeper fibres of the lower portion of the muscle are inserted into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.

* Paterson describes the Pectineus as consisting of two incompletely separated strata; the outer or dorsal stratum, which is constant, is supplied by a branch from the anterior crural nerve, or in the absence of this branch by the accessory obturator, with which it is intimately related; while the inner or ventral stratum, when present, is supplied by the obturator nerve.—*Journal of Anatomy and Physiology*, vol. xxvi. p. 43.

Fig. 544.—Muscles of the hip and thigh.



Three *synovial bursæ* are usually found in relation with the deep surface of this muscle. One of these, of large size, and generally multilocular, separates it from the great trochanter. A second, often wanting, is situated on the tuberosity of the ischium. A third is found between the tendon of the muscle and that of the Vastus externus.

Relations. — The Gluteus maximus is in relation by its *superficial surface* with a thin fascia which separates it from the subcutaneous tissue; by its *deep surface*, from above downwards, with the ilium, sacrum, coccyx, and great sacro-sciatic ligament, part of the Gluteus medius, Pyriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origins of the Biceps, Semitendinosus, Semimembranosus, and the Adductor magnus. The superficial part of the gluteal artery reaches the deep surface of the muscle by passing between the Pyriformis and the Gluteus medius; the sciatic and internal pudic vessels and nerves, and muscular branches from the sacral plexus, issue from the pelvis below the Pyriformis. The first perforating artery and the terminal branches of the internal circumflex artery are also found under cover of the lower part of the muscle. Its *upper border* is thin, and connected with the Gluteus medius by the fascia lata. Its *lower border* is free and prominent, and is crossed by the fold of the nates.

The **Gluteus medius** is a broad, thick, radiating muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus, its anterior two-thirds by the fascia lata, which separates it from the superficial fascia and integument. It arises from the outer surface of the ilium, between the superior and middle curved lines, and from the outer lip of that portion of the crest which is between them; it also arises from the dense fascia (gluteal

aponeurosis) covering its outer surface. The fibres converge to a strong flattened tendon, which is inserted into the oblique ridge which runs downwards and forwards on the outer surface of the great trochanter. A synovial bursa separates the tendon of the muscle from the surface of the trochanter in front of its insertion.

The **Gluteus minimus,** the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the middle and inferior curved lines, and behind, from the margin of the great sacro-sciatic notch. The fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is inserted into an impression on the anterior border of the great trochanter, and gives an expansion to the capsule of the hip-joint. A synovial bursa is interposed between the tendon and the great trochanter. Between the Gluteus medius and Gluteus minimus are the deep branches of the gluteal vessels and the superior gluteal nerve. The deep surface of the Gluteus minimus is in relation with the reflected tendon of the Rectus femoris and the capsular ligament of the hip-joint.

The **Pyriformis** is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis against its posterior wall, and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also to the grooves leading from the foramina: a few fibres also arise from the margin of the great sacro-sciatic foramen, and from the anterior surface of the great sacro-sciatic ligament. The muscle passes out of the pelvis through the great sacro-sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the great trochanter, behind, but often partly blended with, the tendon of the Obturator internus and Gemelli.

Relations.—*Within the pelvis* the Pyriformis is in relation by its *anterior surface* with the rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels, and by its *posterior surface* with the sacrum. *External to the pelvis*, its *anterior surface* is in contact with the posterior surface of the ischium and capsular ligament of the hip-joint; and its *posterior surface*, with the Gluteus maximus; its *upper border* is in relation with the Gluteus medius, and the gluteal vessels and superior gluteal nerve; its *lower border*, with the Gemellus superior and Coccygeus, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles. The muscle is frequently pierced by the external popliteal nerve.

The **obturator membrane** (fig. 444) is a thin layer of interlacing fibres, which almost completely closes the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischio-pubic ramus, below and internal to the margin of the foramen. At its upper and outer part it is deficient, leaving a small canal, which is bounded below by a thickened band of fibres, and gives passage to the obturator vessels and nerve (see page 326). Both Obturator muscles are connected with this membrane.

The **Obturator internus,** like the preceding muscle, is situated partly within the cavity of the pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the antero-lateral wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the descending ramus of the pubis and the ramus of the ischium, and at the side to the inner surface of the innominate bone below and behind the pelvic brim, reaching from the upper part of the great sacro-sciatic foramen above and behind to the obturator foramen below and in front. It also arises from the inner surface of the obturator membrane except at its posterior part, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve, and to a slight extent from the obturator layer of the pelvic fascia, which covers it. The fibres converge rapidly towards the small sacro-sciatic foramen, and terminate in four or five tendinous bands, which are found on the deep surface of the muscle; these bands are reflected at a right angle over the grooved surface of the ischium between its spine

and tuberosity. This bony surface is covered by smooth cartilage, which is separated from the tendon by a synovial bursa, and presents one or more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis by the small sacro-sciatic foramen and unite into a single flattened tendon, which passes horizontally outwards, and, after receiving the attachments of the Gemelli, is inserted into the fore part of the inner surface of the great trochanter in front of the Pyriformis. A synovial bursa, narrow and elongated in form, is usually found between the tendon and the capsular ligament of the hip: it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium.

Relations.—*Within the pelvis,* this muscle is in relation, by its *anterior surface,* with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *posterior surface,* with the obturator fascia, and the origin of the Levator ani, and with the internal pudic vessels and nerve which cross it. The posterior surface forms the outer boundary of the ischio-rectal fossa. *External to the pelvis,* the muscle is covered by the Gluteus maximus, crossed by the great sciatic nerve, and rests on the back part of the hip-joint. When the tendon of the Obturator internus emerges from the small sacro-sciatic foramen it is overlapped both in front and behind by the two Gemelli which form a muscular canal for it; near its insertion the Gemelli pass in front of the tendon and form a groove in which it lies.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus which is received into a groove between them. They are called *superior* and *inferior.*

The **Gemellus superior,** the smaller of the two, arises from the outer surface of the spine of the ischium, and passing horizontally outwards becomes blended with the upper part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter. It is sometimes wanting.

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon. Passing horizontally outwards, it blends with the lower part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter.

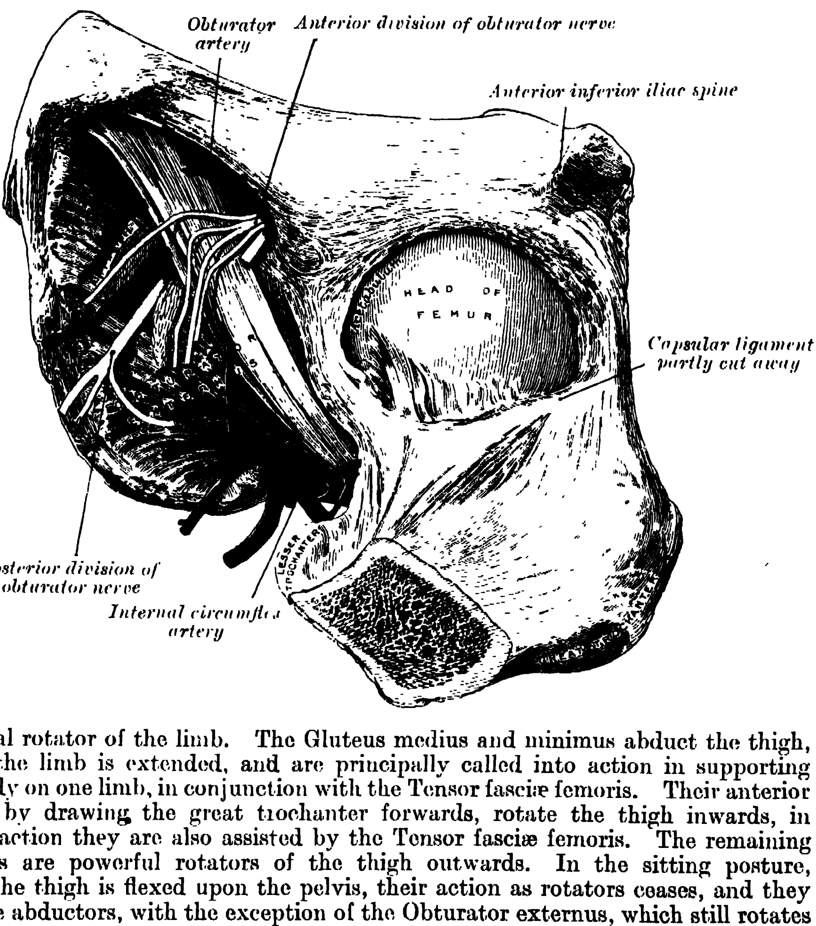
The **Quadratus femoris** is a flat, quadrilateral muscle, between the Gemellus inferior and the upper margin of the Adductor magnus; it is separated from the latter by the terminal branches of the internal circumflex vessels. It arises from the upper part of the external lip of the tuberosity of the ischium, and, proceeding horizontally outwards, is inserted into the upper part of the linea quadrata—that is, the line which extends vertically downwards from the posterior intertrochanteric line. A synovial bursa is often found between the front of this muscle and the small trochanter which it covers.

The **Obturator externus** (fig. 545) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of bone immediately around the inner side of the obturator foramen, viz. from the body and ramus of the pubis, and the ramus of the ischium; it also arises from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres from the pubic arch extend on to the inner surface of the bone, where they obtain a narrow origin between the margin of the foramen and the attachment of the membrane. The fibres converge and pass backwards, outwards, and upwards, and terminate in a tendon which runs across the back part of the hip-joint and is inserted into the digital fossa of the femur. The obturator vessels lie between the muscle and the obturator membrane; the superficial part of the obturator nerve reaches the thigh by passing in front of the muscle, and the deep branch of the same nerve by piercing it.

Nerves.—The Gluteus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the fourth and fifth lumbar and first sacral nerves through the superior gluteal; the Pyriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerves; the Gemellus superior and Obturator internus by the first, second, and third sacral nerves, and the Obturator externus by the third and fourth lumbar nerves through the obturator.

Actions.—The Gluteus maximus, when it takes its fixed point from the pelvis, extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the trunk upon the head of the femur; this is especially obvious in standing on one leg. Its most powerful action is to cause the body to regain the erect position after stooping, by drawing the pelvis backwards, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the ilio-tibial band steadies the femur on the articular surfaces of the tibia during standing, when the Extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and

FIG. 545.—Obturator externus muscle.
(From a preparation in the Museum of the Royal College of Surgeons of England.)



external rotator of the limb. The Gluteus medius and minimus abduct the thigh, when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciæ femoris. Their anterior fibres, by drawing the great trochanter forwards, rotate the thigh inwards, in which action they are also assisted by the Tensor fasciæ femoris. The remaining muscles are powerful rotators of the thigh outwards. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotators ceases, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outwards.

4. *Posterior Femoral Region* (fig. 544)

Biceps. Semitendinosus. Semimembranosus.

The **Biceps** (m. biceps femoris) is a large muscle, of considerable length, situated on the posterior and outer aspect of the thigh. It has two heads of origin: one, the long head (caput longum), arises from the lower and inner impression on the back part of the tuberosity of the ischium, by a tendon common to it and the Semitendinosus, and from the lower part of the great sacro-sciatic ligament; the other, or short head (caput breve), from the outer lip of the linea aspera, between the Adductor magnus and

Vastus externus, extending up almost as high as the insertion of the Gluteus maximus ; from the outer prolongation of the linea aspera to within two inches of the outer condyle ; and from the external intermuscular septum. The fibres of the long head form a fusiform belly, which passes obliquely downwards and outwards across the great sciatic nerve to terminate in an aponeurosis which covers the posterior surface of the muscle, and receives the fibres of the short head : this aponeurosis becomes gradually contracted into a tendon, which is inserted into the outer side of the head of the fibula, and by a small slip into the lateral surface of the external tuberosity of the tibia. At its insertion the tendon divides into two portions, which embrace the long external lateral ligament of the knee-joint. From the posterior border of the tendon a thin expansion is given off to the fascia of the leg. The tendon of this muscle forms the outer hamstring ; the external popliteal nerve descends along its inner border.

The **Semitendinosus**, remarkable for the great length of its tendon, is situated at the posterior and inner aspect of the thigh. It arises from the lower and inner impression on the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps ; it also arises from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about three inches from their origin. It forms a fusiform muscle, which, passing downwards and inwards, terminates a little below the middle of the thigh in a long round tendon which lies along the inner side of the popliteal space ; it then curves around the inner tuberosity of the tibia and passes over the internal lateral ligament of the knee-joint, from which it is separated by a bursa, and is inserted into the upper part of the inner surface of the shaft of the tibia, nearly as far forwards as its anterior border. At its insertion it gives off from its lower border a prolongation to the deep fascia of the leg. This tendon lies behind the tendon of the Sartorius, and below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscle.

The **Semimembranosus**, so called from its membranous tendon of origin, is situated at the back part and inner side of the thigh. It arises by a thick tendon from the upper and outer impression on the back part of the tuberosity of the ischium, above and to the outer side of the Biceps and Semitendinosus, and is inserted into the groove on the inner and back part of the inner tuberosity of the tibia. The tendon of the muscle at its origin expands into an aponeurosis, which covers the upper part of its anterior surface : from this aponeurosis muscular fibres arise, and converge to another aponeurosis which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of insertion gives off certain fibrous expansions : one of these, of considerable size, passes upwards and outwards to be inserted into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint ; a second is continued downwards to the fascia which covers the Popliteus muscle ; while a few fibres join the internal lateral ligament of the joint and the fascia of the leg. The muscle overlaps the upper part of the popliteal vessels.

The tendons of the two preceding muscles form the inner hamstrings.

Nerves.—The muscles of this region are supplied by the fourth and fifth lumbar and the first, second, and third sacral nerves through the great sciatic nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps, in consequence of its oblique direction downwards and outwards, rotates the leg slightly outwards ; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inwards, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur, and to draw the trunk directly backwards, as in raising it from the stooping position or in feats of strength, when the body is thrown backwards in the form of an arch. As already indicated on page 427, complete flexion of the hip cannot be effected unless the knee-joint is also flexed, on account of the shortness of the hamstring muscles.

***Applied Anatomy.*—In disease of the knee-joint, contraction of the hamstring tendons is a frequent complication ; this causes flexion of the leg, and a partial dislocation of the**

tibia backwards, with a slight degree of rotation outwards, probably due to the action of the Biceps muscle. The hamstring tendons occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the Flexor muscles, or from contracture of the ligamentous and other tissues surrounding the joint, the result of disease. This is effected by putting the tendon upon the stretch, and inserting a narrow, sharp-pointed knife between it and the skin: the cutting edge being then turned towards the tendon, it should be divided, taking care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve, which lies in close apposition to the inner border of the tendon of the Biceps, must always be borne in mind in dividing this tendon, and a free incision with exposure of the tendon, before division, is the safer proceeding.

III. Muscles and Fasciæ of the Leg

The muscles of the leg may be divided into three groups: those on the anterior, those on the posterior, and those on the outer side.

5. *Anterior Tibio-fibular Region* (fig. 546)

Tibialis anticus.
Extensor proprius hallucis.
Extensor longus digitorum.
Peroneus tertius.

The **deep fascia** of the leg forms a complete investment to the muscles, and is fused with the periosteum over the subcutaneous surfaces of the bones. It is continuous above with the fascia lata, and is attached around the knee to the patella, the ligamentum patellæ, the tubercle and tuberosities of the tibia, and the head of the fibula. Behind, it forms the popliteal fascia, covering in the popliteal space; here it is specially thick, being strengthened by transverse fibres, and is perforated by the external saphenous vein. It receives an expansion from the tendon of the Biceps on the outer side, and from the tendons of the Sartorius, Gracilis, Semitendinosus, and Semimembranosus on the inner side; in front, it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; below, it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles; but thinner behind, where it covers the Gastrocnemius and Soleus muscles. It gives off from its deep surface, on the outer side of the leg, two strong intermuscular septa, the *anterior* and *posterior peroneal*

Fig. 546.—Muscles of the front of the leg.

septa, which enclose the Peronei longus et brevis, and separate them from the muscles on the anterior and posterior tibial regions, and several smaller and more slender processes which enclose the individual muscles in each region. At the same time a broad transverse intermuscular septum, called the *deep transverse fascia of the leg*, intervenes between the superficial and deep muscles in the posterior tibio-fibular region.

The **Tibialis anticus** (m. tibialis anterior) is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It arises from the outer tuberosity and upper half or two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum. The fibres pass vertically downwards, and terminate in a tendon, which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is inserted into the inner and under surface of the internal cuneiform bone, and the base of the metatarsal bone of the great toe. This muscle overlaps the anterior tibial vessels and nerve in the upper part of the leg.

The **Extensor proprius hallucis** (m. extensor hallucis longus) is a thin, elongated, and flattened muscle, situated between the Tibialis anticus and Extensor longus digitorum. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also arises from the interosseous membrane to a similar extent. The anterior tibial vessels and nerve lie between it and the Tibialis anticus. The fibres pass downwards, and terminate in a tendon, which occupies the anterior border of the muscle, passes through a distinct compartment in the lower portion of the annular ligament, crosses, from without inwards, the anterior tibial vessels near the bend of the ankle, and is inserted into the base of the last phalanx of the great toe. Opposite the metatarso-phalangeal articulation, the tendon gives off a thin prolongation on each side, to cover the surface of the joint. An expansion, from the inner side of the tendon, usually passes across to be inserted into the base of the first phalanx.

The **Extensor longus digitorum** is an elongated, flattened, penniform muscle, situated at the outer part of the front of the leg. It arises from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the upper part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner, and the Peronei on the outer side. Between it and the Tibialis anticus are the upper portions of the anterior tibial vessels and nerve. The tendon passes under the annular ligament in company with the Peroneus tertius, and divides into four slips, which run forward on the dorsum of the foot, and are inserted into the second and third phalanges of the four lesser toes. Each of the three inner tendons, opposite the metatarso-phalangeal articulation, is joined, on its outer side, by a tendon of the Extensor brevis digitorum. The tendons are inserted in the following manner: each receives a fibrous expansion from the Interossei and Lumbricales, and then spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips, a middle one, which is inserted into the base of the second phalanx; and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onwards, to be inserted into the base of the third.

The **Peroneus tertius** is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower third or more of the anterior surface of the fibula; from the lower part of the interosseous membrane; and from an intermuscular septum between it and the Peroneus brevis. The tendon, after passing through the same canal in the annular ligament as the Extensor longus digitorum, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the anterior tibial nerve.

Actions.—The Tibialis anticus and Peroneus tertius are the direct flexors of the foot at the ankle-joint; the former muscle, when acting in conjunction with the Tibialis posticus, raises the inner border of the foot (i.e. inverts the foot); and the latter, acting with the Peronei brevis et longus, raises the outer border of the foot (i.e. everts the foot). The Extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed points from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position, and give increased strength to the ankle-joint.

6. *Posterior Tibio-fibular Region*

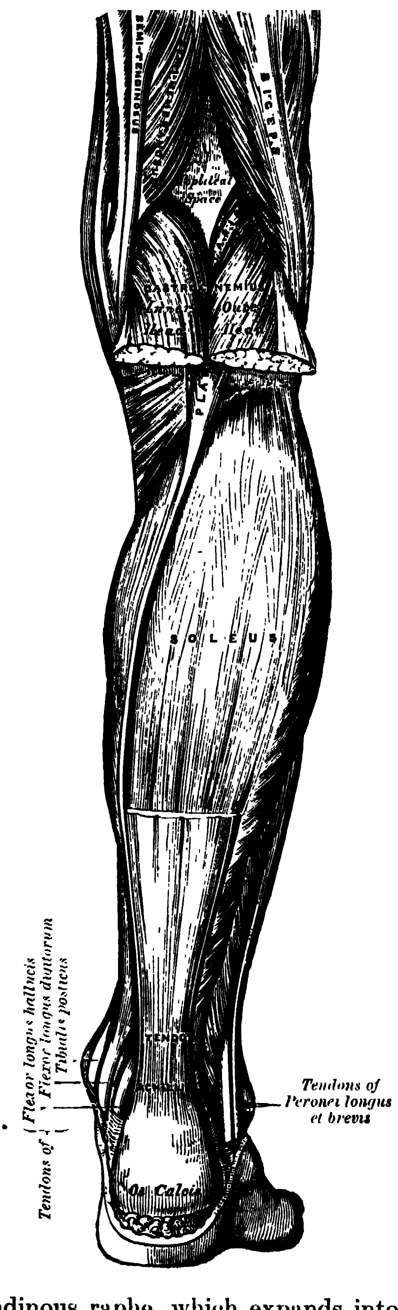
The muscles in this region of the leg are subdivided into two layers—superficial and deep. Those of the superficial layer constitute a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct relation to his ordinary attitude and mode of progression.

Superficial Layer (fig. 547)

Gastrocnemius. Soleus.
Plantaris.

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by two strong, flat tendons. The inner and larger head (caput mediale) takes its origin from a depression at the upper and back part of the inner condyle and from the adjacent part of the femur. The outer head (caput laterale) arises from an impression on the outer side of the external condyle and from the posterior surface of the femur immediately above the outer part of the condyle. Both heads, also, arise from the subjacent part of the capsular ligament of the knee. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs. From the anterior surfaces of these tendinous expansions, muscular fibres are given off; those of the inner head being thicker and extending lower than those of the outer. The fibres in the median line unite at an angle in a median tendinous raphe, which expands into a broad aponeurosis on the anterior surface of the muscle, and into this the remaining fibres are inserted. The aponeurosis, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendo Achillis.

FIG. 547.—Muscles of the back of the leg. Superficial layer.



Relations.—The Gastrocnemius is in relation by its *superficial surface* with the fascia of the leg, which separates it from the external saphenous vein and nerve; by its *deep surface* with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. Beneath the tendon of the inner head is a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head sometimes contains a sesamoid fibro-cartilage or bone, where it plays over the corresponding outer condyle; and one is occasionally found in the tendon of the inner head.

The **Soleus** is a broad flat muscle situated immediately beneath the Gastrocnemius. It arises by tendinous fibres from the back part of the head of the fibula, and from the upper third of the posterior surface of its shaft; from the oblique line of the tibia, and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the popliteal vessels and internal popliteal nerve run. The fibres pass backwards to an aponeurosis which covers the posterior surface of the muscle, and this, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo Achillis.

Relations.—By its *superficial surface* it is in relation with the Gastrocnemius and Plantaris; by its *deep surface*, with the Flexor longus digitorum, Flexor longus hallucis, Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The **tendo Achillis** (tendo calcaneus), the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest tendon in the body. It is about six inches in length, and commences near the middle of the leg, but receives fleshy fibres on its anterior surface, almost to its lower end. Gradually becoming contracted below, it is inserted into the middle part of the posterior surface of the os calcis, a synovial bursa being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, and is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its outer side, but superficial to it, is the external saphenous vein.

The **Plantaris** is an extremely diminutive muscle, placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It arises from the lower part of the outer prolongation of the linea aspera, and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and runs along the inner border of the tendo Achillis, to be inserted with it into the posterior part of the os calcis. This muscle is sometimes double, and at other times wanting. Occasionally, its tendon is lost in the internal annular ligament, or in the fascia of the leg.

Nerves.—The Gastrocnemius is supplied by the first and second sacral nerves, and the Plantaris by the fourth and fifth lumbar and first sacral nerves, through the internal popliteal. The Soleus is supplied by the first and second sacral nerves through the internal popliteal and posterior tibial.

Actions.—The muscles of the calf are the chief extensors of the foot at the ankle-joint. They possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking, these muscles draw powerfully upon the os calcis, raising the heel from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forwards. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot and prevents the body from falling forwards, to which there is a constant tendency from the superincumbent weight. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia, assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which in some of the lower animals is continued over the os calcis to be inserted into the plantar fascia. In man it is an accessory to the Gastrocnemius, extending the ankle if the foot be free, or bending the knee if the foot be fixed.

Possibly, acting from below, by its attachment to the posterior ligament of the knee-joint, it may pull that ligament backwards during flexion, and so protect it from being compressed between the two articular surfaces.

Deep Layer (fig. 548)

Popliteus.	Flexor longus digitorum.
Flexor longus hallucis.	Tibialis posticus.

The **deep transverse fascia** of the leg is a transversely placed, intermuscular septum, between the superficial and deep muscles in the posterior tibio-fibular region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the leg; but below, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the internal annular ligament.

The **Popliteus** is a thin, flat, triangular muscle, which forms the lower part of the floor of the popliteal space. It arises by a strong tendon about an inch in length, from a depression at the anterior part of the popliteal groove on the outer side of the external condyle of the femur, and to a small extent from the posterior ligament of the knee-joint; and is inserted into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle.

Relations.—The tendon of the muscle is covered by that of the Biceps and by the external lateral ligament of the knee-joint; it grooves the posterior border of the external semilunar fibro-cartilage, and is invested by the synovial membrane of the knee-joint. The fascia covering the muscle separates it from the Gastrocnemius, Plantaris, popliteal vessels, and internal popliteal nerve. The deep surface of the muscle is in contact with the posterior ligament of the knee-joint and the back of the tibia.

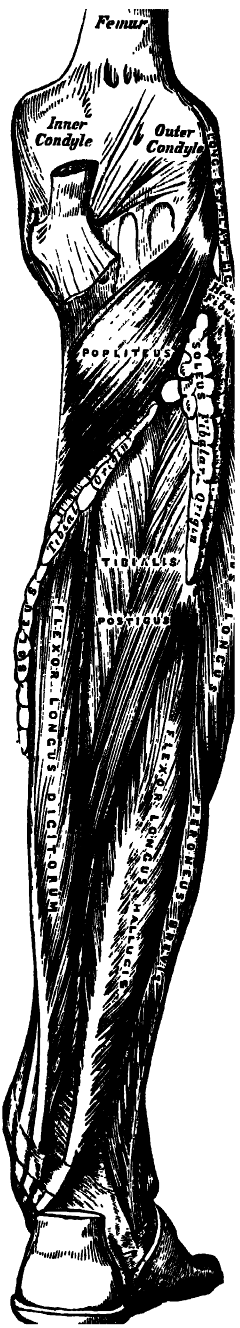
The **Flexor longus hallucis** is situated on the fibular side of the leg. It arises from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the Peronei, externally; and from the fascia covering the Tibialis posticus internally. The fibres pass obliquely downwards and backwards, and terminate in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon lies in a groove which crosses the posterior surface of the lower end of the tibia, the posterior surface of the astragalus, and the under surface of the sustentaculum tali of the os calcis; in the sole of the foot it runs forwards between the two heads of the Flexor brevis hallucis, and is inserted into the base of the last phalanx of the great toe. The grooves on the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals, lined by synovial membrane. As the tendon passes forwards in the sole of the foot, it is situated above, and crosses, from without inwards, the tendon of the Flexor longus digitorum, to which it is connected by a tendinous slip.

Relations.—The Flexor longus hallucis is in relation by its *superficial surface* with the Soleus and tendo Achillis, from which it is separated by the deep transverse fascia; by its *deep surface*, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; by its *outer border*, with the Peronei; by its *inner border*, with the Tibialis posticus and posterior tibial vessels and nerve.

The **Flexor longus digitorum** is situated on the tibial side of the leg. At its origin it is thin and pointed, but it gradually increases in size as it descends. It arises from the posterior surface of the shaft of the tibia, from immediately below the oblique line to within three inches of its lower extremity, internal to the tibial origin of the Tibialis posticus; it also arises from the fascia covering the Tibialis posticus. The fibres terminate in a tendon, which runs nearly the whole length of the posterior surface of the muscle. This

tendon passes behind the internal malleolus, in a groove, common to it and the Tibialis posticus, but separated from the latter by a fibrous septum, each tendon being contained in a special sheath lined by a separate synovial membrane. It passes obliquely forwards and outwards, superficial to the internal lateral ligament, into the sole of the foot (fig. 550), where it crosses the tendon of the Flexor longus hallucis,* lying on its plantar aspect and receiving from it a strong tendinous slip. It then becomes expanded and is joined by the Flexor accessorius, and finally divides into four tendons, which are inserted into the bases of the last phalanges of the four lesser toes, each tendon passing through an opening in the corresponding tendon of the Flexor brevis digitorum opposite the base of the first phalanx.

Fig. 548.—Muscles of the back of the leg. Deep layer.



Relations.—In the leg this muscle is in relation by its *superficial surface* with the posterior tibial vessels and nerve, and the deep transverse fascia which separates it from the Soleus; by its *deep surface*, with the tibia and Tibialis posticus. In the foot, it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The **Tibialis posticus** (m. tibialis posterior) lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It commences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forwards to the front of the leg. It arises from the whole of the posterior surface of the interosseous membrane, excepting its lowest part; from the outer portion of the posterior surface of the shaft of the tibia, between the commencement of the oblique line above and the junction of the middle and lower thirds of the shaft below; and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles on either side. In the lower fourth of the leg it passes in front of the Flexor longus digitorum and terminates in a tendon, which lies in a groove behind the inner malleolus, with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneo-navicular ligament. The tendon contains a sesamoid fibro-cartilage, as it runs under the inferior calcaneo-navicular ligament. It is inserted into the tuberosity of the navicular bone, and gives off fibrous expansions, one of which passes backwards to the sustentaculum tali of the os calcis, others forwards and outwards to the three cuneiforms, the cuboid, and the bases of the second, third, and fourth metatarsal bones.

* That is, in the order of dissection of the sole of the foot.

Relations.—**The Tibialis posticus is in relation by its *superficial surface* with the Soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels; by its *deep surface*, with the interosseous ligament, the tibia, fibula, and ankle-joint.**

Nerves.—The Popliteus is supplied by the fourth and fifth lumbar, and first sacral nerves, through the internal popliteal nerve; the Flexor longus digitorum and Tibialis posticus by the fifth lumbar and first sacral, and the Flexor longus hallucis by the fifth lumbar, and the first and second sacral nerves, through the posterior tibial nerve.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inwards. It is especially called into action at the beginning of the act of bending the knee, inasmuch as it produces the slight inward rotation of the tibia which is essential in the early stage of this movement. The Tibialis posticus is a direct extensor of the foot at the ankle joint; acting in conjunction with the Tibialis anticus, it turns the sole of the foot inwards (i.e. inverts the foot), antagonising the Peronei, which turn it outwards (evert it). In the sole of the foot the tendon of the Tibialis posticus lies directly below the inferior calcaneo-navicular ligament, and is therefore an important factor in maintaining the arch of the foot. The Flexor longus digitorum and Flexor longus hallucis are the direct flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking, or in standing on tiptoe. In consequence of the oblique direction of the tendon of the Flexor longus digitorum, the toes would be drawn inwards, were it not for the Flexor accessorius muscle, which is inserted into the outer side of its tendon, and draws it to the middle line of the foot during its action. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly upon the ankle-joint. They also serve to raise these bones from the oblique position they assume in the stooping posture.

7. *Fibular region*

Peroneus longus. Peroneus brevis.

The **Peroneus longus** is situated at the upper part of the outer side of the leg, and is the more superficial of the two muscles. It arises from the head and upper two-thirds of the outer surface of the shaft of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the front and back of the leg: occasionally also by a few fibres from the outer tuberosity of the tibia. Between its attachments to the head and to the shaft of the fibula there is a small area of bone from which no muscular fibres arise; here the external popliteal nerve passes beneath the muscle. It terminates in a long tendon, which runs behind the outer malleolus, in a groove common to it and the tendon of the Peroneus brevis, behind which it lies; the groove is converted into a canal by a fibrous band, and the tendons in it are invested by a common synovial membrane. The tendon then extends obliquely forwards across the outer side of the os calcis, below the peroneal tubercle, in a separate fibrous sheath lined by a prolongation of the synovial membrane which lines the groove behind the malleolus. It crosses the outer side of the cuboid, and then runs on the under surface of that bone in a groove, which is converted into a canal by the long calcaneo-cuboid ligament and lined by a synovial membrane: the tendon then crosses the sole of the foot obliquely, and is inserted into the outer side of the base of the metatarsal bone of the great toe and the outer side of the internal cuneiform. Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points: first, behind the external malleolus; secondly, on the outer side of the cuboid bone; in both of these situations the tendon is thickened, and, in the latter, a sesamoid fibro-cartilage, or sometimes a bone, is usually developed in its substance.

The **Peroneus brevis** lies under cover of the Peroneus longus, and is a shorter and smaller muscle. It arises from the lower two-thirds of the external surface of the shaft of the fibula, internal to the Peroneus longus;

and from the intermuscular septa separating it from the adjacent muscles on the front and back part of the leg. The fibres pass vertically downwards, and terminate in a tendon which runs in front of that of the preceding muscle, through the same groove behind the external malleolus, in the same fibrous sheath, and lubricated by the same synovial membrane. It then passes through a separate sheath on the outer side of the os calcis, above that for the tendon of the Peroneus longus, the two tendons being here separated by the peroneal tubercle, and is finally inserted into the tuberosity at the base of the metatarsal bone of the little toe, on its outer side.

Nerves.—The Peronei longus et brevis are supplied by the fourth and fifth lumbar and first sacral nerves through the musculo-cutaneous branch of the external popliteal nerve.

Actions.—The Peronei longus et brevis extend the foot upon the leg, in conjunction with the Tibialis posticus, antagonising the Tibialis anticus and Peroneus tertius, which are flexors of the foot. The Peroneus longus also everts the sole of the foot, and from the oblique direction of the tendon across the sole of the foot is an important agent in the maintenance of the transverse arch. Taking their fixed points below, the Peronei serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the tendency of the superincumbent weight is to throw the leg inwards: the Peroneus longus overcomes this tendency by drawing on the outer side of the leg, and thus maintains the perpendicular direction of the limb.

Applied Anatomy.—The student should now consider the position of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding blood-vessels, and especially their actions upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as *club foot.* The most simple and common deformity, and one that is rarely, if ever, congenital, is *talipes equinus*, the heel being raised by rigidity and contraction of the Gastrocnemius so that the patient walks upon the ball of the foot. In *talipes varus*, the foot is forcibly adducted and the inner side of the sole raised, sometimes to a right angle with the ground, by the action of the Tibiales anticus and posticus. In *talipes valgus*, the outer edge of the foot is raised by the Peronei, and the patient walks on the inner ankle. In *talipes calcaneus* the toes are raised by the Extensor muscles, the heel is depressed and the patient walks upon it. Other varieties of deformity are met with, as *talipes equinovarus*, *equinovalgus*, and *calcaneovalgus*, whose names sufficiently indicate their nature. Of these, talipes equinovarus is the most common congenital form; the heel is raised by the tendo Achillis, the inner border of the foot drawn upwards by the Tibialis anticus, the anterior two-thirds twisted inwards by the Tibialis posticus, and the arch increased by the contraction of the plantar fascia, so that the patient walks on the middle of the outer border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia: by this means the foot regains its proper position, and the tendons heal by the organisation of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it.

Rupture of a few of the fibres of the Gastrocnemius, or rupture of the Plantaris tendon, not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn tennis, and is hence known as 'lawn-tennis leg.' The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo Achillis is also sometimes ruptured. It is stated that John Hunter ruptured his tendo Achillis while dancing, at the age of forty. The bursa beneath the tendo Achillis, between it and the posterior surface of the os calcis, sometimes becomes inflamed, especially in pedestrians and 'long-distance' walkers. It causes great and disabling pain, and entirely prevents the sufferer from continuing his walk.

IV. Muscles and Fasciæ of the Foot

The fibrous bands, or thickened portions of the fascia of the leg, which bind down the tendons in front of and behind the ankle in their passage to the foot, are termed the *annular ligaments*, and are three in number—anterior, internal and external.

The **anterior annular ligament** (fig. 546) consists of a superior or transverse portion, which binds down the Extensor tendons as they descend on the front of the tibia and fibula; and an inferior or Y-shaped portion, which retains them in connection with the tarsus, the two portions being joined by a thin intervening layer of fascia. The transverse portion is attached externally to the lower end of the fibula and internally to the tibia; above,

it is continuous with the fascia of the leg; it contains one synovial sheath for the tendon of the Tibialis anticus; the other tendons and the anterior tibial vessels and nerve pass beneath it, but without any synovial sheaths. The Y-shaped portion is placed in front of the ankle-joint, the stem of the Y being attached externally to the upper surface of the os calcis, in front of the depression for the interosseous ligament; it is directed inwards as a double layer, one lamina passing in front of, and the other behind, the tendons of the Peroneus tertius and Extensor longus digitorum. At the inner border of the latter tendon these two layers join together, forming a sheath in which the tendons are enclosed, surrounded by a synovial membrane. From the inner extremity of this sheath the two limbs of the Y diverge: one is directed upwards and inwards, to be attached to the internal malleolus, passing over the Extensor proprius hallucis and the vessels and nerves, but enclosing the Tibialis anticus and its synovial sheath by a splitting of its fibres. The other limb extends downwards and inwards to be attached to the inner border of the plantar fascia, and passes over the tendons of the Extensor proprius hallucis and Tibialis anticus and also the vessels and nerves. These two tendons are contained in separate synovial sheaths situated beneath the ligament.

The **internal annular ligament** is a strong fibrous band, which extends from the internal malleolus above to the margin of the os calcis below, converting a series of grooves in this situation into canals, for the passage of the tendons of the Flexor muscles and the posterior tibial vessels and nerve into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar fascia and the fibres of origin of the Abductor hallucis muscle. The four canals which it forms transmit, from within outwards, the tendon of the Tibialis posticus; the tendon of the Flexor longus digitorum; the posterior tibial vessels and nerve, which run through a broad space beneath the ligament; and lastly, in a canal formed partly by the astragalus, the tendon of the Flexor longus hallucis. The canals for the tendons are lined by separate synovial membranes.

The **external annular ligament** extends from the extremity of the external malleolus to the outer surface of the os calcis: it binds down the tendons of the Peronei longus et brevis in their passage beneath the outer ankle. The two tendons are enclosed in one synovial sheath.

8. *Dorsal Region* (fig. 546)

Extensor brevis digitorum.

The **fascia** on the dorsum of the foot (fascia dorsalis pedis) is a thin membranous layer, continuous above with the anterior margin of the lower part of the annular ligament; on either side it blends with the lateral portions of the plantar fascia; anteriorly it forms a sheath for the tendons on the dorsum of the foot.

The **Extensor brevis digitorum** (fig. 546) is a broad, thin muscle, which arises from the fore part of the upper and outer surfaces of the os calcis, in front of the groove for the Peroneus brevis; from the external calcaneo-astragaloid ligament; and from the common limb of the Y-shaped portion of the anterior annular ligament. It passes obliquely across the dorsum of the foot, and terminates in four tendons. The innermost, which is the largest, is inserted into the dorsal surface of the base of the first phalanx of the great toe, crossing the dorsalis pedis artery; the other three, into the outer sides of the long Extensor tendons of the second, third, and fourth toes.

Nerves.—It is supplied by the anterior tibial nerve.

Actions.—The Extensor brevis digitorum extends the phalanges of the four inner toes, but in the great toe acts only on the first phalanx. The obliquity of its direction counteracts the oblique movement given to the toes by the long Extensor, so that when both muscles act, the toes are evenly extended.

9. *Plantar Region*

The **plantar fascia** (aponeurosis plantaris) is of great strength, and consists of pearly-white glistening fibres, disposed, for the most part, longitudinally: it is divided into a central and two lateral portions.

The *central portion*, the thickest, is narrow behind and attached to the inner tubercle of the os calcis, posterior to the origin of the Flexor brevis digitorum; and becoming broader and thinner in front, divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes divides opposite the metatarso-phalangeal articulation into two strata, superficial and deep. The superficial stratum is inserted into the skin of the transverse sulcus which separates the toes from the sole. The deeper stratum divides into two slips which embrace the side of the Flexor tendons of the toes, and blend with the sheaths of the tendons, and laterally with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long Flexors pass to the toes. The intervals left between the five processes allow the digital vessels and nerves, and the tendons of the Lumbricales to become superficial. At the point of division of the fascia, numerous transverse fibres (fasciculi transversi) are superadded, which serve to increase the strength of the fascia at this part by binding the processes together, and connecting them with the integument. The central portion of the plantar fascia is continuous with the lateral portions at either side, and sends upwards into the foot, at the lines of junction, two strong vertical intermuscular septa, broader in front than behind, which separate the middle from the external and internal plantar group of muscles; from these again are derived thinner transverse septa which separate the various layers of muscles in this region. The upper surface of this fascia gives attachment behind to the Flexor brevis digitorum.

The *lateral portions* of the plantar fascia are thinner than the central piece, and cover the sides of the foot.

The *outer portion* covers the under surface of the Abductor minimi digiti; it is thin in front and thick behind, where it forms a strong band between the outer tubercle of the os calcis and the base of the fifth metatarsal bone; it is continuous internally with the middle portion of the plantar fascia, and externally with the dorsal fascia.

The *inner portion* is thin, and covers the under aspect of the Abductor hallucis; it is attached behind to the internal annular ligament, and is continuous around the side of the foot with the dorsal fascia, and externally with the middle portion of the plantar fascia.

The muscles in the plantar region of the foot may be divided into three groups, in a similar manner to those in the hand. Those of the internal plantar region are connected with the great toe, and correspond with those of the thumb; those of the external plantar region are connected with the little toe, and correspond with those of the little finger; and those of the middle plantar region are connected with the tendons intervening between the two former groups. But in order to facilitate the description of these muscles, it will be found more convenient to divide them into four layers, in the order in which they are successively exposed.

First Layer (fig. 549)

Abductor hallucis. Flexor brevis digitorum.
Abductor minimi digiti.

The **Abductor hallucis** lies along the inner border of the foot and covers the origins of the plantar vessels and nerves. It arises from the inner tubercle on the under surface of the os calcis; from the internal annular ligament; from the plantar fascia covering it; and from the intermuscular septum between it and the Flexor brevis digitorum. The fibres terminate in a tendon, which is inserted, together with the innermost tendon of the Flexor brevis hallucis, into the inner side of the base of the first phalanx of the great toe.

The **Flexor brevis digitorum** lies in the middle of the sole of the foot, immediately beneath * the central part of the plantar fascia, with which it is firmly united. Its deep surface is separated from the external plantar vessels and nerves by a thin layer of fascia. It arises by a narrow tendinous process, from the inner tubercle of the os calcis, from the central part of the

* That is, in the order of dissection of the sole of the foot.

plantar fascia, and from the intermuscular septa between it and the adjacent muscles. It passes forwards, and divides into four tendons, one for each of the four outer toes. Opposite the bases of the first phalanges, each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor longus digitorum ; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long Flexor tendon. Finally, it divides a second time, to be inserted into the sides of the second phalanx about its middle. The mode of division of the tendons of the Flexor brevis digitorum, and of their insertion into the phalanges, is analogous to that of the tendons of the Flexor sublimis digitorum in the hand.

FIG. 549.—Muscles of the sole of the foot. First layer.

Fibrous sheaths of the Flexor tendons.—These are not so well marked as in the fingers. The Flexor tendons of the toes as they run along the phalanges are retained against the bones by fibrous sheaths. These sheaths are formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely ; but opposite the joints it is much thinner, and the fibres are directed obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendon.

The **Abductor minimi digiti** (m. abductor quinti digiti) lies along the outer border of the foot, and is in relation by its inner margin with the external plantar vessels and nerves. It arises, by a very broad origin, from the outer tubercle of the os calcis, from the under surface of the os calcis between the two tubercles, from the fore part of the inner tubercle, from the plantar fascia, and from the intermuscular septum between it and the Flexor brevis digitorum. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is inserted, with the short Flexor of the little toe, into the outer side of the base of the first phalanx of this toe.

Second Layer (fig. 550)

Flexor accessorius.
Lumbricales.

The **Flexor accessorius** (m. quadratæ plantæ) is separated from the muscles of the first layer by the external plantar vessels and nerves. It arises by two heads, which are separated from each other by the long plantar ligament : the inner or larger, which is muscular, is attached to the inner concave surface of the os calcis, below the groove which lodges the tendon of the Flexor longus hallucis ; the outer head, flat and tendinous, to the outer border of the inferior surface of the os calcis, in front of its lesser tubercle, and to the long plantar ligament. The two portions join at an acute angle, and are inserted into the outer margin and upper and under surfaces of the tendon

of the Flexor longus digitorum, forming a kind of groove, in which the tendon is lodged.*

The **Lumbricales** are four small muscles, accessory to the tendons of the Flexor longus digitorum : they arise from the tendons of the long Flexor, as far back as their angles of division, each arising from two tendons, except

FIG. 550.—Muscles of the sole of the foot. Second layer.

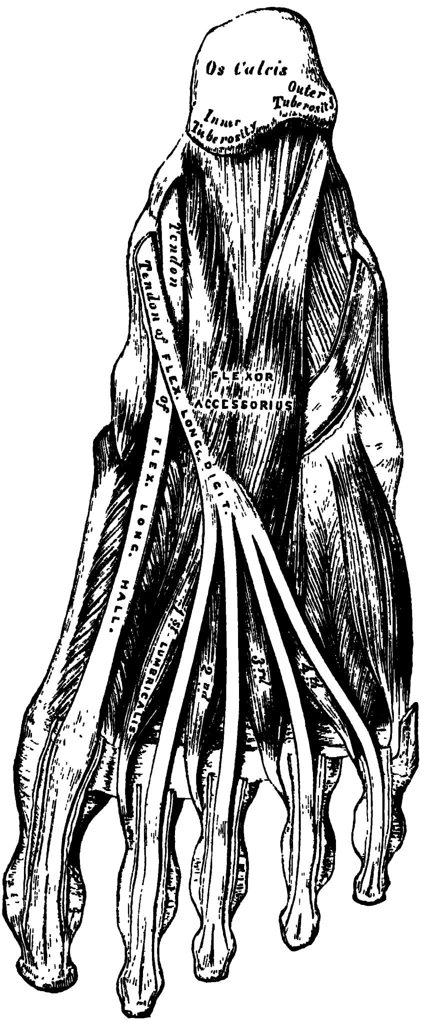


FIG. 551.—Muscles of the sole of the foot. Third layer.

the innermost. Each muscle ends in a tendon, which passes forwards on the inner side of the four lesser toes, and is inserted into the expansion of the long Extensor tendon on the dorsum of the first phalanx of the corresponding toe.

Third Layer (fig. 551)

Flexor brevis hallucis.	Adductor transversus hallucis.
Adductor obliquus hallucis.	Flexor brevis minimi digiti.

The **Flexor brevis hallucis** arises, by a pointed tendinous process, from the inner part of the under surface of the cuboid bone, from the contiguous

* Turner pointed out that the fibres of the Flexor accessorius end in aponeurotic bands, which contribute slips to the second, third, and fourth digits.

portion of the external cuneiform, and from the prolongation of the tendon of the Tibialis posticus which is attached to that bone. The muscle divides in front into two portions, which are inserted into the inner and outer sides of the base of the first phalanx of the great toe, a sesamoid bone being developed in each tendon at its insertion. The inner portion of this muscle is blended with the Abductor hallucis previous to its insertion; the outer with the Adductor obliquus hallucis; the tendon of the Flexor longus hallucis lies in a groove between them.

The **Adductor obliquus hallucis** is a large, thick, fleshy mass, passing obliquely across the foot, and occupying the hollow space between the inner four metatarsal bones. It arises from the tarsal extremities of the second, third, and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus, and is inserted, together with the outer portion of the Flexor brevis hallucis, into the outer side of the base of the first phalanx of the great toe.

The **Adductor transversus hallucis** (*Transversus pedis*) is a narrow, flat, muscular fasciculus, stretched transversely across the heads of the metatarsal bones, between them and the Flexor tendons. It arises from the inferior metatarso-phalangeal ligaments of the three outer toes, sometimes only from the third and fourth, and from the transverse ligament of the metatarsus. It is inserted into the outer side of the base of the first phalanx of the great toe, its fibres being blended with the tendon of insertion of the Adductor obliquus hallucis.

The small muscles of the great toe, the Abductor, Flexor brevis, Adductor obliquus, and Adductor transversus, like the similar muscles of the thumb, give off, at their insertions, fibrous expansions to blend with the long Extensor tendons.

The **Flexor brevis minimi digiti** (m. flexor brevis digiti quinti) lies on the metatarsal bone of the little toe, and much resembles one of the Interossei. It arises from the base of the metatarsal bone of the little toe, and from the sheath of the Peroneus longus; its tendon is inserted into the base of the first phalanx of the little toe on its outer side. Occasionally some of the deeper fibres of the muscle are inserted into the outer part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the Opponens minimi digiti.

Fourth Layer (figs. 552, 553)

Interossei.

The **Interossei** in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the *second* digit, instead of that of the *third*. They are seven in number, and consist of two groups, dorsal and plantar.

The **Dorsal interossei** (interossei dorsales) (fig. 552), four in number, are situated between the metatarsal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metatarsal bones between which they are placed; their tendons are inserted into the bases of the first phalanges, and into the aponeurosis of the common Extensor tendon. In the angular interval left between the heads of each of the three outer muscles, one of the perforating arteries passes to the dorsum of the foot; through the space between the heads of the First interosseous muscle the communicating branch of the dorsalis pedis artery enters the sole of the foot. The First dorsal interosseous muscle is inserted into the inner side of the second toe; the other three are inserted into the outer sides of the second, third, and fourth toes.

The **Plantar interossei** (interossei plantares) (fig. 553), three in number, lie beneath rather than between the metatarsal bones, and each is connected with but one metatarsal bone. They arise from the bases and inner sides of the shafts of the third, fourth, and fifth metatarsal bones, and are inserted into the inner sides of the bases of the first phalanges of the same toes, and into the aponeuroses of the common Extensor tendons.

Nerves.—The Flexor brevis digitorum, the Flexor brevis and Abductor hallucis, and the innermost Lumbrical are supplied by the internal plantar nerve; all

the other muscles in the sole of the foot by the external plantar. The First dorsal interosseous muscle frequently receives an extra filament from the internal branch of the anterior tibial nerve on the dorsum of the foot, and the Second dorsal interosseous a twig from the external branch of the same nerve.

Actions.—All the muscles of the foot act upon the toes, and in describing their action they may be grouped as Abductors, Adductors, Flexors, or Extensors. The *abductors* are the Dorsal interossei, the Abductor hallucis, and the Abductor minimi digiti. The Dorsal interossei are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe inwards, towards the great toe, the second muscle draws the same toe outwards, the third draws the third toe, and the fourth draws the fourth toe in the same direction. Like the Interossei in the hand, each assists in flexing the proximal phalanx and extending the two terminal phalanges. The Abductor hallucis abducts the great toe from the others, and also flexes the proximal phalanx of this toe. In the same way the action of the Abductor minimi digiti is two-fold, as an abductor of this toe from the others, and also as a flexor of its proximal phalanx. The *adductors* are the Plantar interossei, the Adductor obliquus

Fig. 552.—The Dorsal interossei. Left foot.

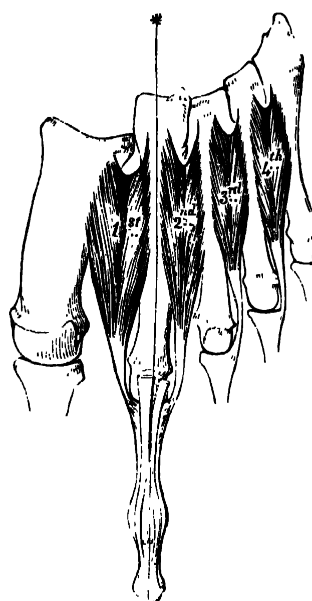

Fig. 553.—The Plantar interossei. Left foot.

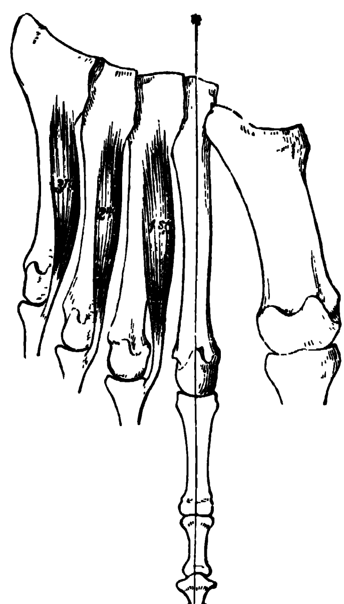


hallucis, and the Adductor transversus hallucis. The Plantar interosseous muscles adduct the third, fourth, and fifth toes towards the imaginary line passing through the second toe, and by means of their insertions into the aponeuroses of the Extensor tendons they assist in flexing the proximal phalanges and extending the middle and terminal phalanges. The Adductor obliquus hallucis is chiefly concerned in adducting the great toe towards the second one, but also assists in flexing this toe. The Adductor transversus hallucis approximates all the toes and thus increases the curve of the transverse arch of the metatarsus. The *flexors* are the Flexor brevis digitorum, the Flexor accessorius, the Flexor brevis hallucis, the Flexor brevis minimi digiti, and the Lumbricales. The Flexor brevis digitorum flexes the second phalanges upon the first, and, continuing its action, flexes the first phalanges also, and brings the toes together. The Flexor accessorius assists the long Flexor of the toes and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor brevis minimi digiti flexes the little toe and draws its metatarsal bone downwards and inwards. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanges, and by their insertions into the long

Extensor tendons aid that muscle in straightening the middle and terminal phalanges. The only muscle in the *extensor* group is the Extensor brevis digitorum. It extends the first phalanx of the great toe and assists the long Extensor in extending the next three toes, and at the same time gives to the toes an outward direction when they are extended.

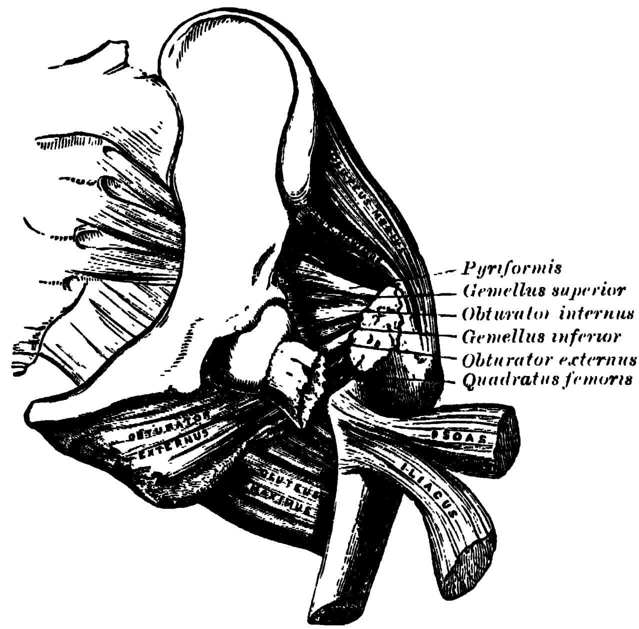
Surface Form.—The skin of the thigh, especially above in the hollow of the groin and on the inner side, is thin, smooth, and elastic, and contains few hairs, except in the neighbourhood of the pubes. Towards the outer side it becomes thicker, and the hairs are more numerous. The skin over the buttock is also fairly thick, with low sensibility and vascularity. As a rule, it is destitute of conspicuous hairs, except towards the post-anal furrow, where, in some males, an abundant development of hair is present. The skin over the front of the knee is covered by thickened epidermis; it is loose and thrown into transverse wrinkles when the leg is extended: that of the leg is thin, especially on the inner side, and covered with numerous large hairs. On the dorsum of the foot the skin is thin, loosely connected to subjacent parts, and contains few hairs. On the sole, and especially the heel, the epidermis is of great thickness, and here, as in the palm of the hand, there are no hairs or sebaceous follicles.

Of the muscles of the thigh, those of the anterior femoral region largely contribute to the surface form of this part of the limb. The *Tensor fasciæ femoris* produces a broad elevation immediately below the anterior portion of the crest of the ilium and behind the anterior superior spinous process. From its lower border, a longitudinal groove, corresponding to the ilio-tibial band, extends to the outer side of the knee-joint. The *Sartorius*, when it is brought into action by flexing the leg on the thigh, and the thigh on the pelvis, and rotating the thigh outwards, presents a well-marked surface form. At its upper part, where it constitutes the outer boundary of Scarpa's triangle, it forms a prominent oblique ridge, which becomes changed into a flattened plane below, and this gradually merges in a general fulness on the inner side of the knee-joint. When the Sartorius is not in action, a depression exists between the Quadriceps extensor and the Adductor muscles, and extends obliquely downwards and inwards from the apex of Scarpa's triangle to the inner side of the knee. In the angle formed by the divergence of the Sartorius and Tensor fasciæ femoris muscles, just below the anterior superior spine of the ilium, the *Rectus femoris* muscle appears, and, below this, determines to a great extent the convex form of the front of the thigh. In a well-developed subject, the borders of the muscle, when in action, can be clearly defined. The *Vastus externus* forms a long flattened plane on the outer side of the thigh, traversed by the longitudinal groove formed by the ilio-tibial band. The *Vastus internus*, on the inner side of the lower half of the thigh, gives rise to a considerable prominence, which increases towards the knee and terminates somewhat abruptly in this situation with a full, curved outline. The *Crureus* and *Subcrureus* are completely hidden, and do not directly influence surface form. The *Adductor muscles*, constituting the internal femoral group, cannot be distinguished from each other, with the exception of the upper tendon of the Adductor longus and the lower tendon of the Adductor magnus. When the *Adductor longus* is in action its upper tendon stands out as a prominent ridge, which runs obliquely downwards and outwards from the neighbourhood of the pubic spine, and forms the inner boundary of Scarpa's triangle. The lower tendon of the *Adductor magnus* can be distinctly felt as a short ridge extending down to he adductor tubercle on the internal condyle, between the Sartorius and Vastus internus. The Adductor group of muscles fills in the triangular space at the upper part of the thigh, between the oblique femur and the pelvis, and to them is due the contour of the inner border of the thigh, the *Gracilis* largely contributing to the smoothness of the outline. These muscles are not marked off on the surface from the hamstrings by any intermuscular depression; but on the outer side of the thigh the latter are defined from the Vastus externus by a distinct marking, corresponding to the external intermuscular septum. The *Gluteus maximus*, and the *Gluteus medius* in its upper part, are the only muscles of the buttock which influence surface form. The lower part of the Gluteus medius, the Gluteus minimus, and the External rotators are completely hidden. The *Gluteus maximus* forms the full rounded outline of the buttock; it is more prominent behind, compressed in front, and terminates at its tendinous insertion in a depression immediately behind the great trochanter. Its lower border does not correspond to the gluteal fold, but is much more oblique, being marked by a line drawn from the side of the coccyx to the junction of the upper with the middle third of the thigh on the outer side. From beneath the lower margin of this muscle the *Hamstring muscles* appear, at first narrow and not well marked, but, as they descend, they become more prominent, and eventually divide into two well-marked ridges formed by their tendons, which constitute the upper boundaries of the popliteal space. In the upper part of the thigh these muscles cannot be individually distinguished from each other; but lower down, the separation between the Semitendinosus and Semimembranosus is denoted by a slight intermuscular marking. The external hamstring tendon formed by the *Biceps* is seen as a thick cord running down to the head of the fibula. The inner hamstring tendons comprise the Semitendinosus and the Semimembranosus. The *Semitendinosus* is the more internal, and can be felt, in certain

positions of the limb, as a sharp cord, while the *Semimembranosus* is thick. The *Gracilis* is situated a little in front of them.

The *Tibialis anticus* presents a fusiform enlargement at the outer side of the tibia, and projects beyond the crest of the shin bone. From the muscular mass, its tendon may be traced downward, standing out boldly, when the muscle is in action, on the front of the tibia and ankle-joint, and coursing down along the inner border of the foot to its insertion. The fleshy fibres of the *Peroneus longus* are strongly marked at the upper part of the outer side of the leg, especially when the muscle is in action. It forms a bold swelling, separated by furrows from the Extensor longus digitorum in front and the Soleus behind. Below, the fleshy fibres terminate abruptly in a tendon which overlaps the more flattened form of the *Peroneus brevis*. Below the external malleolus the tendon of the Peroneus brevis is more marked than that of the Peroneus longus. On the dorsum of the foot the tendons emerging from beneath the anterior annular ligament spread out, and can be distinguished, as follows: the innermost and largest is the Tibialis anticus; the next is the Extensor proprius hallucis; then the Extensor longus digitorum, dividing into four tendons to the four outer toes; and lastly, the Peroneus tertius. The flattened form of the dorsum of the foot is relieved by the rounded outline of the fleshy belly of the *Extensor brevis digitorum*, which produces a fulness on the outer side of the tarsus in front of the external malleolus, and by the Dorsal interossei, which bulge between the metatarsal bones. At

FIG. 554.—Fracture of the neck of the femur within the capsular ligament.



the back of the knee is the popliteal space, bounded above by the tendons of the Hamstring muscles; below, by the two heads of the Gastrocnemius. Below this space is the prominent fleshy mass of the calf of the leg, produced by the *Gastrocnemius* and *Soleus*. When these muscles are in action, as in standing on tiptoe, the borders of the Gastrocnemius are well defined, presenting two curved lines, which converge to the tendon of insertion. Of these borders, the inner is more prominent than the outer. The fleshy mass of the calf terminates somewhat abruptly below in the tendo Achillis, which stands out prominently on the lower part of the back of the leg. It presents a somewhat tapering form in the upper three-fourths of its extent, but widens out slightly below. When the muscles of the calf are in action, the lateral portions of the *Soleus* may be seen, forming curved eminences, of which the outer is the longer, on either side of the Gastrocnemius. Behind the inner border of the lower part of the shaft of the tibia, a well-marked ridge, produced by the tendon of the Tibialis posticus, is visible when this muscle is in a state of contraction.

On the sole of the foot the superficial layer of muscles influences surface form. The *Abductor minimi digiti* forms a narrow rounded elevation along the outer border of the foot, while the *Abductor hallucis* does the same, though to a less extent, on the inner side. The *Flexor brevis digitorum*, bound down by the plantar fascia, is not very apparent; it produces a flattened form, and is covered by the thickened skin of the sole, which is here thrown into numerous wrinkles.

Applied Anatomy.—The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fracture are selected for illustration and description.

In fracture of the *neck of the femur internal to the capsular ligament* (fig. 554), the characteristic signs are slight shortening of the limb, and eversion of the foot, neither of which occurs, however, in some cases until some time after the injury. The eversion is caused by the weight of the limb rotating it outwards. The shortening is produced by the action of the Glutei, and by the Rectus femoris in front, and the Biceps, Semitendinosus and Semimembranosus behind.

In fracture of the *femur just below the trochanters* (fig. 555), the upper fragment is tilted forwards almost at right angles with the pelvis, by the Ilio-psoas; and, at the same time, everted and drawn outwards by the external rotator muscles and Glutei, causing a marked prominence at the upper and outer side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, because the lower fragment is drawn upwards by the Rectus in front, and the Biceps, Semimembranosus and Semitendinosus behind; it is, at the same time, everted. This fracture may be reduced by relaxation of all the muscles involved, to effect which the limb should be put up with the thigh flexed on the pelvis and the leg on the thigh.

FIG. 555.—Fracture of the femur below the trochanters.

FIG. 556.—Fracture of the femur above the condyles.

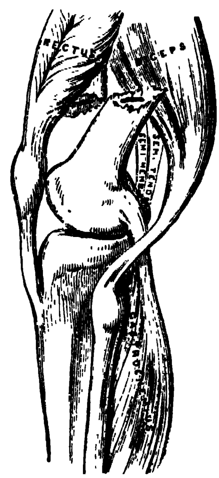


FIG. 557.—Fracture of the patella.

Oblique fracture of the femur *immediately above the condyles* (fig. 556) is a formidable injury, and attended with considerable displacement. On examination of the limb, the lower fragment may be felt deep in the popliteal space, being drawn backwards by the Gastrocnemius, and upwards by the Hamstring and Rectus muscles. The pointed end of the upper fragment is drawn inwards by the Pectineus and Adductor muscles, and tilted forwards by the Psoas and Iliacus, piercing the Rectus muscle, and occasionally the integument. Relaxation of these muscles, and direct approximation of the broken fragments, are effected by placing the limb on a double inclined plane. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed, the Rectus muscle being held down by the fractured end of the bone, and the patella, when elevated, being drawn upwards against the projecting fragment.

In transverse fracture of the *patella* (fig. 557) the fragments are separated by the action of the Quadriceps extensor and by the effusion which takes place into the joint; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone.

In oblique fracture of the *shaft of the tibia* (fig. 558), if the fracture has taken place obliquely from above, downwards and forwards, the fragments ride over one another, the lower fragment being drawn backwards and upwards by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forwards immediately beneath the integument, often protruding through it, and rendering the

fracture a compound one. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forwards, rising up on the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is sometimes necessary, however, in compound

Fig. 558.—Oblique fracture of the shaft of the tibia.

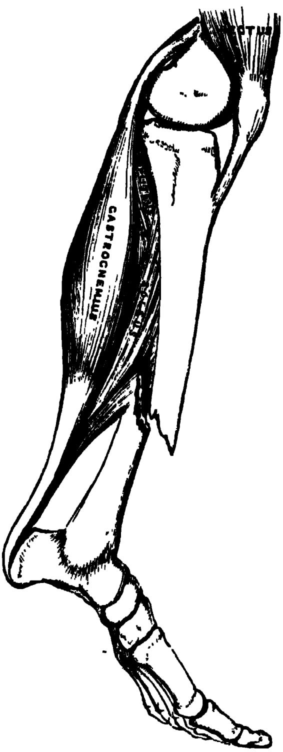

Fig. 559.—Fracture of the fibula, with dislocation of the foot outwards—'Pott's fracture.'

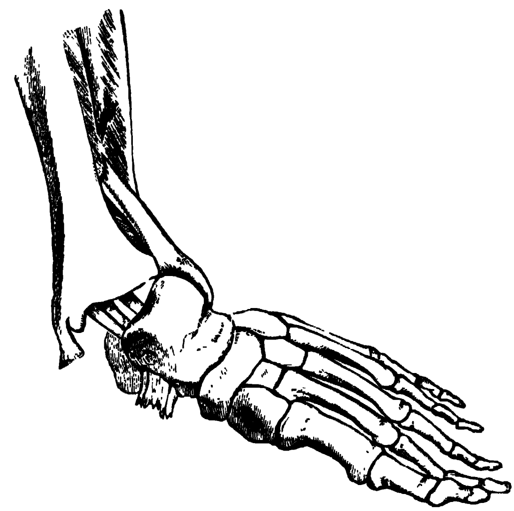

fracture to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

Fracture of the *fibula with dislocation of the foot outwards* (fig. 559), commonly known as 'Pott's fracture,' is one of the most frequent injuries in the region of the ankle-joint. The fibula is fractured about three inches above the ankle; in addition to this the internal malleolus is broken off, or the deltoid ligament torn through, and the astragalus displaced from the corresponding surface of the tibia. The foot is markedly everted, and the sharp edge of the upper end of the fractured malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury can generally be reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counter-extension at the knee. There is later a great tendency for the foot to fall backwards at the ankle-joint, and constant supervision is required to counteract this.

ANGIOLOGY

THE vascular system is divided for descriptive purposes into (*a*) the *blood vascular system*, which comprises the heart and blood-vessels for the circulation of the blood; and (*b*) the *lymph vascular system*, consisting of lymphatic glands and vessels, through which a colourless fluid, the lymph, circulates. It must be noted, however, that the two systems communicate with each other and are intimately associated developmentally.

The heart is the central organ of the blood vascular system, and consists of a hollow muscle; by its contraction the blood is pumped to all parts of the body through a complicated series of tubes, termed *arteries*. The arteries undergo enormous ramification in their course throughout the body, and end in very minute vessels, called *arterioles*, which in their turn open into a close-meshed network of microscopic vessels, termed *capillaries*. After the blood has passed through the capillaries it is collected into a series of larger vessels, called *veins*, by which it is again returned to the heart. The passage of the blood through the heart and blood-vessels constitutes what is termed the *circulation* of the blood, of which the following is an outline.*
